This diagram illustrates a pedal-action w.c.; also a pull as at A. The pedal is fitted to the riser of the w.c., and is so arranged that the pedal-lever will lift up the lever of the valve or pan-closet exactly in the same manner as the closet-lever does the valve-lever of the water supply. This treadle is also made to allow the lever of the closet to fall, notwithstanding it is kept pressed down, so that it becomes a waste-preventer.

Fig. 183 A illustrates a flap-valve for the end of a safe-pipe to prevent wind getting into the overflow pipe. A is the flap, B the seating, and C the inlet. These valves can be made with the lead pipe and a piece of copper for the valve, or can be bought ready-made. E, F, G, H, and C is a spreader for screwing into the closet basin, which is an improvement so far as the doing away with the putty joint; but I cannot say that the spreading qualities are at all times good. The same kind of spreader is at times used for the inlet to lavatory basins, which see further on.

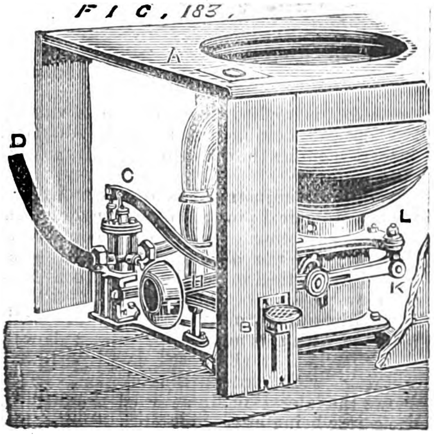

FIG. 183.

Urinals.—"Running Water Supply" (Fig. 184).

Perhaps the simplest kind of water-supply to serve, especially to public urinals, is the ordinary running supply through a pierced pipe down a stone slab, or a bent pipe as at G H (Fig. 184), which, of course, may derive its supply from any source. The pan B holds a large body of water, and has a standing waste that receives the overflow, and which can be lifted for emptying say once in 24 hours. The pan is sometimes made to empty itself by means of a siphon or other equivalent arrangement. This kind of urinal is greatly in use in the public buildings and places about London.

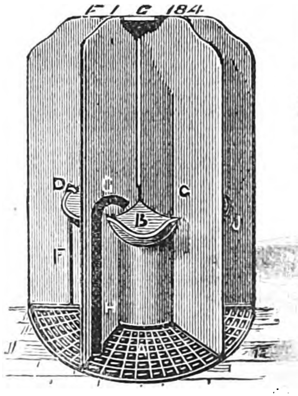

FIG. 184.

The next simple method of water-supply to urinals is the ordinary stop-cock, as shown at M I N (Fig. 185), and next the spring thumb valve, as shown at M N (Fig. 186), and P Q (Fig. 187).

Fig. 185 illustrates an "Angle Urinal," the water supply of which may be governed by a spring cock, stop-cock, or waste-preventing cock, as shown in section at O P Q (Fig. 185), or it may be constructed on the diaphragm (Fig. 161) principle. When these cocks are used, it is the general custom to fix them direct to the arm of the urinal by means of a putty joint, or at other times by a short length of leaden pipe to connect the cock and urinal. The outlet S of the urinal is generally fitted into a stink trap of some kind, and the urinal lugs T T screwed to a plugged wall. The proper height from the top of the lip V to the floor should be 2ft., and should not ever exceed 2ft. 4in.

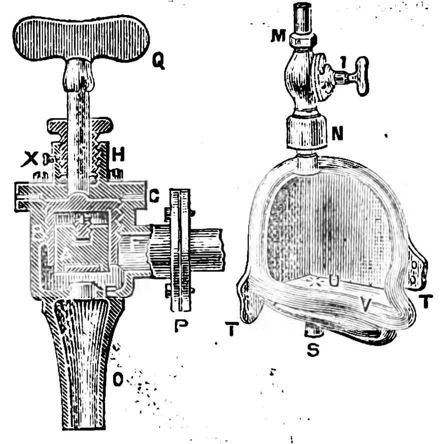

FIG. 185.

This is a section of a treadle urinal, showing the fitting with pipes complete. J K is the cradle union so frequently used to let into a wall, &c. K is the outgo, leading into the trap L. This trap should be fixed so that it can readily be cleaned out with spirits of salts, &c. I is the supply-pipe, which is made good to the arm of the urinal by means of a putty joint, or a really good plan is to have a socket, O section (Fig. 186), with centre pipe as at P, to enter the inlet, the socket O to be filled up with red and white-lead and simply pushed over the arm as at N (Fig. 185), when the surplus red-lead will be pressed out and joint made. O L (Fig. 187) is an elevation of the socket, but bent as at O, to show that the pipe may be brought in from behind, and the socket unscrewed at the flange to allow the urinal to be taken down at any time without disturbing the walls, &c.

A (Fig. 186) is a section of the treadle which is held up by the head of the stud (*) fixed upon the end of the weighted lever D. It will be seen that by placing the foot upon this treadle (as in the seat-action closets) the lever D is brought up, and so opens the valve to allow the water to run; but the moment the user of the urinal walks away, the water ceases to flow.

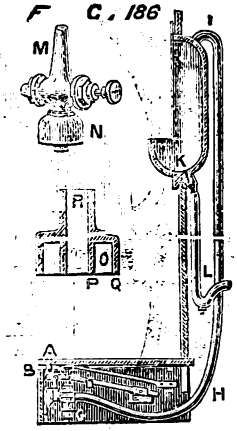

FIG. 186

Fig. 187 illustrates an elevation of the method of fitting up a lipped urinal for fixing against a flat wall with treadle apparatus. The frame employed for fitting the valve is an improvement on the last-mentioned in so far that it forms a safe to catch any water that may leak from the valve, &c. G is the waste or overflow pipe.

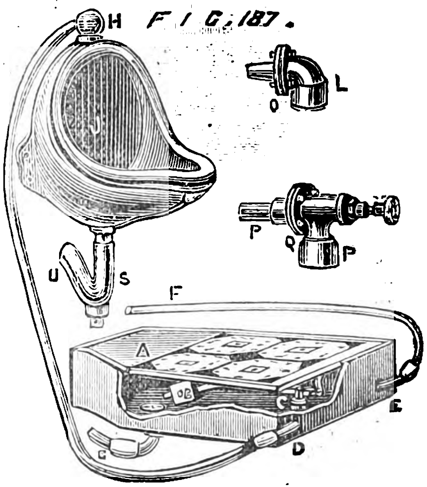

FIG. 187.

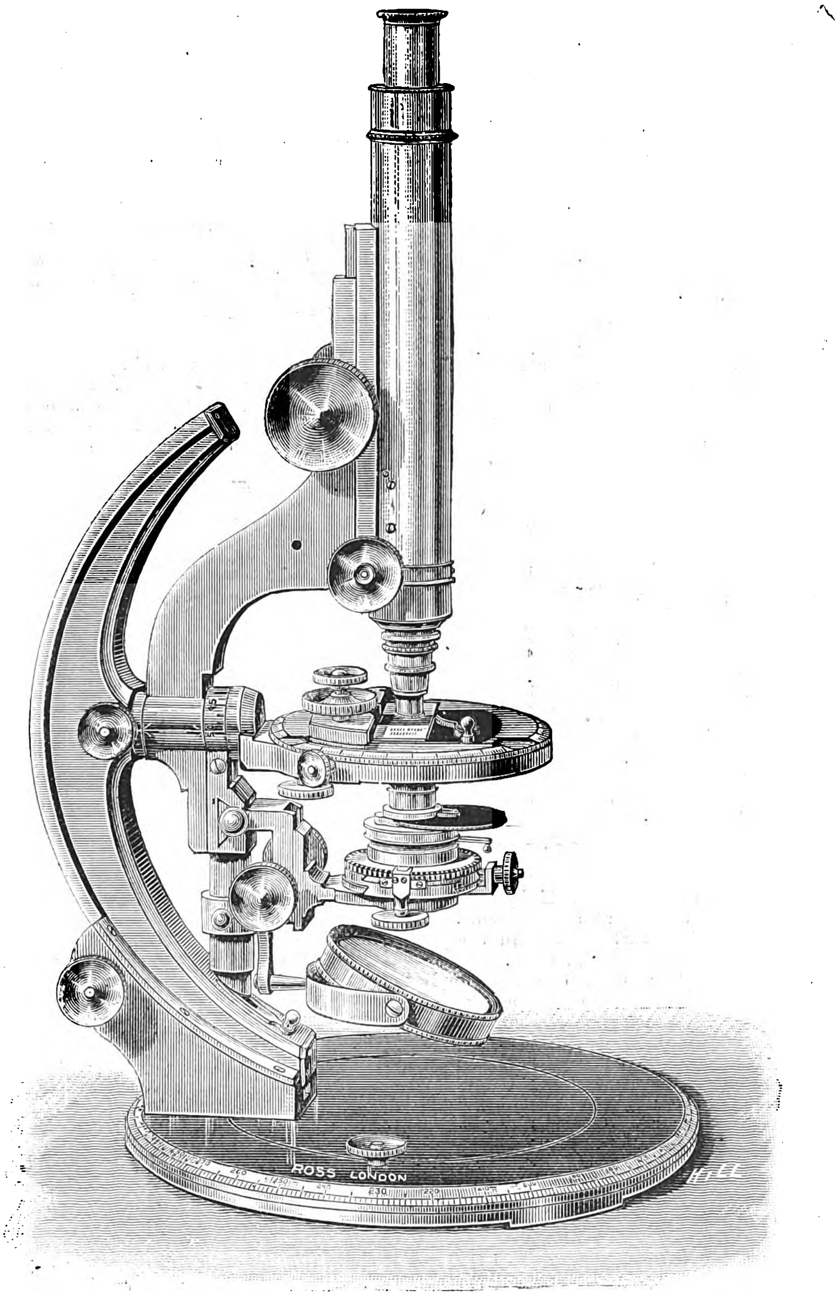
(To be continued).

WENHAM'S UNIVERSAL INCLINING AND ROTATING MICROSCOPE.

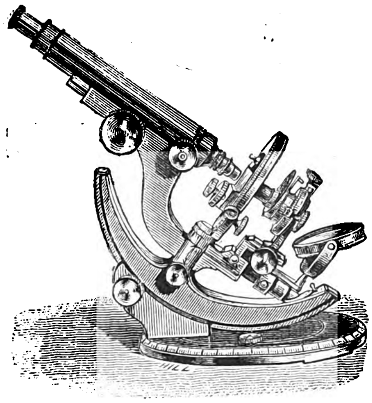
THIS new microscope (Fig. 1) has been devised by Mr. Wenham specially to obtain a large range of effects of oblique light both in altitude and azimuth. The principal movements are as follows:—(1) An inclination of the limb together with the body-tube, stage, substage, and mirror, in a sector sliding within jaws attached to the rotating base-plate. The centre of this inclining motion is (very approximately) the point where the plane of the object cuts the optic axis, *i.e.*, a point situated about the thick-

FIG. 1.



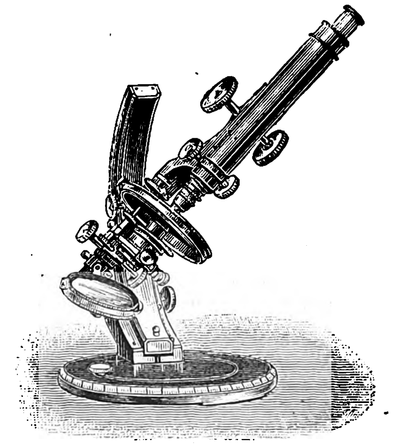
ness of an ordinary object slide above the centre of the surface of the stage. (2) An inclination of the limb to either side upon an axis attached to the centre of the sector. The centre line of this axis prolonged forwards also intersects the optic axis in the plane of the object on the stage. (3) A rotation of the instrument upon its circular base, the optic axis being the centre of motion.

FIG. 2.



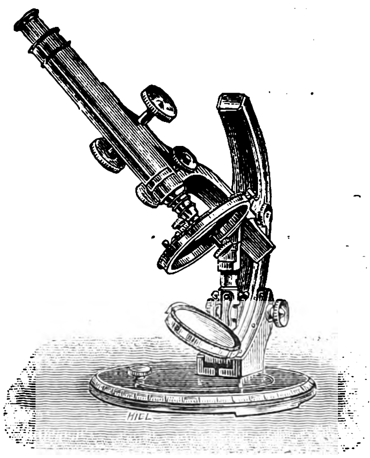
The leading principle followed in the construction of the stand is, that when it is inclined backwards (as in Fig. 2) or turned laterally (as in Figs. 3, 4, and 5), or rotated on the base-plate, a pencil of light from a fixed source will always reach the object, all the movements, whether separate or combined, radiating from the object (or the prolongations of its axes) as a centre.

FIG. 3.



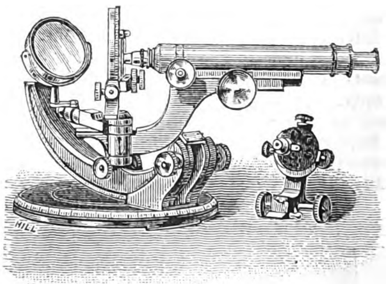
The mechanical stage rotates completely, and is a modification of that of Mr. Tolles (of Boston, U.S.A.), in which the rectangular motions are effected by milled heads acting on the surface and entirely within the circumference. In recent volumes of the ENGLISH MECHANIC we have several times referred to Mr. Tolles' stage, and in No. 866 we gave a Fig. and full description of his latest modifications in the construction; we therefore dispense with a detailed description of this stage, remarking that with the exception of the very ingenious flange devised by Mr. Tolles to which we directed special attention, all the essential points in the two stages are similar. Mr. Wenham's stage is mounted on the Zentmayer system: it can thus be easily removed, or replaced by a glass or metal friction-stage, &c. The rotating plate is graduated near the edge on the surface, and "finders" are engraved in convenient positions; the rotation can be effected by rack and pinion (milled head shown beneath the stage); two centering screws enable the exact rotation round the optic axis to be secured. A simple and effective plan has been adopted of applying the iris-diaphragm, hemispherical immersion illuminator, or Wenham's "half-disc" beneath the stage, where they are held in position by a small flange and a spring latchet.

FIG. 4.



The substage can be removed entirely from the lower part of the limb by means of a metal dove-tail slide, and it has the usual rectangular (centering) and rotating motions. The substage condenser has a centering cap, and a rotating plate of the usual series of slots, central stops, &c., is applied close to the lower surface of the optical combination; an iris-diaphragm beneath modifies the diameter of the illuminating pencil.

FIG. 5.

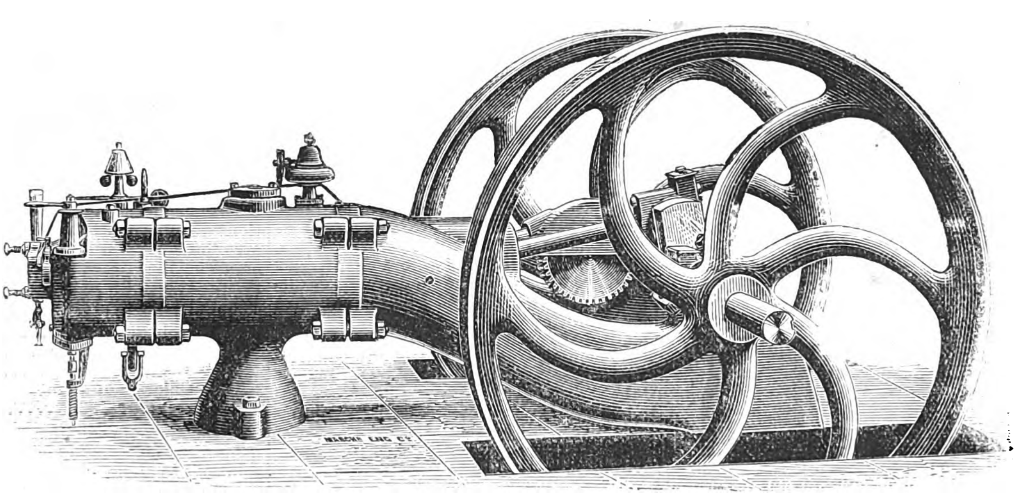


The coarse adjustment is of the "Jackson" form, with spiral pinion and diagonal rackwork. The fine adjustment acts directly upon a vertical slide carrying the objective only, and is controlled by vertical milled heads on both sides of the nose-piece.

In illustration of the variety of motions obtained with this microscope, Fig. 2 shows the sector inclined at about the usual position for working with central illumination. Fig. 3 shows the lateral inclination of the limb, &c., the sector being at its highest position. Fig. 4 shows the Zentmayer swinging tail-piece clamped to the sector (as suggested by Mr. J. Mayall, jun.), the limb being inclined laterally, and the substage removed: this lateral inclination of the limb (the tail-piece with mirror, &c., being fixed) causes the stage to revolve upon a central horizontal axis, so as to present the object to the illuminating pencil at all obliquities. Fig. 5 shows the sector at the lowest position, so that the microscope-body is horizontal, the tail-piece is clamped to the sector, the limb swung laterally about 45° to the right, and the substage removed: this position of the sector is that required for measuring angles of aperture by the graduations on the circular base. The axis of the lateral inclining motion is also graduated, so that either the degree of inclination of the limb or that of the swinging tail-piece can be registered. In all these positions, and, indeed, in every position in which the various movements enable it to be placed, the microscope is very steady.

The construction of the stand has been carried out by Messrs. Ross, under Mr. Wenham's instructions, and we understand that they purpose making such modifications as will permit a lamp to be carried by the swinging tail-piece, or placed at the lower end of the sector, and the mirror to be attached at pleasure to a rotating slide in the centre of the base: these alterations will add still more to the facilities for obtaining obliquely incident light.—*Journal, Royal Micr. Soc.* (with additions).

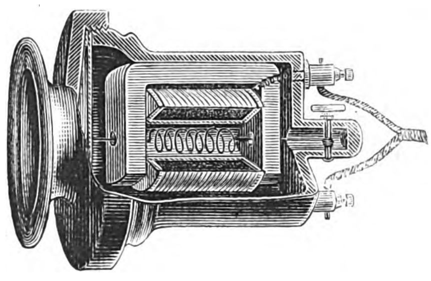
THE NEW "OTTO" GAS-ENGINE.



IN the engraving below we give a view of the new 16 horse-power Otto-Crossley gas-engine, which can be seen at work in the West Corridor at the Crystal Palace driving some of the dynamos. Messrs. Crossley exhibit altogether eight engines; but that shown in the engraving is the largest single-cylinder gas-engine ever made. So far as the framing is concerned, the engine is of novel design, and it has an improved governor, which renders the engine especially adapted for driving electric machines. Nominally of 16 horse-power, it indicates 40 horse-power, and a glance at the figure will show that it is simplicity itself in the matter of fixing. The numbers of gas-engines now in use would be enormously increased if the gas companies, taking advantage of their position, would but supply heating-gas by a separate service. By dispensing with the costly purifying processes, it is known that coal-gas could be sold at a profit for little more than one shilling per 1,000 cubic feet, and at that rate power-users could, by means of one of these engines, have 40 I.H.P. for 10d. an hour, or, at the rate of one farthing per horse-power per hour. No words are needed to explain what an important effect so cheap a motive-power would have on the industries of the country.

A NEW TELEPHONE RECEIVER.

WE illustrate a new telephone-receiver, the action of which is due to the contraction of a spiral magnet core under the influence of the current traversing the bobbin. The spiral core is attached at one end to the diaphragm, and is connected at the other end with an adjusting-screw. The spiral core is perfectly free to work in the helix, and the contraction or expansion of the spiral under the influence of the current from the transmitter acts on the diaphragm in much the same manner as though it was attracted by a magnet, the results being the same as in Bell's, Gray's, or Phelps' instruments. A permanent magnet placed outside the bobbin magnetises the "spiral core" by induction, so that the spiral is very sensitive, thereby making it sensitive to the influence of currents passing in the bobbin. The inventor expects to, partially at least, overcome the influence of induced currents in the receiver, and to obtain more distinct articulation. The construction of the telephone will be readily understood by reference to the engraving, in which a portion of the instrument is broken away to show the internal parts. The diaphragm is mounted on a mouthpiece of the usual description, and the permanent magnet and bobbin with the inclosed spiral is placed in a small casing attached to the mouthpiece. The instrument is provided with the usual binding posts and flexible connections. This receiver is the invention of H. S. Thornberry, of Winona, Minn., who may be addressed for further particulars. — *Scientific American.*



THE APPLICATIONS OF ELECTRICITY.[*]

(*Continued from page* 96.)

WE have here a piece of soft iron bent into the shape of a horseshoe, and surrounded by several turns of silk-covered copper wire. This piece of iron is altogether incapable of exercising any attraction on the small bar of iron, which stands at about half an inch from it. If, however, we send an electrical current through the wires, the soft iron is instantly converted into a powerful magnet; you see the piece of iron rushes upwards, and sticks to the electro-magnet thus formed, so that I cannot tear it off. I will attach several weights to the attracted piece of iron to show you that our small electro-magnet is strong enough to sustain them. Let us now interrupt the current; the instant it ceases to pass, the piece of iron ceases to be magnetic, and the weights fall down. This is a most important experiment, and capable of an endless number of applications; indeed, I may almost say that the principal part of nearly all our electrical instruments is an electro-magnet. Several telegraphs entirely depend upon this property of soft iron to become magnetic by the electric current. In Wheatstone's A B C dial telegraph the receiving instrument consists of a dial, around which are marked the letters of the alphabet. Every time the current is sent from the sending instrument an electro-magnet in the receiving instrument attracts a piece of soft iron or armature, which works an escapement and sends the needle on one letter. The message is thus easily spelt out. Wheatstone invented a very perfect A B C instrument, which needed no battery, but was worked by magneto-electric currents. This instrument is not employed in France, but is much in favour in England, especially on short lines between business houses.

In France the only A B C telegraph in use is Breguet's. In this telegraph clockwork is employed, and the escapement is worked by an ordinary electro-magnet. The hand can thus turn round the dial and indicate the message, letter by letter. You see that all these telegraphs leave no permanent record of the despatches; this is a grave defect in several cases. Morse's printing telegraph is admirably suited to meet this difficulty. The principal and active part of the apparatus is, of course, an electro-magnet; but here we do not use it to turn a hand round a dial, but to work a small lever carrying at its end a wheel wetted with printing-ink. Every time the current is sent from the sending-station the lever is worked and the inking-wheel is brought to bear against a long and thin strip of paper, which is moved uniformly by clockwork. You easily see that if I only close the current for an instant, I produce a dot on the paper; whereas, if I keep the current on for a longer space of time, the inking-wheel will trace a line or dash on the strip. A certain number of dots and dashes are attributed to each letter of the alphabet, just as a certain number of right and left deflections are attributed to each letter of the alphabet in Wheatstone's single-needle telegraph which I have already described. The Morse telegraph is in use in all countries. In order to make it more rapid, Wheatstone rendered it automatic and dispensed with the sending clerk. In this system the message is given to several clerks, who punch it out—that is to say, they perforate a strip of paper, so that when it is passed through the sending instrument, it will do exactly what a sending clerk would do. It will allow the current to pass at regular intervals to form the dots and dashes in the receiving instrument; it goes, however, much quicker, for the perforated strip can be passed very rapidly through the sending instrument. This system is much used where heavy work is required. In France we much like Hughes's printing telegraph, which prints the message in typographical characters ready to be sent to destination and readable by everybody. It is a very delicate and complicated piece of apparatus. The chief part of it is a type-wheel, on whose circumference are engraved the letters of the alphabet, moved by clockwork. The clockwork is let off or stopped by an electro-magnet, and it will easily be understood that the type-wheel may be brought with the desired letter opposite a strip of paper, on to which it will be impressed by movement of the latter. The sending instrument consists of a keyboard; the sending clerk presses the appropriate key in order to print the corresponding letter.

(*To be continued.*)

GALVANIC BATTERIES FROM ELEMENTS ALONE.

IT has been commonly supposed that the action of a galvanic combination requires that at least one constituent be a body that conducts electrolytically, a decomposable liquid. Combinations formed simply from elements would, it has been thought, be inactive. According to the chemical theory of the galvanic current, however, in every case where there is a reciprocal chemical action of two substances, with loss of potential energy, there is also electricity; it does not matter whether these substances are elementary or not. If they are capable of conducting electricity, and care is taken to conduct away continuously the electricity generated, a galvanic element is formed.

---

[*] Lectures delivered by C. Detaille, at the Palais du Trocadéro, Paris.

With this view, the well-known Austrian physicist, Prof. Exner, lately sought to form galvanic batteries with elements alone. Of all combinations that present themselves, those of metals and bromine or iodine appear the most suitable, because bromine and iodine attack metals considerably, and as the heats of combination have been very exactly determined by Herr J. Thomsen, a quantitative comparison of experiment with theory is rendered possible.

The very first experiments made, with two metals and bromine, proved the correctness of the hypothesis. According to the metallic combination, galvanic elements more or less strong, and quite constant, are formed, and there is, of course, no polarisation.

On account of the very small conductivity of bromine and iodine, which generally pass for insulators, the measurements were made with a Branley quadrant electrometer (with mirror). The bromine was chemically pure, as used for quantitative analysis, and underwent no degradation of purity by an electrolyte; this was proved both by later measurements of conductivity, and by the fact that there was not the slightest trace of polarisation. The metal to be examined was, simultaneously with a carbon electrode, inserted in the bromine, and the latter connected with earth, the former with an electrometer. The electrometer, which a Daniell element deflected to the extent of 23·6 divisions, indicated the electromotive force of the combination. Separate portions of bromine were used for each experiment, which lasted only a few seconds. The metals tried were: magnesium, aluminium, zinc, lead, silver, copper, and platinum.

Similar experiments to those with bromine were made with iodine, and the average value of the electromotive force reduced to Daniells, and compared with those calculated from the heat of combination, are given in the following table:

Element.		Electromotive Force.	
		Observed.	Calculated.
		D	D
Mg	Br	2·36	—
Al	Br	1·60	1·61
Zn	Br	1·52	1·52
Pb	Br	1.29	1·29
Ag	Br	0·91	0 91
Cu	Br	0·51	0 65
Pt	Br	0·04	—
Mg	I	1·57	—
Zn	I	0·96	0·98
Al	I	0.77	0 93
Hg	I	0·55	0·68
Ag	I	0·56	0·55
Pt	I	0·313	—

There is, with some difference, a very satisfactory amount of agreement. The calculation was made on the assumption, that besides the reaction between the metal and bromine or iodine, no other circumstance participated in the formation of a current. Thus, it appears, that elementary substances, where they act chemically on each other, are capable of forming galvanic combinations. This was supported by the fact that none of the combinations showed a trace of polarisation, which must have occurred if their action had been caused by electrolytes.

The conductivity of iodine and bromine was also investigated by Prof. Exner, and found (unlike that of metals) to increase with the temperature. This fact (says the author) is perhaps of interest with regard to a theory of conduction, for it seems to indicate that the increased conductivity is connected with the liquid state. Mercury, whose conductivity, of course, decreases with the temperature, has a considerably less coefficient of temperature than all solid metals; it seems to me, therefore, not singular, that in the case of other substances, in which, perhaps, the influence of the liquid state preponderates over that of the metallic nature, the temperature-coefficient also changes sign.

NEW AND DELICATE TEST FOR AMMONIA.

A NEW and delicate test for ammonia in the gaseous form is described by G. Kroupa in the *Chemiker Zeitung*. When fuchsine is dissolved in water and dilute sulphuric acid added, its red colour will be changed to a yellowish brown (the mono acid becomes converted into the di or tri sulphate). If stripes of unsized paper be dipped in a not too dilute solution of rosaniline and dried, they will appear—similar to turmeric—of a beautiful yellowish colour. Paper prepared in the above-described manner is permanently coloured carmine by ammonia when it is in the form of a vapour. The action of the ammonia is to convert the poly-acid—rosaniline into a monacid fuchsine. This paper is of use for the detection of ammonium salts when they are present in small quantities. The substance to be tested is placed in a bottle and moistened with calcium hydrate. The bottle is closed with a piece of the test attached to the lower part of the stopper. It is best to employ the paper when it is in a dry state, because when it is moistened it becomes bluish and its change to red is not so readily perceptible. In order to hasten the decomposition of the ammonium salts, the bottle with its contents may be warmed, as the paper is not affected by steam. By this means a beautiful red colour may be produced with 0 0005 gramme ammonium chloride, and 0·0005 gramme ammonium carbonate in a very short while. When it is exposed to the air it is liable to be attacked by moisture, though only after some time; it is, therefore, best to preserve it in well closed vessels. It cannot, however, be kept indefinitely, as it is too fragile.

SUGGESTED ANALOGY BETWEEN "WATER-HAMMER" ACTION AND EARTHQUAKE AND VOLCANIC PHENOMENA.*

PROFESSOR PRESTWICH, in his paper in the January number of this Magazine on the "Causes of Volcanic Action," assumes the existance of hot reservoirs or cavities filled with molten rock, and cold reservoirs or cavities, nearer the surface, filled with water; and he supposes the shrinkage of the Earth to squeeze up the molten rock till it meets with the water, which then explodes, producing a volcano. I would suggest that the action which goes on in the fissures that connect the hot and cold cavities is similar to the "water-hammer" action, so well known to engineers. This assumption is necessary, it seems to me, to render the theory completely satisfactory. Water hammer action manifests itself where steam has to be conveyed to considerable distances from its source without any return communication or easy vent. It occurs in this way. The steam, on being turned into the cold pipes, is quickly condensed, and in a short time a quantity of water is formed. The steam condensing most quickly at the end furthest from the inlet, there is there formed a partial vacuum. The steam rushing forward in consequence, gathers up the water into a plug, which fills the sectional area of the pipe, and forms, indeed, a water-piston. This water-piston is dashed by the force of the steam against the end of the pipe, producing a severe shock, accompanied by a loud report; and then follows, by natural sequence, a rebound, which must be a rebound of a compound character, made up in part of the rebound of the steam, in part of the rebound of the water, and in part of the effort of the water to regain its level by gravity. The first two are probably of momentary existence, but the last takes time, and proceeds with a measured swing like a mighty pendulum. When the force of the return wave is spent, and the steam again gets the advantage, condensation having in the mean time been going on behind the return wave, this piston of water advances a second time, and is dashed with increased fury against the obstruction in the pipe. This action in a few strokes arrives at its maximum, and thence, if the pipe has been able to withstand the shocks, gradually diminishes and dies away. There are two operations at work affecting its destiny. The quantity of water set in motion is increasing, tending to increase the shock, and the temperature of the pipe is heightening, tending to diminish the shock by reducing the difference of pressure between the spaces before and behind the water-plug. The latter is by far the more potent agent, and quickly reduces the water-hammer action to nothing. Now the essentials to this kind of action are—1. A length of passage confined at its extremity. 2. A fluid. 3. A condensible vapour. 4. A difference of temperature at the two extremities of the passage. 5. The initial action, which is merely the introduction of the condensible vapour into the colder end of the passage from the hotter, so that it may be under conditions producing condensation, and thus commence the water-hammer action. That this kind of action, owing largely to the very low compressibility of water, is capable of producing very severe shocks, even when the essential factors are of comparatively low value, is seen from the fact that stout iron pipes of only a few inches in diameter are often burst into fragments by it, even when the difference of pressure developed cannot be more than about 50lb. per square inch, and where the length of pipe is not many yards. Given, therefore, subterranean reservoirs, as Professor Prestwich supposes, we have only to assume a communication formed between these two reservoirs by a fissure, and we shall have the conditions favourable for the water-hammer action on such a gigantic scale as appears competent to account for the phenomena of earthquakes and volcanoes. Immediately a fissure is formed connecting the reservoirs of water nearer the surface and at comparatively low temperature with the more deep-seated reservoirs of molten rock, steam is formed, which, passing along the fissure, becomes condensed, difference of pressure is set up, the water and molten rock form a fluid piston or plug, and shocks proportionate to the difference of pressure, the length and sectional area of the passage, and to the quantity of matter set in motion, are thence inevitable. If, when this action arrives at its maximum, the water cavity is incapable of sustaining the shock, and gives way, its broken walls are thrown out as dust and ash, the whole body of the water, which had become superheated, bursts into steam, and the molten rock is poured out as lava. There is another analogy indirectly connected with this matter, which appears to hold between the conditions beneath the crust of the earth and those in a steam-boiler, to which I shall only make a brief reference, as the question has been dealt with in well-known geological works. It bears upon the observed fact that mountain ranges occur mainly along lines of thick deposit. If a sediment (especially one of a loose or of a greasy character) be allowed to accumulate on the outside of the firetube of a boiler, the heat is prevented from getting through the iron plate sufficiently fast to prevent overheating. The contact of the plate with the water is broken, and the sediment is a bad conductor. The result is that the plate becomes overheated, and the external pressure on the firetube thrusts it out of shape, producing what is known as a "collapsed furnace." This seems to illustrate what takes place on a large scale in areas of great deposition. The thick, loose sediment forms a bad conductor, overheating takes place, and that first, of course, along the line of thickest deposit, and the pressure being internal instead of external, a ridge outside is the result, instead of a collapse.

GELATINO-CHLORIDE OF SILVER PICTURES BY DEVELOPMENT.*

I PROPOSE this evening to demonstrate the method of producing transparencies on gelatino-chloride plates, and to describe certain modifications in the development which I have found to give the best results. For the preparation of the emulsion the following simple formula is all that is required:—

Gelatine	300 grains.
Cold water............	4 ounces.
Nitrate of silver	240 grains.
Distilled water	2 ounces.
Chloride of ammonium..	100 grains.
Water	4 ounces.

Mix the above in three separate vessels, allow the gelatine to soak for ten minutes, and warm all the solutions to about 120° F. Now add the silver to the gelatine, and immediately afterwards add the chloride. Emulsify at the same temperature for about an hour; then allow the emulsion to set. Pass through canvas, and wash in running water for some hours in the usual way. When washed and dissolved by gentle heat the emulsion will be ready for coating the plates. The glass chosen should be as thin and flat as possible, to insure contact in printing from the negative. The dried film should appear pure white by reflected light, and of an orange tint by transmitted light. The latter colour is owing to the chloride of silver being held in an extremely fine state of division. With regard to the sensitiveness of these plates, I have found them at least a hundred times less sensitive than ordinary gelatino-bromide plates. The time of exposure will depend, to a great extent, upon the colour desired in the transparency and the strength of the developer. With a moderately-strong developer an exposure of two or three seconds to diffused light under an ordinary negative will give all the detail. The developer I use is a modification of Doctor Eder's formula and that of Captain Abney. A stock solution is made as follows:—

Citric acid	5 ounces.
Distilled water	20 ,,
Strong ammonia	2 ,,

The heat produced by the addition of the ammonia will cause the crystals of citric acid rapidly to dissolve. As soon as the mixture is sufficiently cooled the solution is ready and will keep a long time. When required for use, mix three parts of the above solution with one part of the ordinary ferrous oxalate developer freshly made, by adding one part of a saturated solution of sulphate of iron to three parts of a saturated solution of neutral oxalate of potash. Now add to each ounce of the mixture two or three drops of a twenty-grain solution of bromide of potassium.

---

* By THOMAS MUDD, of Hartlepool, extracted from the *Geological Magazine*.

*Extracted from a paper by B. J. EDWARDS, read before the South London Photographic Society.

This will form a very powerful developer for the gelatino-chloride plates, and with a moderately-short exposure will give a rich purple tone to the transparency. For a pure black tone expose less time and use equal parts of the ferrous oxalate and citrate of ammonia solutions, with an extra drop or two of restrainer, if required. If much warmer tones are desired, six or eight parts of the citrate solution should be used to one part of the ferrous oxalate. Any shade of colour may be obtained, from jet black to bright ruby red; but with the weaker developer it will be necessary to increase the exposure considerably. For instance, to obtain the ruby colour two or three times the exposure will be required than for the black tones with the stronger developer. In this way a great variety of beautiful tones may be produced at will; but the great advantage of this method of development consists in the very great latitude allowed in the exposure. When working by daylight and with negatives of different degrees of density it is practically impossible to be sure of getting the correct exposure except by repeated trials, unless the developer can be regulated to suit the exposure given. By my method this is easily done. I make three or more portions of developer of different degrees of energy; that is, containing a greater or less proportion of the ferrous oxalate. Should the transparency appear under-exposed the developer is at once poured off and the development completed with a more energetic solution. In the case of over-exposure the operations are reversed. This power of correcting under or over-exposure in the development of pictures on chloride of silver has not hitherto been obtained by any known method; and I think I may venture to assert that, without the power of compensating for errors in exposure, the process of printing by development on chloride of silver, however beautiful in some of its results, would be practically useless. With regard to the keeping qualities of the developer, I find that after being mixed it gradually but slowly loses its energy, otherwise keeping in perfect condition for several weeks. It can, however, at any time be restored to any desired strength by adding the proper proportion of freshly-made ferrous oxalate developer, as in the first instance. With regard to the utility of this really beautiful process, I think few will question its superiority for the production of the most exquisite transparencies for lantern slides or for making enlarged negatives. There is, however, another application of the process which may eventually prove of far greater importance. I allude to the rapid production of silver prints on paper by development, instead of the present slow process of printing out under the negative. I have already made a few experiments in this direction, and from the results I have already obtained I should judge that it is not improbable that the process I have described to you to-night will prove in time the quick-printing process of the future.

USEFUL AND SCIENTIFIC NOTES.

◆◆◆

Lacquers.—The following have been given as lacquers for brass:—(1) Seed lac, dragon's blood, annatto, and gamboge, each 4oz.; saffron, 1oz.; wine spirit, 10 pints. (2) Turmeric, 1lb.; annatto, 2oz.; shellac and gum juniper, each 12oz.; wine spirit, 12oz. (3) Seed lac, 6oz.; dragon's blood, 40gr.; amber and copal triturated in a mortar, 2oz.; extract of red sanders, ½ drachm; Oriental saffron, 36gr.; coarsely-powdered glass, 4oz.; absolute alcohol, 40oz. (very fine). (4) Seed lac, 3oz.; amber and gamboge, each 2oz.; extract of red sanders, ½ drachm; dragon's blood, 1 drachm; saffron, ½ drachm; wine spirit, 2 pints 4oz. (5) Turmeric, 6 drachms; saffron, 15gr.; hot alcohol, 1 pint; draw the tincture and add: gamboge, 6 drachms; gum sandarac and gum elemi, each 2oz.; dragon's blood and seed lac, each 1oz. (6) Alcohol, 1 pint; turmeric, 1oz.; annatto and saffron, 2 drachms each. Agitate frequently for a week, filter into a clean bottle, and add seed lac, 3oz. Let stand, with occasional agitation, for about two weeks. (7) Gamboge, ½oz.; aloes, 1½oz.; shellac (fine), 8oz.; wine spirit, 1 gallon.

THE four-track line of the New York Central is now complete from Albany to Buffalo, 298 miles. The *Railroad Gazette* says there is nothing like this four-track road from Albany to Buffalo anywhere else in the world. There are short sections of four-track roads on several lines, and the London and North-Western expects to be compelled to have separate freight and passenger tracks for a considerable portion of its road, we believe; but nowhere else in the world can be found a continuous four-track line 300 miles long.

THERE does not appear to be any intention at present in Russia to raise the duty on bar, plate, or other iron, although most of the duties on other imports are being raised.

SCIENTIFIC SOCIETIES.

◆◆◆

ROYAL ASTRONOMICAL SOCIETY.

THE April meeting of the Society was held on the 14th inst., at Burlington House, Mr. E. J. Stone, president of the society, and director of the Radcliffe Observatory, Oxford, occupied the chair.

Mr. Robert T. Pett, of the Royal Observatory, Cape of Good Hope, was balloted for and duly elected a Fellow of the Society.

Among the presents which had been received by the Society, Mr. Knobel called attention to a number of the "Bulletin des Sciences Mathématiques et Astronomiques," in which was re-published a curious catalogue of Southern stars which had been observed by Frederic Houtman, in Sumatra, in the year 1600. It had been originally published at Amsterdam, but was extremely rare and little known.

Mr. Glaisher read two papers by Prof. Asaph Hall, "On the conjunctions of the interior satellites of Saturn," and "Observations of the companion of Sirius, made at the United States Naval Observatory, Washington.

Mr. Glaisher also read a paper by Prof. E. S. Holden, "On the inclination of the ring of Saturn to its orbit, deduced from the Washington observations made during 1877 to 1879 with the 26in. refractor. The observations seemed to indicate a diminution of the inclination.

A list of errata in the first Melbourne General Catalogue of Stars, by Mr. Ellery, was also read, in reference to which Mr. Downing remarked that a comparison of Lacaille's places with the places in Mr. Stone's catalogue gives nearly the same proper motions as the comparison with the Melbourne catalogue. It would appear from this, therefore, that Lacaille's places are useless for the determination of proper motions.

Mr. Glaisher read a paper by Mr. T. E. Espin, on the variable star β Ursæ Minoris.

Mr. Knobel read a paper by Professor Newcomb, entitled, "Remarks on the Instructions for Observing the Transit of Venus, Formulated by the Paris International Conference." The writer stated that he hesitated to suggest improvements upon the instructions drawn up by the eminent astronomers who took part in the Conference, but the subject was of great importance to Americans, as their observers would probably be as numerous as those of all the other countries who would send out expeditions to observe the Transit. With regard to the first three articles of the instructions, he would only suggest that the use of a silvered objective might in some cases diminish the light of the sun too much. Everything really depended upon the observers seeing the gradual approach of the cusps round Venus, and estimating the moment when the thread of light became visible. This would be best seen if the solar disc were as bright as the eye could bear with comfort.

Prof. Newcomb did not clearly understand some expressions in article four of the Instructions, and proceeded to make some general statements with regard to the phenomena of contact. The moment of true internal contact is when the points of the cusps begin to meet round the planet; the imperfections of definition, however, never allowed this moment to be fixed with perfect accuracy. The instructions endeavour to surmount this difficulty by explaining the phenomena to be expected, but these are not described with sufficient precision, and would probably lead to the time of ingress being noted too late, and of egress too early, as appears to have been the case with Mr. Tebbutt in his observations of the Transit of 1874. The instructions seem to indicate that there is a precise moment when a shade appears upon the line of light between the planet and the sun's limb, which is not the case, and also that the "shade" and the "black drop" are two distinct phenomena. The phenomena observed are, in fact, not always the same, but if sufficient precautions are taken there should be only two causes of difference—viz., different atmospheric conditions and differences of contrast between the brilliancy of the sun and of the sky. Observers should concentrate their attention upon the cusps, and endeavour to estimate the moment when they would meet round the planet if they were sharply defined instead of being indefinite. He was sorry that observations of exterior contacts should be neglected, and thought that in the Instructions the observer should have been warned against mistaking the line of light seen round the portion of the planet outside the Sun, for the solar limb. He strongly recommended practice with an artificial transit, and concluded with a few remarks upon the employment of photography.

The President said we should have been very glad if we had received this communication earlier, as the committee had been most desirous to obtain the views of the American astronomers before the Instructions were drawn up. Last October a provisional list was sent to America, but no suggestions were received by the committee. I believe most of Prof. Newcomb's objections are mere criticisms of verbiage, and that had he attended the conference, an agreement might easily have been arrived at. We have recommended observers to note at ingress the last moment of discontinuity of the limb, while Prof. Newcomb directs attention to the cusps, and to the instant when they would meet round the planet; but these are the same things described in different words. With regard to the line of light round Venus, we have been very desirous that observers should not mistake this for the limb of the Sun.

Mr. Christie said: I agree in the main with Mr. Stone, but there are difficulties with regard to some of the Colonial observations, in which different phases of contact are described, differing from one another by minutes. It is often very difficult to decide which phase the observer intends to describe, as they frequently do not express themselves definitely.

Mr. Rand Capron mentioned a photograph which he had taken of the last partial eclipse of the sun under unfavourable atmospheric conditions, but in which the solar limb was well defined, and asked if this might be due to the shortness of the exposure.

Capt. Abney said that it was a matter of chance whether the photograph would be well defined or not, but good definition was more likely to be obtained with extremely short exposures.

The Rev. S. J. Perry said that in M. André's experiments with an artificial transit, the difference between the time of *actual* contact and of the last appearance observed was from 1½ to between 3 or 4 minutes. He also found, at ingress, that the cusps invariably appeared flattened, and at egress rounded. The black drop could always be obtained by varying the illumination. Perhaps it might be possible, in actual observation, to destroy the black drop as it formed, by decreasing the illumination, so as to obtain true contact. The atmosphere of Venus will not be likely to mislead observers, if they do not use the double-image micrometer up to the last moment, as they will be able, with care, to discriminate between the line of light and the solar limb.

Mr. Green called attention to the remarkable drawing of Mars made by Professor Schiaparelli, in which the greater number of the fine lines represented in his former drawings were delineated as *doubled*. Fine lines upon the planet Mars have been described by Mr. Dawes and Mr. Banks, which do not appear on Signor Schiaparelli's drawing. Mr. Burton has drawn some delicate markings which cannot be reconciled with drawings made at another time. These lines should not be regarded as facts until they have been repeatedly seen by other observers.

Mr. Maunder said: I have observed fine lines on Mars, which appear to correspond with those on Schiaparelli's drawing; but not perfectly. One fine marking, in particular, I have repeatedly observed under favourable circumstances; have frequently seen what might be the commencement and the ending of canals which Schiaparelli has marked, but which I have not been able to trace in their entirety. In many cases I should consider the "canals" rather as the boundaries of delicate tints. I have, however, generally been able to make out the stronger markings that Schiaparelli has delineated.

Mr. Knobel said that in some drawings which he had made in 1879 there were some confirmations of Schiaparelli's markings. He had also distinct markings made on three different nights which were not on Mr. Green's map, and which had not been drawn by Schiaparelli.

The President read a paper on the results obtained from meridian observations of Mars made during the opposition of 1877 at the Cape, at Melbourne, at Leyden, and at Washington.

Mr. Downing thought that the different methods of observation which had been employed might have introduced systematic errors, and asked if Mr. Stone had discovered any difference in the observations made before and after opposition.

The President said that he saw no difference. He did not think that the different methods of observation had introduced any considerable systematic errors.

The following communications were also announced and partly read:—Lieut. W. U. Moore, "Alleged errors in the time-record of observations of the Transit of Venus, 1874, made at Hermitage, Rodriguez"; and D. Gill, "On the best mode of undertaking a discussion of the observations of contact to be made at the approaching Transit of Venus."

ROYAL MICROSCOPICAL SOCIETY.

THE seventh meeting of the session of the above Society was held on the 12th inst. at King's College, Strand, the President (Prof. P. Martin Duncan, F.R.S.) in the chair.

The minutes of the previous meeting were read and confirmed, and the list of donations was submitted, and the thanks of the Society given to the donors.

Mr. M. M. Hartog (of Owens College) described some specimens which he exhibited under microscopes. One of these was Apus cancriformis, the largest of the water-fleas. It had not, to his knowledge, been hitherto recorded in England, the specimen shown having been obtained this spring from some mud received from Germany. The other exhibits were a series of sections of Entomostraca, which had been prepared for histological study. The specimens were killed by adding a few drops of osmic acid to the water in which they were placed, and as soon as they fell to the bottom they were removed to spirit direct. This plan had its advantage inasmuch as any mutilation was thereby avoided; but, on the other hand, by opening them in the osmic acid, a certain amount of maceration was unavoidable, which might sometimes prove to be detrimental to the histology. They were at first transferred to spirit of 30 per cent., and then to 50 per cent., after which they were placed in cochineal solution, and were then washed repeatedly in 70 per cent. alcohol, until they yielded no more colour to it, and afterwards they were placed in 90 per cent., and then in absolute alcohol. They were next treated with a greasy medium, and for this purpose, whilst they were in the absolute alcohol, a small quantity of oil of cloves was poured in; this sank to the bottom of the tube, and the entomostraca would then lie, not at the bottom, but just between the alcohol and the oil of cloves. In this way he had, with specimens which had been unopened, obtained preparations in which there had been absolutely no shrinkage of the protoplasm. Most of the oil of cloves was then poured away, and the specimens having been embedded in a mixture of spermaceti and castor-oil, the sections were cut in the usual way. It would be noticed that the sections were arranged in series on the slide; to do this some benzole was poured on the glass and left to evaporate, and this was sufficient to cement them to it. By this means of preparation he had been able to make out some very important points. The specimens exhibited the entire organs of the body; the nervous cord could be well seen, as could also the gullet with its muscles. A rough sketch made to illustrate the chief points of interest was also exhibited.

Mr. Beck thought the remarks of Mr. Hartog were exceedingly interesting, for if they were ever really to understand these structures, it must be by means of taking sections. He was glad to have heard the very practical remarks which had been made, and hoped they would be the means of inducing others to practise the process, feeling sure that such a study would elucidate many points which were now involved in mystery.

Mr. Stewart said he should like to ask whether, in cutting these sections, a microtome was used, or whether they were cut by hand with a razor. It also occurred to him that this process might also be very useful in the preparation of sections of many of the soft-bodied creatures, such as the mites or the arachnida, for it was very difficult to make out many parts of their anatomy by any process of dissection.

Mr. Hartog, in reply, said that as in all cases where sections had to be cut in series, a microtome was used, in order to insure perfect regularity of thickness; in this case, Zeiss' microtome was employed, using oil to moisten the razor. He agreed that the process would be very useful in the case of mites and spiders; but he thought it well to remark that picric acid—so much in favour with some persons—should be avoided, as it penetrated too freely.

Mr. Crisp called attention to two microscopes which he had brought for exhibition. One of these—which it had been proposed to call the "Jumbo" microscope—stood about 4ft. 6in. high, and weighed about 1¼cwt. It must have been made about fifty years ago. The other, the "Midget"—shown by way of contrast—was completely finished for use, its entire height being only 4in., and its weight a few ounces. Six of such microscopes could be inclosed in the eyepiece of the larger one.

Mr. Beck examined the "Jumbo" instrument, and made some remarks as to the peculiarity of its construction.

Mr. Crisp read a note received from Dr. Loew as to the chemical difference between living and dead protoplasm, and exhibited a photograph illustrating Loew and Bokormy's statement as to the different reaction of dead and living protoplasm on silver salts.

Mr. A. W. Bennett said that the photograph represented two filaments of *Spirogyra nitida*. One of these (*b*) had been subjected in a living condition to the silver reagent; the reducing effect of the living protoplasm had converted the cell-contents into a black opaque mass. The other filament (*a*) had been killed by a 1 per cent. solution of citric acid before treatment with the silver solution. In this case no reduction and consequent blackening is exhibited, the spiral arrangement of the chlorophyll-bands being still perfectly distinct.

Mr. Stewart said he did not see that they had any actual proof that the protoplasm in the one case was dead and in the other living, especially when it was borne in mind that the way in which it was killed was by means of citric acid, a small residual quantity of which he thought might have some effect upon the result.

Mr. Bennett said it was clear that they wanted more particulars before coming to a definite conclusion, though it was naturally to be supposed that all acid had been removed before the tests were applied.

Mr. Hartog referred to the silver-staining processes recently described in the *Journal*.

Mr. Stewart said if they wanted to make silver-staining a test in the case of the tissues of living animals, it would not always be found an easy thing to do. In cases of operations they could probably get living tissues, but there were many parts which it would be very desirable to test with, which could not be obtained until after 24 hours from the time of death, and yet he thought that in such cases the outlines of a cell were as perfectly rendered as if they were living. He was afraid that unless the citric acid were entirely eliminated, it would probably exercise an important influence on the results.

Dr. Matthews felt sure that such would be the case, for it was well known that in photography the developing fluids had been acidified, and this especially by citric acid, for the purpose of retarding the reduction of the silver salt, so that the results where acid had been concerned would be very suspicious. The use of alkaline instead of acid preparations was the secret of the modern rapid processes of photographic development.

Mr. J. E. Ingpen read a paper on the use of diaphragms, illustrating his remarks by drawings upon the black-board. He said the principle governing the application of diaphragms was that they should cut down the cone of rays reflected from the mirror, illustrating the case by drawing on the black-board a cone, having the object on the stage for its apex, and the active diameter of the mirror as its base. That was the cone to be acted upon by any system of diaphragms. He showed that the ordinary wheel of diaphragms in very general use was effective to a certain extent; but he gave the preference very decidedly to the sliding cylinder-diaphragm so largely adopted on the Continent, and stated that the most perfect form of it that he had seen was devised many years ago by M. Varley, in which a double cylinder was used—one working within the other,—the outer one with moderate-sized opening sliding up in the substage, or in the ring provided for the purpose beneath the stage, until in contact with the slide. This cylinder was lined with cloth, to facilitate the sliding-in of the second cylinder, having a similar opening in the cap. By the proper use of this double cylinder the cone of light could be modified in the most perfect manner,—in fact, it left nothing to be desired. Mr. Ingpen further said that diaphragms had been recently brought forward in which the essential principle of action to which he had just directed attention had been entirely ignored. As an example, he referred to a plate of diaphragms devised by Dr. Anthony, consisting of a series of apertures punched in a strip of vellum, to be slid immediately beneath the slide upon the stage, the action of which he described as "merely cutting off stray light." This device did not appear to him effective as a diaphragm on the illuminating cone, inasmuch as at the position in which Dr. Anthony placed it the cone of rays was far too small to be affected by the size of apertures adopted, passing, in fact, completely within the apertures. He might apply the same remarks to the action of the *calotte* diaphragms, which he equally regarded as based on a wrong conception of the action of diaphragms. Mr. Ingpen also said he could not commend the use of the Iris diaphragm, on the ground that it required a special fitting, and could rarely be used near enough to the slide.

The President said he should be glad to hear remarks upon Mr. Ingpen's communication, as he was sure there were many Fellows present who had made a special study of the use of diaphragms.

Mr. J. Mayall, jun., said he thought Mr. Ingpen had misapprehended the purpose of the diaphragm proposed lately by Dr. Anthony. On the supposition that the sole purpose of diaphragms was to reduce the entire cone of the illuminating pencil, Mr. Ingpen had no difficulty in showing that the aperture in Dr. Anthony's diaphragm was too large to be effective in the position in which he placed it—that is, immediately beneath the slide. But there was another purpose in the application of diaphragms—a purpose not touched upon in Mr. Ingpen's remarks, namely, the cutting off different portions of the illuminating pencil, which all workers with high powers on diaphanous structure had felt the need of, and for which innumerable contrivances had been devised.

The mere cutting down the diameter of the illuminating beam was, of course, the main object of the wheel of apertures in common use, and of the cylinder diaphragms referred to by Mr. Ingpen. But Dr. Anthony's diaphragm was intended to supplement the action of the strictly central aperture by a series of apertures that could be easily applied to cut off more or less of the beam after all had been done that was possible in modifying the light with the central apertures—in fact, to use a phrase of Dr. Anthony's, "to give the finishing touch to the illumination."

Mr. Ingpen's statement that this diaphragm served no other purpose than to "stop off stray light" was thus shown to be an error. Regarding the *calotte* diaphragm, Mr. Mayall said he could not agree with Mr. Ingpen's general condemnation. He might remind Mr. Ingpen that the recent application of the *calotte*—used as a diaphragm alone — immediately beneath the slide, was due to Mr. Zeiss, of Jena, who was hardly likely to have adopted it with his portable microscope unless he had found it effective. The still more recent application of the *calotte* *above* the achromatic condenser must be regarded as a step in advance. Mr. Bullock, of Chicago, appeared to be one of the earliest in the field to see that the system of dirphragms supplied *beneath* the optical combination in Gillett's condenser, might be advantageously applied *above* the lenses, where, obviously, the cone of rays is so short and of such great angular extension that every variation in size or shape in the apertures of the *calotte* would be effective. He might also mention that Mr. Swift had adopted the *calotte* in connection with the achromatic condenser. As to the use of the Iris diaphragm, Mr. Mayall thought it was effective for low powers, especially when mounted to fit in the stage itself, as adopted by Messrs Ross; but, so far as his own observations went, he had not been satisfied with it in connection with the achromatic condenser. He believed there were difficulties in the construction which rendered it almost impossible to close the aperture with sufficiently accurate centring to be of real service with the condenser. In conclusion, Mr. Mayall said that the great number of devices that had been brought forward in recent years to cut off portions of the illuminating pencil independently of the mere reduction of the cone by strictly central apertures, proved conclusively that a need was felt in that direction.

Mr. Beck said he could hardly understand what was meant by saying that with the Zeiss diaphragm they could not cut off any portion of the cone of rays, because if it was properly made they could cut off all the rays entirely. Though there might be differences of opinion as to what was the most valuable kind, he thought no one would dispute the great importance of a good diaphragm, which was of extreme value in rendering visible portions of an object which otherwise could not be seen.

Mr. Ingpen said that his remarks were merely taking things as they stood, and did not, of course, apply to the use of the *calotte* diaphragm with the achromatic condenser. The *calotte* diaphragm, as drawn by Mr. Mayall, was very effective, but almost every effect could be obtained by a very small number of stops with tolerably small apertures. Professor Abbe had satisfied himself of this entirely.

The President read a note on the histology of Temnopleuridæ ("Sea Urchins") which he illustrated by drawings upon the blackboard.

Mr. Stewart called attention to a curious change which took place under certain circumstances in the reticulated network. Where there was any friction going on it was found that the interstices became filled up with carbonate of lime, and this seemed to be a case of precisely the same kind as what went on in bone tissues under similar circumstances. Besides the spicules in the hard tissues, there was found a remarkable exception in the structure of the teeth, which more closely resembled silicious rather than calcareous spicules.

Mr. Hartog said that in studying the structure of these organisms it was important to study the soft parts in connection with the hard ones. To do this the specimen should be first stained and then saturated with liquid Canada balsam, which should then be evaporated down to a resin; sections could then be cut through the shell and the soft parts at the same time, showing them together *in situ*, and stained so far as they could be. This was, he said, Koch's method.

Mr. Stewart said that in Koch's method it was solid copal varnish which was used instead of solid Canada balsam, the latter being too brittle to enable good sections to be cut. He had seen sections which had been made by this method, and they certainly showed the structure remarkably well in the corals, &c.

The President said that Koch's method was a most excellent one as applied to corals, but it did not answer so well for Echinoderms. He had found it a very good plan to dissolve out the calcareous portions with weak acid. With regard to the fossil forms, they all knew that the reticulated structure was entirely lost during fossilisation when it seemed entirely filled up by calcite.

Mr. Stewart remarked that this complex network showed under the polariscope a common axis of tension passing through the entire body.

The President announced the second conversazione of the session for the 26th April; he then adjourned the meeting to May 12th.

SCIENTIFIC NEWS.

◆◆◆

THE installation of the Edison electric lighting system on the Holborn Viaduct has been the most interesting event of the past week, and we have now an application of the new light to the wants of everyday life. The incandescent lamps are employed for illuminating a chapel, the front of a railway station, a hotel, a restaurant, and sundry shops, warehouses, and offices. Besides those instances, there are a number of street-lamps, and as Siemens's regenerative gas-burners are in use from the Viaduct to Holborn Bars, a capital opportunity is afforded for direct comparison of the rival systems. The dynamo is the large machine exhibited at Paris, which is driven by a Porter-Allen engine fixed on the same base-plate. The armature makes 350 revolutions a minute, and the current produced is over 1,000 ampères, sufficient to supply about 1,000 lamps of 16 candle-power. The lamps being all arranged in what is known as multiple arc, the E.M.F. of the machine is very low, and the whole current can be passed through the body without injury.

Mr. J. R. Hind writes that, from observations at Harvard, Vienna, and Rome, he has determined the following orbit for comet Wells:—T. June 9·9697; π 54° 25′ 17″, ☊ 204° 37′ 42″, i 73° 35 39″, log q 8·748238. According to this orbit, the theoretical intensity of the comet's light at noon, June 10, will be 3,600 times greater than on March 19. The comet will be a naked-eye object in the latter part of May, and be visible in powerful telescopes in broad daylight. It will be always above the horizon of these latitudes until the beginning of June. The R.A. on April 22 will be 0h. 25m. 49s., N.D., 59° 31′ Greenwich midnight.

The English observers of the eclipse of the 17th May are busy preparing for their departure. Captain Abney will, we believe, not be able to go, but Dr. A. Schuster will take his place. Mr. Ranyard has made elaborate arrangements for securing photographs of the eclipse in all its stages.

The French commission, for the observation of the Transit of Venus, have completed their arrangements, and the astronomers selected for the work are already practising with the instruments. Three kinds of observations will be made—viz., photographic, direct contact, and by means of refracting prisms and micrometrical distances. The stations selected are Gaudaloupe or Martinique, under M. Tisserand, Cuba, M. d'Abadie; Florida, Colonel Perrier; Mexico, M. Bouquet de la Grye; Patagonia, M. Perrotin; Santa Cruz, Captain Fleuriais. Ingress and egress will be observed at all stations.

Mr. W. Peck has published (Archibald and Peck, Edinburgh) charts and diagrams of the transit, with explanations, showing at a glance all the places that are favourably situated for observation, and the times of beginning and ending, over the globe.

Mr. Stretton's pamphlet on railway accidents, the new edition of which we referred to last week, has been issued. It will be found interesting by all who are in any way concerned with railways, whether as shareholders, operators, or travellers. It is published by Spencer Bros. and Russell, Leicester.

Edison's electric railway at Menlo Park is making rapid progress, several miles being now complete and in working order. The line has several curves and gradients, one of 1 in 176. The current is conveyed by two wires of large section, one connected to each rail, which is insulated.

The *Alaska*, probably owing to the prevalence of easterly winds, has beaten her own record on the Transatlantic passage. On her last voyage she completed the run from Queenstown to New York in 7 days, 4 hours, 24 minutes, two hours and twenty minutes less than the voyage from New York to Queenstown. She has thus established her reputation as the fastest vessel following the shortest track across the Atlantic. The Cunarders go further south and make a longer distance of the voyage.

The rumours of new steamers being built in the United States are not with foundation, and we can wait with patience for their promised performances. The following is the description which has been published, and which has not been contradicted. "The vessel is built of wood, has a turtle-back deck, no masts, and nothing on deck except a pilot-house, ventilators, and the smoke pipe. The length is 151½ft., the breadth of beam is 22ft., the depth of the hold 16½ft., the draught forward is 5½ft., and aft 10½ft. The capacity is 512 tons. She will have three screws; the main one of four blades and of such pitch as to be capable of a speed of 30 knots an hour. The others will be fitted in the stern, behind the plates, and will be used in case of accident, when the plates will be used to steer with. The engines are of new design, and the ship is to be named the *Meteor*." Messrs. Biven and Lorillard are the active agents in the new scheme, which, judging by the above, has some peculiar features.

The Viceroy of India recently laid the foundation stone of the new buildings at Calcutta of the Indian Association for the Cultivation of Science. The object of the institution is to afford students the opportunity of pursuing their studies after they have left college.

Mr. Jennings, of Baltimore, U.S., patents a method of utilising the volatile matters given off by coffee-beans when roasting. The fumes are first passed through hot water, then through cold to separate the constituents, which are subsequently mixed with a mucilaginous vehicle, and used to coat the roasted beans.

Mr. Banks, of Birmingham, has hit upon a method of combining the pickling of metal plates with the production of electricity, and has obtained a patent. It is No. 3,771, of 1881.

An interesting simplification of dynamo-electric machines has been recently described to the Belgian Academy by Capt. Plucker, of Antwerp. It consists in substitution of a solenoid for the electro-magnet, whose branches (in the Gramme machine) embrace the cylindrical surface of the rotating coil. The arrangement is that of a movable coil, rotated within a fixed coil. The inducing current traverses the solenoid, and develops, in the movable coil, induced currents which are employed as in the Gramme. The induction is strengthened by means of iron armatures placed near. Captain Plucker put electro-magnets in place of the solenoid, and obtained the same effect. He claims for his system the advantage of smaller weight and volume.

In a recent memoir on landslips, Professor Heim distinguishes two principal categories of these: descent of movable ground, and that of rocks in position. Among the former cases he distinguishes first those which are characterised by slipping: this has been frequent in the history of the Swiss Alps, and a good example is the village of Fetan, in the Engadine, the position of which becomes increasingly critical, through the ground about it gradually sliding down. Then there are the cases of descent of rolling materials; *e.g.* at Bilten in the canton of Glaris (29 April, 1868). As to descent of rocks in position, one may again distinguish cases of slipping, such as that of the Rossberg, which buried Goldau on 2nd Sept., 1806; and falls of rocks, or fragments of mountain more or less considerable. It is to this last category that most of the cases in Switzerland must be referred. Professor Heim gives a catalogue of the chief landslips, from that of 13th June, 1486, which destroyed Zarera, in the valley of Poschiavo, to that of Elm. A large number are of combined types, and some cases (currents of mud, subsidence) do not find a place in the above classification. As a rule, the outline of mountains is but little affected by the loss of those portions which descend from them.

An important industry (we learn from *La Nature*) has sprung up within the last few years in the French department of Landes, through the enterprise of M. Charavil. It consists in extraction and applications of oils from pine. These oils are of two sorts: the heavy (pinoleum), obtained by distilling the resinous wood at a low temperature, and used for painting and wood-preserving; and the light oil for illumination, got by distilling in special apparatus, and purified with chemical agents. This light oil has the same chemical composition as oil of turpentine ($C_{20}H_{16}$), and distils at the same temperature (150° to 160°), but has the advantage of not resinifying. It contains neither pinic nor sylvic acid. As it does not emit vapours except at a high temperature, its use for lighting purposes is quite safe. Its luminous intensity is greater than that of petroleum; it contains 88 per cent. of carbon, while petroleum has 82 per cent. Two similar burners showed the pine oil to have an advantage of 33 per cent. in luminous intensity; the consumption was also less. In the department of Landes, roots and old stumps of pine, formerly unutilised, are now made to render considerable quantities of oil.

It is now recognised that a plant does not draw its food from a nutritive solution fully prepared, but prepares it itself by direct and intimate contact of its cells (which have always a slightly acid reaction) with the earth particles, in which nutritive elements have been fixed by way of physical absorption or chemical precipitation. The analytical chemist has to use strong mineral acids to redissolve these fixed matters, and there is the inconvenience that the acids also dissolve elements in combination by which a plant could not directly benefit. Hence imperfect information as to the degree of fertility of soils. M. Petermann is now seeking to develop a new method of analysis—viz., by dialysis of arable soil. In a preliminary paper to the Belgian Academy he finds that (1) arable soil yields to distilled water, from which it is separated by a vegetal membrane, the following nutritive substances: lime, magnesia, oxide of iron, potash, soda, chlorine, sulphuric acid, silicic acid, phosphoric acid, and nitric acid. (2) Arable soil contains organic matters which pass easily by diffusion through a vegetal membrane.

The American silk industry, according to Mr. Blodget (in a recent paper to the Franklin Institute), is the third of the textile class in the country; it amounts to nearly 50 million dollars in value of actual manufactures, as compared with 250 million for cotton, and 300 million for woollen and woollen-mixed goods. Silk goods are imported to the extent of 35 millions. Most of the raw material is, of course, imported from Japan and China (about 4 million pounds of raw silk, 3 million of reeled, and one million of spun and waste silk). Philadelphia has several new machines and combinations for silk manufacture, greatly superior to those used in Europe. There are several hundred compound looms there, each doing the work of ten to sixteen hand-loom weavers. Mr. Blodget denies the alleged inferiority of silk grown in America, and urges an extended culture of it. It has been the object of the "Women's Silk Culture Association of the United States," since 1880, to promote this culture, and there is a great demand all over the country for the instruction they supply.

A new incandescence-lamp has been recently invented by Dr. Regnard, and is suitable for projections, where the electricity or the lime-light cannot be had, as well as for other purposes. In it a mixture of air and petroleum vapour is burnt on a piece of platinum net, which is thus raised to a white heat. The lamp consists of a Bunsen burner, the mouth of which is closed by a small cage of platinum wire. The burner is connected below by means of caoutchouc tubing with a stoppered jar holding petroleum; the stopper supports a longer and a shorter glass tube, the former dipping in the liquid and being connected with bellows, or other blowing apparatus; the other connected with the lamp. With a continuous air-current, several of the lamps may be kept in action at once, to light halls, &c., and the aspect resembles that of a Swan lamp. (The lamp is illustrated in *La Nature*, April 8).

A recent inquiry by Herr Wollny into the influence of colour of ground on its heating, yields the following results. (1) The colour of arable land of approximately the same nature, affects its heating to a comparatively great depth. This influence is different according to the season, time of day, and amount of cloudiness. In the warm season, at the time of daily maximum of ground-temperature, and with unhindered radiation, the ground is hotter the darker the colour. The differences of temperature between bright and dark-coloured ground disappear more or less in the cold season, at the time of the daily minimum of temperature, with diminished insolation, and at great depths. (2) The daily variations of temperature are greater with dark coloration than with bright. They are generally greater, the greater the differences in the mean temperature, and conversely. (3

The influence of colour indicated in (1) decreases in proportion as the water-content increases, and the other factors which determine the heating of arable land (especially heat, heat-conduction, absorption of heat through evaporation, &c)., gain the preponderance. With great differences in physical properties, chiefly caused by a larger amount of humus, and water capacity, the influence of colour may be wholly set aside.

The value of sulphurous anhydride as a disinfectant has been well demonstrated of late by M. Fatio. A great difficulty, however, presented itself in the imperfection of the instruments for decanting and distributing the gas liquefied under strong pressure. M. Fatio has devised suitable apparatus for the purpose, and describes it in detail in the *Archives des Sciences*, under the name of *siphonoid* apparatus, and a special *transvaseur*, which admits of charging quickly and without danger his flagons for application of the substance, or the vessels in which the Industrial Company for R. Pictet's processes delivers anhydrous sulphurous acid.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor *of the* English Mechanic, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. Passmore Edwards.

⁂ *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."
—*Montaigne's Essays.*

A REMARKABLE SUNSPOT — THE MOTION OF SIRIUS IN SPACE—SCIENTIFIC RESEARCH AND THE ROYAL SOCIETY—OCCULTATION OF A STAR—LENGTH OF A DEGREE OF LONGITUDE—ο LEONIS, &c.

[19935.]—I am curious to know if any of my brother-readers noticed a very remarkable spot—or group of Spots—just to the North of the Sun's Equator, and somewhat to the East of his central Meridian, on the 11th inst.? It consisted of one normally shaped spot, equably surrounded by its penumbra; but connected with this by a line of small ones was another, having the form of a *line* of irregular thickness, suggesting the idea of a black "rill." Of course, everyone who has ever looked at the Sun at all, is familiar with the effect of foreshortening on Spots, in virtue of which they present a linear effect when close to the Solar limb; but in this case the Spot was not so very far from the Sun's centre. I invite attention to this, because it seems difficult to account for the existence of a ditch-shaped orifice in the extremely mobile envelope of the Sun, upon any recognised dynamical principles. By the bye, there is a remarkably fine and singularly complicated group of spots just coming on to the Sun's following limb this (Friday) morning.

There are half a dozen lines on p. 234 of the current number of the R.A.S. *Monthly Notices* which, while in all probability they will be passed over cursorily by two-thirds of its readers, contain the record of a fact of the very highest physical interest. All who have followed the masterly researches of the head of British Spectroscopy, Dr. Huggins, and the almost equally valuable work performed at Greenwich by Messrs. Christie and Maunder, must be familiar with the fact that Sirius has been for some years travelling away from the Earth at a rate which, at the time Dr. Huggins first detected its recession, amounted to 29½ miles per second. Since then this has been a gradually diminishing quantity, and for a time last year Sirius appeared to be stationary. Now the measures which, as I have intimated above, are recorded in the *Monthly Notices* for March, show that the sign of the star's motion in the line of sight has changed, and that Sirius is approaching us again. Here, then, is a most remarkable confirmation of the hypothesis that the Dog-star is describing a stupendous orbit round some invisible centre.

Mr. Bruce Allen (letter 19920, p. 127) may rest assured that the excellent suggestion contained in his concluding paragraph will never be carried out, so long as the present ring of wire-pullers at Brompton are suffered to influence the scientific advisers to the Government. To divide the sum now annually voted for (so-called) "scientific research," and to commit its administration to the societies specially qualified to deal with it advantageously to the sciences they were respectively established to promote, would be to inflict a death-blow upon jobbery, which is now rampant. Depend upon it, that an annual grant to the Royal Astronomical Society would be expended in a way which would do ten times more towards the advance of astronomy than five times the amount would if distributed by the Royal Society; and, *mutato nomine*, the same thing may be definitely predicated of Government contributions intrusted to the Geological, Chemical, Linnæan, or other Societies. But this would cut at the root of a system in virtue of which the quacks, humbugs, and self-advertisers of science at present get the lion's share of whatever is going in the shape of Government grants and appointments, and would seriously diminish the receipts of some of the disinterested scientific advisers of the Ministry.

I regret my inability to clear up the difficulty of "W.S." (query 46622, p. 138); but I can, at all events, assure him that π Leonis was not the star which he saw occulted on the 30th ult. The Moon passed considerably to the south of π, as seen from Greenwich, and, *à fortiori*, must have gone further south of it still, as observed at Sheffield. "W.S.'s" object may possibly have been an unnamed 6th mag. star N. of 9 Sextantis, shown on Map 6 of Proctor's large "Star Atlas."

I must ask Mr. Atkinson (query 46645, p. 139) to forgive me for pointing out that he is slightly confusing two different things: linear and angular measure. Every parallel of latitude on the Earth's surface, from the equator to the Poles, is supposed to be divided, indifferently, into 360° or 24 hours; and consequently 15″ of arc are as much equivalent to 1sec. of time in Spitzbergen as they are on the Gaboon. But the actual length of a degree *in miles* differs widely at any two places so far separated as these in latitude. At the equator we may take such length to be 69·1634 miles; and, assuming for our present purpose that the earth is a sphere, we have only to multiply this quantity by the cosine of the latitude of any given station to determine the length of a degree there. Performing this operation for the latitude of Greenwich, 51° 30′, we find that a degree must there measure 43·0552 miles. Bear in mind, though, that these 43·0552 miles take 4 minutes to travel through 1-360th of the circumference of the celestial vault, just as do the 69·1634 miles at the Equator. My querist will find a very extensive table of the "Length of a Degree of Longitude and Latitude, &c.," at the end of Loomis's "Practical Astronomy." This is accurately calculated from the ascertained data of the Earth's spheroidal form.

In reply to query 46647 (p. 139), I know nothing of ο Leonis as a double star, beyond the fact that it is so marked in Proctor's large "Star Atlas." I would add that stars 100″ apart are not nowadays regarded as "double" at all—but as two separate ones. Doubtless "J. A." has not found anything new. I cannot answer his question as to the present magnitude of R Leonis, as this letter must be posted in daylight on the day that his query appears.

A Fellow of the Royal Astronomical Society.

COMET "A," 1882—DOUBLE STARS IN "GEMINI," "COMA BERENICES," AND BOÖTES.

[19936.] – Comet A, 1882 (Wells), was observed here last night (April 15) with 4in. Cooke Equatorial.

It was found close to the position assigned to it in Lord Crawford's circular No. 49.

Apparent position at 10h. G.M.T., R.A. 18h. 53·3m., N.D. 52° 32′. Position angle of tail estimated ± 260°.

With low-power positive eyepiece, the tail could be traced a considerable distance, and it was observed to be straight, and without any considerable expansion at its farther end. "Coma" bright, and bore magnifying well. Even with a power of 225, its cometary character was still quite apparent.

This comet is now within the reach of small apertures. A 2¾in. will suffice to pick it up. I found it still plainly visible with a stop of this aperture and powers 36 and 60.

Will Mr. Webb or "F.R.A.S." examine ΟΣ 266 (Coma Berenices)? The latest measures I am aware of give P = 336·1°, D 1·22″ (see Crossley's Handbook). I observed this object on 15th April, and I am of opinion that the distance is now at least 1·5″. The distance seems not to have changed appreciably up to 1877, since measured by ΟΣ in 1846. It would, therefore, seem strange that so considerable an increase of distance should have taken place since 1877. If this star be compared with Σ 1699, in the same constellation, the distance of which is given ("Celestial Objects") as 1·5″, it will be found that the latter is now the closer of the two. They were both perfectly easy objects with 4in. Cooke achromatic, power 225.

μ′ Boötis.—In examining this star on 15th April I was struck by the faintness of the 8th mag. companion. It seems to me to be more like 10 than 8 at present. The night was clear and suitable for faint objects, as I had no difficulty in seeing the small *comes*, *n f.* η Coronæ, spoken of by Smyth as being a glimpse star with 5·9in. aperture.

κ and δ Geminorum.—Mr. Webb, in "Celestial Objects" (4th edition) says the *comes* of κ suspected variable (8·5 – 14). It is now certainly much fainter than the companion of δ, which is rated as 9th mag. by Smyth, and called 8·2 by ΟΣ. I have noted on March 11, 1882, "the small *comes*" of κ is not now brighter than the 14th mag. *comes* of δ seen by Sadler.

David Simms.

Limavady, Co. Derry, April 16.

OBSERVATIONS OF KNOWN DOUBLE STARS—THE VARIABLE STARS 19 PISCIUM, AND IOTA ANDROMEDÆ.

[19937.]—The following objects form the first of a series of observations we hope to give from time to time. We hope to survey the chief objects of interest known in the sky visible in England, and also to find and publish others hitherto unknown, through the pages of the English Mechanic. In order to prevent any observations clashing, we have each taken certain parts of the sky, which will be indicated by the following limits:—

Section I. Mr. Gage's, 0°—40° declination North.
,, II. Mr. Read's, 40°—80° declination North.
,, III. Mr. Espin's, 80°—90° N., and all S of the equator.

But for the convenience of each observer, the original plan has been slightly modified. Some of the constellations in section I. being given to Mr. Read, and *vice versâ*. The telescopes employed are:—

Section I. Mr. Gage, 6¼in. refractor.
,, II. Mr. Read, 4¼ ,,
,, III. Mr. Espin, 5 ,,

Section I.—Mr. Gage's Observations.

ε Arietis, January 9th, 1882.—Easily split with one of Browning's achromatics, power 200.

ι Cancri.—Orange and blue. Is large star double?

ρ Cancri.—Seen triple with 8½ Calver reflector.

ε Hydræ.—January 28th. *Comes* blue.

α Leonis (Regulus).—Saw *comes* double on February 1st, also on March 4th and 14th, with 8½ Calver reflector. Colour of Regulus is bluish-white, and of *comes* deep yellow.

6 Leonis.—I think there is one very faint *comes*, *s p.* 12″ ±, and perhaps another, *s f.* at same distance. P = 180° ±.

88 Leonis.—Yellow and lilac. Close *n.p.* is a wide pair of very minute stars, 13—14 mag. P = 225° ± D, = 20″ ±.

30 Tauri—Easy. Colours white and lilac. Is comes so low as 10 mag.?

Section II.—Mr. Read's Observations.

19 Piscium.—This star is certainly variable. Flammarion ("Les Etoiles, p. 266) remarks:—"L' ètoile 19 Piscium notée de 6e, grandeur par tous les observateurs du siècle dernier et de celui-ci surpasse aujourd'hui les étoiles de la cinquième." He makes it 4·9 mag.; Gould, who suspects it of variation, makes it 4·9; Birmingham makes it 6·2; Espin gives the limits of variation as 4·9 and 6·5. From several observations made Dec., 1881, it was found to be 5·3, or perhaps slightly fainter than this. This star is Birm. 648; in Dec. 1881 it appeared of a fine reddish orange colour. I feel certain, however, that the red tint is not so decided as when I observed it in Dec., 1879; it may possibly vary in colour also. 30 Piscium, marked by Gould as red, I only observed to be golden, with a slight tinge of red. 33 Piscium, 22 Piscium seemed pale golden and pale orange: these are also marked red by Gould—all these stars are, however, well worth looking at. μ, γ, δ, ο Piscium are also fine objects, all of a fine golden colour.

ρ Piscium.—A, pale yellow; B, bluish. This star is variable (vide Webb). Gould gives its magnitude as 4·8. It has, however, brightened slightly of late.

ι Andromedæ.—Gore suspects this star of variation, and thinks the period is probably short (R.A.S. *Notices*, Vol. XXXIX., p. 199). It has been watched on several occasions during November and December, 1881; but no appreciable variation was ever detected in its light. At the same time, if the estimates of it by previous observers are to be at all relied on, it must have varied considerably at different times, and should certainly be watched.

20 Geminorum.—A, col. dull yellow; B, dusky white. B was found slightly fainter and duskier than A; but there was little difference in colour or magnitude. The two stars probably vary in colour and magnitude.

μ and η Geminorum are two very fine objects, very similar in colour, both deep golden. The field round η with a very low power is fine.

Section III.—Mr. Espin's Observations.

19 Piscium.—The following are my estimates of magnitude:—

1880.	September	2	4·8
,,	,,	4	4·8
1881.	August	3	5·7
,,	September	30	6 0
,,	October	1	6·2 or less
,,	,,	15	5·5
,,	,,	17	5·5
,,	December		5·3—5·4 Mr. Read's observations.

The star thus appears to have passed through a maximum and a minimum, and we shall have for comparison with future observations:—

Maximum, 1880, Sept. 3.
Minimum, 1881, Oct. 1.

If this be considered to represent a period and a half (which seems not improbable), we should thus have as an approximate period

$$P = 260 \text{ days,}$$

and a maximum should have taken place about Feb. 11th last.

27 Hydræ.—A wide but fine pair not in "Celestial Objects." The colours were noted on March 15 as yellow and blue.

Σ 1357 Hydræ.—This star will be found 1¼° south of α Hydræ. It is the following star of two bright 7 mag. stars forming a wide pair, and in the same low-powered field is another wide 7 mag. or 8 mag. pair further to the south. The companion of this double star was rated 10·5 by Σ., and as it is only 7″ distant it is not a very easy object. It was rated as 12 mag. of Herschel's scale. When once seen, however, it is not difficult to hold steadily. It was picked up by accident when sweeping over this region a few years ago. The field is fine. The large star is of a deep yellow, while the companion is bluish by contrast, Σ 1367 lies 4min. following it, and about a degree to the South.

ι Leporis.—Here we have another of Σ. stars rated at 10·5 mag. It was rated 12 mag. by Smyth. On one night in January the star was accidentally swept over, and the companion at once seen, and rated about 10½ of Herschel's scale.

Nebula 3900 Virginis.—A pretty object, somewhat circular, and which appeared on March 11 as a sparkling nebulosity. A star 8 mag. lies *s f.* quite close to the nebula. The star is orange. The field is well worth looking at. The nebula can easily be picked up by sweeping between ι and μ Virginis, and it will be found about half-way between the two, and hence to the N. of 106 Virginis.

In our next paper we hope to give the approximate place and positions of some new pairs lately found.

T. E. Espin.
W. H. Gage.
T. Read.

ASTRONOMICAL—ζ CANCRI—R LEONIS—DOUBLE STAR.

[19938.]—I AM much obliged to M. Gaudibert for his courteous anticipation (19888) of my reply to Mr. Mills respecting ζ Cancri. The inquiry had not been forgotten; but, owing to absence and various hindrances, I had for a long time had no opportunity of examining the object. When I attempted it a few nights ago the discs were mere balls of wool in a great haze; but last night being unusually favourable, with only a little unsteadiness, I found, with my beautiful 9⅓in. With mirror, the close pair too hard for a power probably under 200; with a Browning E ocular, about 375, it was distinctly split; and with 450 there was a strong black division, which in better air would probably have more than equalled the half of either disc. M. Gaudibert's telescope (I believe by the same accomplished artist) must be a very fine one. The Washington mean of six not very accordant observations in 1878 was 0·813″. From a communication with which I have been favoured by Mr. Perry, it is now closer still, and forms a severe test for any but first-class instruments.

In reply to "J. A." (46647); he will easily find R Leonis by taking his largest field and putting Regulus boldly out of it to the north, the difference of declination being 34′; a sweep some distance westward will then bring in R, which is now very conspicuous, about 7 mag., and of a splendid red colour. This direction, though intended for an equatorial mounting, will of course apply equally to an altazimuth if the objects are on or near the meridian. Not having previously refreshed my memory from the ENGLISH MECHANIC, I am sorry to say that it did not occur to me to look for the companion to Omicron.

I swept across a pair about 8 and 10 mags., some 29m. E., 25′ S. from Regulus; the place is *very* rough, but sufficient to find it, as it is insulated. Though very wide, the contrast of colour makes it a pretty object.

T. W. Webb.

Hardwick Vicarage, April 15.

TELESCOPES BY THE "OLD MASTERS."

[19939.]—WILL you kindly permit me, in thanking those who have sent information on this subject, to supplement my former letter by stating that to render the proposed tabular arrangement of more interest than a mere list of telescopes, I should be glad to receive particulars of foci as well as apertures of object-glasses and mirrors; experiments to determine their dividing power, details of the powers employed, more especially the results of any experiments with specially high powers, such as were formerly employed in certain cases, and so forth? These results would be only given *generally* in the tabular statements, so as to avoid any appearance of invidious comparisons between the telescopes of different owners; while at the same time they would enable a comparison to be (to a certain extent) made with modern instruments. Comparative light-tests between different specula would also be valuable. I think, in conclusion, I may venture to quote the following from a letter received from our well-known contributor, Mr. P. Vallance—"I hope you will succeed in tracing the fine instruments of Dollond and Tulley, and others of the old makers, as I believe the readers of the ENGLISH MECHANIC would be obliged for a report on them." L. L. L.

DOUBLE OBJECT-GLASSES.

[19940.]—PERHAPS if "E. Y. J." showed his concave to some optician other than the maker, he might learn whether his lens was (in reasonable probability) made of the kind of glass he ordered. It most likely *is* flint-glass, for it is not, I think, usual to grind concaves of crown-glass; but opticians seem not always to be able to supply what they profess. Out of about two dozen, I have three which are not to order or to invoice; but it is something of a favour to supply a lens of an unusual description, and I am afraid a dissatisfied customer for small lenses would not fare particularly well.

I hope "E. Y. J." remembered my caution that his eyepiece, if used with the concave, would very possibly magnify too much. I thought it quite enough as it stood for most nights, and the addition of the concave to *that* power eyepiece would not, I apprehend, improve the definition—probably the reverse.

Webb (page 7) thinks 50 to the inch more than sufficient, generally, upon the *planets* or *moon*; if this be so with well-made expensive achromatics, how can the confessedly inferior construction of the dialyte, or the old refractor, be expected (especially when made by an amateur), to stand it?

"E. Y. J.'s" remarks as to construction of a telescope agree with my experience. I, however, used a *square* tube of thin poplar, and prefer at least 8ft. to 10ft. focus. Arthur Hinde.

THE TELECTROSCOPE, OR "SEEING BY ELECTRICITY."

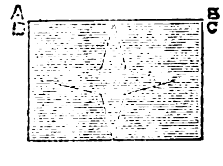
[19941.]—I HAVE lately been giving a good deal of thought to this subject, of which the following apparatus is the result. As, however, there are several points in it about which I am somewhat doubtful, I should be glad if any correspondents would give me their opinions, and the benefit of any knowledge which they have bearing upon the subject.

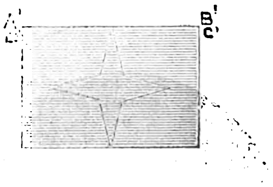
In all previous efforts in this direction, I believe, the image of the object to be transmitted is projected either upon a single selenium cell, which, by itself moving, receives upon it the successive portions of the image, as in Bidwell's apparatus (see Vol. XXXIII., page 180), or upon a plate containing a great number of tiny selenium cells, which is stationary, each cell in turn transmitting a current corresponding to the portion of the image which impinges on it, as in Senlecq's apparatus (see Vol. XXXII., page 534). In both of these instruments, however, no actual image is formed at the receiving end, but merely a printed representation. Now, in the following apparatus, provided I have made no invalid assumption, and that the somewhat numerous practical difficulties can be overcome—an image in light and shade will be formed upon a screen at the receiving end, an exact counterpart of that at the transmitting end; and, more than this, every change in the image in the transmitter will be faithfully depicted upon the screen of the receiver.

Either of the above forms of transmitter may be used. We will suppose, however, that we use one similar to Bidwell's, in which a single selenium cell, by moving in parallel lines very close together, receives upon it, in succession, every portion of the image of the object projected upon it by a powerful lens. We will now turn our attention to the receiver, which is, I believe, quite novel. It consists essentially of an ordinary lantern to project a strong beam of light through a pair of Nicols prisms, and also of a pair of ordinary achromatic prisms, one placed vertically and the other horizontally in front of these, each capable of turning about its axis, and beyond these is placed a screen.

Suppose the Nicol's prisms to be so placed with regard to each other that the maximum amount of light passes through them, then a beam of light from the lantern passes through the two Nicols, next through the vertical prism, then through the horizontal one, and finally forms a small spot of light upon the screen; and it is evident that, by slightly turning the vertical prism about its axis, the spot of light can be moved in a horizontal direction along the screen, and that by turning the horizontal prism it can be moved in a vertical direction. Hence, by combining the motions of these two prisms, the spot of light can be brought into any position whatever upon the screen. Moreover, if one of the Nicols be rotated, the brightness of the spot will gradually diminish, and, finally, when it has been turned through an angle of 90°, altogether disappears. Hence, by this arrangement, we can vary the position of the spot of light upon the screen, and augment or diminish its brightness at will.

Let us suppose that the selenium cell is at a point A, and is moving along the line A B; also that the spot of light is at the point A′ on the screen, and that the vertical prism is turned in such a manner that the spot moves along A′ B′ in the same time that the selenium cell moves along A B.





Next, let the selenium cell move along C D, and let the horizontal prism be so turned that the spot of light is at C′ when the cell is at C, and let the vertical one be turned as before so that the spot travels along C′ D′ in the same time that the cell does along C D, and so on, until the cell has passed over the whole of the image; when this has been accomplished, the cell starting again at A and the spot at A′.

The selenium cell forms part of a circuit which passes round an electro-magnet at the distant receiving station; this, by suitable mechanism, turns one of the Nicols through a greater or less angle—in no case, however, greater than 90°—according as the current passing round the magnet is greater or less, that is, according as a greater or less bright portion of the image impinges on the cell.

Suppose now that the cell is in absolute darkness, and that in this case the Nicols are placed so that no light passes through them; then no spot appears upon the receiving screen, and all is dark. Let the cell be now set in motion, then, as it moves into the light, a stronger current passes, the Nicols are turned by the magnet, and the spot of light flashes on the screen, moving synchronously, as above described, with the selenium cell. Moreover, as the cell moves into brighter portions of the image, the Nicol is turned through a larger angle, and the spot becomes correspondingly brighter, and *vice versâ*; so that the spot not only moves synchronously with the selenium cell, but its brightness also varies as the brightness of the portion of the image which the cell receives upon it.

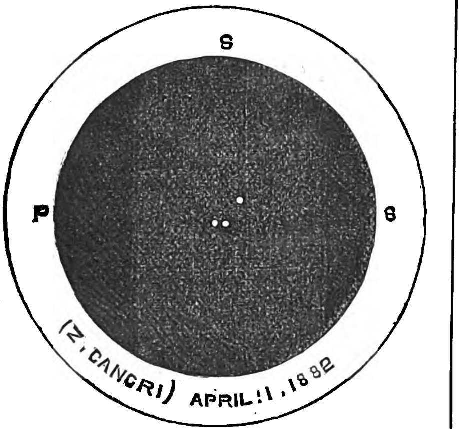
If now the selenium cell moves over the whole image, and again reaches its first position within the time of visual impression, the spot of light on the screen will also move over the whole screen within the time of visual impression, so that the impression of the spot at the first point will not have faded away until the whole screen has been traversed and the first point has again been reached. In this way an image will be apparently produced upon the screen in the same way as a whirling brand produces the impression of a continuous ring of light, and by continuing the motion of the apparatus the image will not merely be momentary, but may be retained for any required length of me.

This completes the description of the outlines of the apparatus. I have confined myself merely to its principles, and have not touched upon the mechanism by which the various motions of the cell and prisms will be produced, for the simple reason that I have not, as yet, fully worked them out. The motions required are somewhat involved, and the fact that they must be synchronous and have a high speed still further complicates the mechanism by which they must be produced; but here I do not think that any insurmountable difficulties will be encountered. There are, however, two points in the principles, both of vital importance, with regard to which I should be particularly glad to have the opinions of others. Firstly, the selenium cell must move at a very rapid rate. Do the changes in the resistance of the cell take place with sufficient rapidity to admit of this? Secondly: Supposing this to be the case, are these changes in the resistance great enough to produce such a change in the current as to produce a corresponding change in the position of the Nicol's prism? That is to say, is the difference in the strengths of the currents when the cell is in absolute darkness, and when it is illuminated by the maximum amount of light, great enough to rotate the Nicols through 90°, mechanism being used to effect this which magnifies as much as possible the movements of the armature of the electro-magnet? The first difficulty could, I think, be overcome by using a transmitter of a form somewhat similar to M. Senlecq's, which has been mentioned above. The description of this, however, I must, I think, defer to another letter, as I fear I shall be trespassing too much on valuable space. **W. L.**

ζ CANCRI.

[19942.]—Thanks to Mr. C. Gaudibert for his interesting observations on ζ Cancri (letter 19888).

On the 1st of April last, when testing a 12¼in. mirror, ground and figured for me by Marsden, I turned it on this star, and with full aperture and powers of 400, divided as in my diagram. I was struck by the position angle of A B. Webb, in his new edition of "Celestial Objects," gives it 108° in 1877; and so also do Crossley and Gledhill. Judging from the appearance of the group, I would be inclined to say the angle must be now about 80° or less Of late years it has been decreasing, and it would be interesting to know at what rate, as the periodic time is variously given by different observers. Will Mr. Gaudibert kindly look again at this star, and note the position angle of its components and say also what power he uses in dividing it with 5½in. aperture?

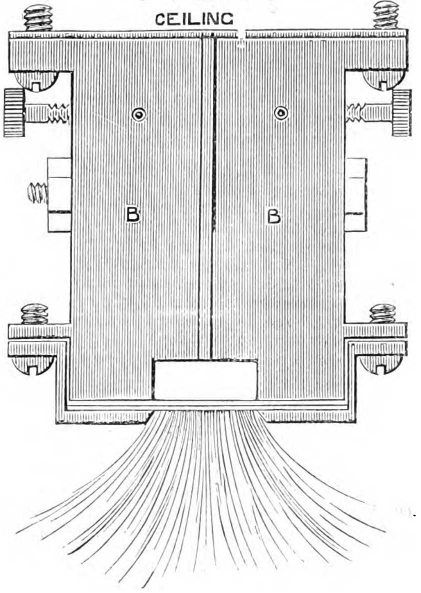


Droylsden Rectory, April 8th. **S. Mills.**

PLATINUM ELECTRIC LIGHT.

[19943.]—Amongst the many ideas which are now occupying the public attention on the new light, I have ventured to forward mine. We are now told that carbon gives out in a short time. Platinum is everything which could be desired, but melts if the current becomes excessive. To obviate this difficulty, I propose to use talc as a medium of protection, which (if I mistake not) resists a great heat, where glass would be inadmissible. Fig. 1, B B, represents two brass castings separated by an insulating material, as is also the ceiling. The binding screws are seen just below the screws which fasten to the ceiling. A bolt passes (insulated) right through the middle to unite the castings. The recess below is to be filled with calcined magnesia, or lime compressed well together, making all a flat surface. A thin piece of platinum, same size, is laid on this surface, and over that a piece of talc, same size, and then the cap, Fig. 2, is put on and screwed up tight, means, of course, being applied for insulation and making airtight. The cap is shown in section in Fig. 1, in order that the layers of platinum and talc may be seen. The terminals are put in the holes above B B, and screwed up. Then all is ready for the current.

FIG. 1.



Here, if the platinum happens to melt, it does not matter, and its resistance to oxygen being also very great, its durability may be expected to be everlasting; and again, no space being left for air or other gases, there is no need for the troublesome exhausting process. Should the talc not be very lasting, it may easily be replaced by pieces of the size kept ready for use (cheaply). As the figures are only given to furnish the method of carrying out the idea, possibly better details might be contrived, which may be left to the experienced electrician, as also the size and thickness of the platinum, the insulation, and other details of dimensions, &c.

FIG. 2.

DYNAMO MACHINES.

[19944.]—In letter 19882 "Conrad" describes a new dynamo-electric machine of his own design, and though perhaps in some ways ingenious, it would, I fear, in practice turn out very ineffective. I do not say it would produce no current, for certainly it would; but for the same weight of machine and speed of revolution it could never approach the Gramme or Brush. In the first place, "Conrad" falls into a mistake with regard to the use of the iron in the armatures of both Gramme and Brush. Instead of its being of little use in these machines, they would, without the iron, produce practically no current at all, and for the following reasons. The general rule governing the induction of currents by magnets is as follows: When any change is made in the number of lines of (magnetic) force cutting the area inclosed by a closed circuit, a current will be induced in the circuit, and the electromotive force producing such current is in direct ratio to the number of lines added or subtracted in unit time. Lines of force must, therefore, pass through the centre of the coils. Suppose, in the Gramme machine, there were no iron in the core of the coils, the lines of force would nearly all pass straight from one pole to the other, as shown (Fig. 1), and would cut but few coils; with iron the magnetic field is spread out, and the lines of force are led round through the coils something as shown (Fig. 2). Thus nearly all the lines of force are utilised, whilst without iron very few are of use.

FIG. 1.

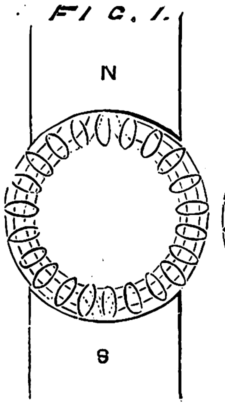

FIG 2

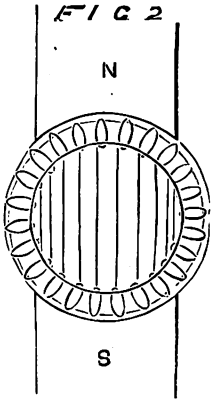

Similarly, in the Brush machine the lines go round the armature from one pole to the other; without iron they would go straight across through the axle of machine. When the bobbins of the Brush machine are directly between the poles, no lines of force cut them; as they pass on, lines are added, till when at the highest or lowest point of the machine they are at a maximum. Then they decrease, the change being accompanied by reversal of current.

Now, in "Conrad's" machine the iron is, indeed, of little value, for in any case the lines would go direct across from the north to the south pole, and the iron does little to concentrate or lead them through the bobbins.

Again, since the electromotive force is proportional to the number of lines added or subtracted in unit time, our aim should be to add or subtract as many per revolution as is possible. In "Conrad's" machine, in every position of the armature a certain number of lines are passing through the coils. These are added to until the coils pass the strongest part of the field; they are then subtracted, and so on. Since adding lines coming from a north pole is the same as subtracting lines coming from a south pole, we should, had a reversal taken place, have added and subtracted just twice as many lines of force in a revolution, and have had twice as much electromotive force, which would have given twice as much current. Since, in "Conrad's" machine, the number of lines cutting the coils is never zero, some part of the magnetic field is never utilised—namely, those lines cutting the coils in the weakest part.

"Conrad" had much better remove the cores from the bobbins, and have reversals of magnetic polarity, than keep the cores and have no such reversal.

In conclusion, I hope "Conrad" will not think this letter written to pick him to pieces; my only wish is to point out his error. **Ll. B. A.**

HARMONIUM BLOWING—VELOCIPEDES.

[19945.]—The object of accompanying drawings, together with explanations, is to make plain and clear the proper method of blowing, and also to describe the method of constructing a simple apparatus, which being practised upon by a student, is so contrived that it *must* work in the way described, as the proper method, which he will thus be taught, as it were, in spite of himself.

I remember, 30 years' since, practising for a whole day, and succeeded in attaining to the proper method, and it has ever since been quite easy to me. I was lately looking into an instruction book issued by a good firm, but found that the directions were not as clear as desirable for beginners, though rather lengthy. I think it would have been better, merely to have said that one foot should begin pressure before the other had done, and that in order to allow time for this, each foot in its turn should be *quickly* lifted up, and commence *gradually* again.

I will now give my version of the proper method, introductory to the description of the apparatus, Figs. 4, and 5, which is based on this principle.

The travel of the footboards is divided into three parts for explanatory purposes. In Fig. 1, one of the footboards, A C, is pressed down, two-thirds ready for the start. Fig. 2 shows, then, that boards A B and A C have each travelled a third part. Fig. 3 shows that A B has further travelled the middle third, while in the *same* time A C has (by quickly lifting the foot), travelled back the whole distance ready for another start; and observe, now, the boards in Fig. 3 agree in position with Fig. 1. Hence repetition is all that is required.

FIG. 1.

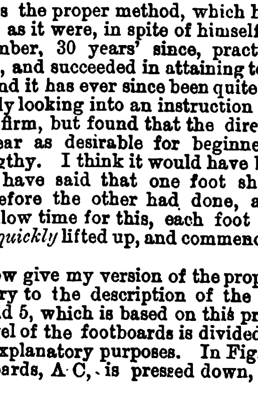

Fig. 5 and 4 is the apparatus referred to. Fig. 5 shows, in section, two circular plates, into which is firmly keyed a short axle, rotating on an upright standard, passing up between the plates, and fastened down upon the middle of the foundation board, which is 12in. square. The pins, D E, are diametrically opposite, and carry the connecting rods (not shown here), the other ends of which are at the side of the end of footboards. The fronts of the footboards are hinged to the foundation board.

FIG. 2.

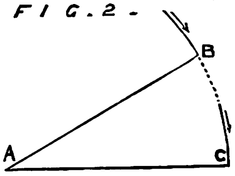

FIG. 3.

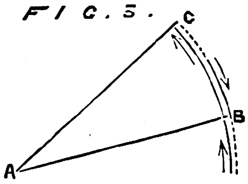

In Fig. 4, the pins project from the dotted circle. The boards and connecting rods are each shown in 2 positions. Thus, A B D is in its lowest position, and at the dead point, but observe A C E (the other board) is in a good position for work to carry point E round to E′, during which time A B will have been carried right up. as at A B′; but here, particular attention is required to the position of its connecting-rod B′ D′, which is not seen, being in a line with its footboard. But here, again, is the other dead point; and observe, again, the position of A C′ E′, which also has a good purchase and arrives at its lowest position, and we proceed as before.

FIG. 4.

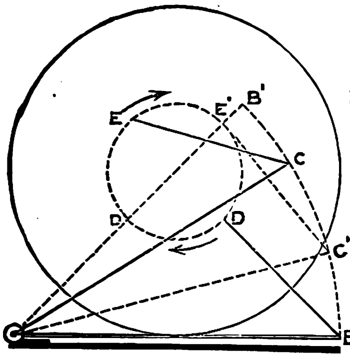

FIG. 5

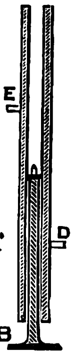


The plates spoken of are used instead of cranks, in order. by their weight, to get a momentum.

It having been here shown that, by the adoption of this principle, no hindrances arise from dead points, its applicability to many other cases is evident. But I now call attention to the advantage which may be derived from its adaptation to velocipedes. On level roads, the momentum is sufficient to make the cranks pass the dead points; but on a rise, this is generally not so, and the rider has to dismount, and (like "the old man and his ass") become the steed. But, adapting the principle of this invention, we have seen that one crank would always be in a position for work, and so, to dismount would be unnecessary.

I omitted to say, that space should be left between the footboards, for Fig. 5 and connecting-rods, which would then admit of the boards being about 4½in. wide, and these should be helped to rise by a spiral spring underneath (to prevent lagging), as is done with the ordinary feed-bellows. In all adaptations this help (modified to suit), should be applied. Fig. 4 is represented by lines only, in order that the measurements may be better understood, and the scale is 1-6th, or 2in. to the foot.

Barry-road, S.E. **J. H. Huxley.**

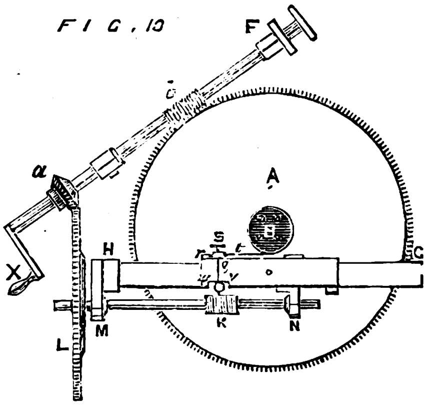
RAMSDEN'S DIVIDING MACHINES.—

Part III.

Ramsden's Engine for Dividing Straight Lines.

[19946.]—IN this machine a screw is used to give motion to a rectangular plate, which has one of its edges cut into teeth, whose distance apart is the same as that of the threads upon the screw. In order that the plate may receive equal and uniform motion, the pitch of the screw must be invariable throughout its length, since the whole number of threads is engaged at once. Fig. 10 represents a plan of the apparatus for cutting a screw of invariable pitch. A is a strong circular plate of brass, having its edge ratched as described in the account of the circular dividing engine; on its centre is firmly fixed the pulley B by four screws, having a groove turned in its cylindrical part perfectly concentric with the plate A. E represents an endless screw which gives motion to the plate A. F is a circular divided small plate, or micrometer head, which may be turned with or without the endless screw; and on the other end of this screw arbor is a large pinion a, with bevelled teeth on its edge, together with a winch X to turn it by. G is a triangular bar of steel, which passes over the circular plate A, and is firmly fixed to the frame of the engine at H and I; K is a piece of steel forming the arbor of the screw intended to be cut, having a wheel L on one end, acting with the pinion a. M and N are two strong pieces of brass, in which the arbor turns, and are firmly fixed to the bar G. O is a piece of brass that slides on G, the two extremities of which are made to fit the bar. Near one end of O is an angular groove q, that holds the tool, by which the threads are cut, and is pointed with diamond, in order to cut the steel after it is hardened and tempered; the cock w serves to fasten the tool, which may be set to take proper hold on the steel by turning the finger-screw s, and is fixed there by the screw v.

FIG. 10



To make a perfect screw, it is only required to give the point that cuts the threads a uniform motion parallel to itself, and also to the axis of the intended screw; and that this motion may be proportioned to the revolutions of the intended screw, as the number of threads may require. To effect this, a piece of tempered steel t, exactly of the same thickness throughout, is fastened to the slide O at r, the other end of the spring being fastened to the pulley B in the groove; now while the circle A with the pulley is turned round its centre, by turning the endless screw to the right the spring t draws the slider O with the attached cutter q along the triangular bar; at the same time the steel arbor K of the screw to be cut revolves by means of the communication of its wheel L with the revolving pinion a.

The screw E of the circular plate has 20 threads per inch; therefore, if the number of teeth on the pinion a be to the number in the wheel L as the number of teeth on the circular plate A is to the number of 20ths of an inch round the circumference of B, allowing for part of the thickness of the spring, the spaces between each of the threads of the screw to be cut will be also 20ths of an inch. The size of the pulley B was determined thus: the endless screw E being disengaged from the plate A, the slider O was drawn back till the end of it came nearly to the piece M; the endless screw was again engaged in the plate A; then, having two very small dots on the slide O, set off parallel to one side, at exactly 5in. apart, the slider was moved by turning E till one of its dots was bisected by a small silver wire, fixed across a hole made in a thin piece of brass, fast to the piece N; then, O on the micrometer head F being put to the index without moving the screw, the pulley was tried and reduced, till just 600 revolutions of the screw E brought the second dot to be exactly bisected by the fixed wire. These bisections were examined by a lens of ½in. focus, that was fixed perpendicularly over the wire."

It is unnecessary to give a full account of the machine for cutting divisions on straight lines. It consists essentially of a rectangular brass plate, moving easily, but without shake, on the top of a rigid iron frame. The teeth on the edge of the plate, and the threads on the screw, are each 1-20in. pitch; on the screw arbor is a micrometer head, divided into 50 parts, each of which is subdivided by a vernier in five parts, so that the motion of the screw, equal to 1-5000in., may be read. A tracing or cutting-frame is arranged in a manner similar to that on the circular engine; but as the cuts are not always required to be square to the edge of the plate, it is made to turn on a centre, so that the lines may be traced at any desired angle.

"When lines are to be divided by divisions not commensurable with English inches, which constitute the scale, the line to be divided may be laid down, not parallel to the plate, but obliquely, so as to make any angle with it, or become the hypotenuse of a right-angled triangle; which line shall, by calculation, be to the base as the denomination of measure, when longer, is to the English inch—that is, as the secant to the radius, provided the lines are traced square to the side of the plate; but if square to the line to be divided, then the divisions on that line will be shorter than they would be on a parallel line of the plate, in the proportion of the cosine of the angle of inclination to the radius. In order to adjust the inclination of the ruler, two sectoral portions of a circle are laid down at one end of the movable plate; the outer one divided into degrees, numbered from 1 to 9, and subdivided to 10 minutes, and the inner in the proportion of cosines to radius 10,000; and its divisions numbered 10, 20, and to 140. The use of this contrivance will be best understood by an example; for instance, if a line of 9 999·1000 were to be divided in the same number of divisions, and in the same manner, as if it were 10in. long; put the ruler to the cutting frame, and move the apparatus till the edge of the ruler cuts the central point and first division 0 of the inner sector; then screw the ruler fast to the plate, and when it has moved 10in. in its own direction the whole length of the divisions on the line divided, will be only 9 999-1000in., but the divided spaces will be respectively equal among themselves."

The contrivance for regulating the angular motion of the screw is worthy of notice.

"Besides the micrometer head already named, the arbor of the dividing screws, which has its thread similar to those of the notched ratching screw, has at its opposite end two sets of ratched wheels: one set for turning the screw, and the other set for stopping it at the proper times. These sets are each composed of three wheels, of which one has 32 teeth, the second 48, and the third 50, which afford the means of subdividing the inch into spaces of different denominations; those wheels used in stopping the screw are ratched with teeth pointing in a contrary direction to those for putting it in motion. I (Fig. 11) represents a cylinder of brass, having on one end two steel rings a and b, with their contiguous edges cut into ratched teeth in contrary directions, so as to fit each other; on one of these rings is an index, and the other has its teeth numbered 10, 20 and to 50; the other end of the cylinder is made hollow, and contains one of the sets of ratched-wheels already named. There are two slits opposite each other, pierced through the hollow part of the cylinder W, in each of which is a click, turning on an axis, and pressed into the teeth of the ratched-wheels by a small spring; these clicks may be moved along their axis so as to catch in any one of the three ratched wheels, and may be fastened by a small tightening screw, s. The cylinder I, with the clicks, turns on a steel axis attached to the piece K, in a line with the axis of the endless screw. Motion is given to the cylinder by a piece of catgut, one end of which is fastened to the ring b, and the other, after passing four or five times round the cylinder, is fastened to a treadle. On the treadle being depressed, the clicks s catch

FIG. 11.

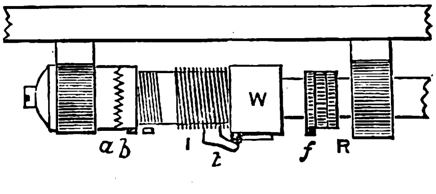


FIG. 12.

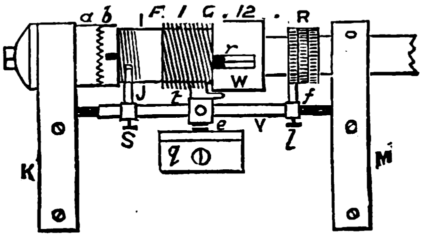

in the teeth of one of the ratchet-wheels, and turn the screw, and at the same time a spiral spring is compressed which, on releasing the treadle, turns back the cylinder i, and raises the treadle to its former position. V is a small, square, steel bar, with cylirdrical extremities, which work in steel bushes in D and K. This bar carries three different pieces: the middle one, t, lies in the interval between the threads of the screws, and passes nearly half-round it; it is kept in the threads by a spring e pressing on the piece q, attached to the frame, this piece t being fastened to the bar V by a screw. The motion of the cylinder I moves V in a longitudinal direction. The upper end of f is formed into a hook, which may be set to catch in the teeth of any of the ratchet-wheels, and then fastened to V by a screw, i. Near the other end of the bar is a stop piece, j, which may be set in any position by the screw s. When the engine is used, the treadle is pressed down and the catgut turns the cylinder I. In the mean time the piece t moves along the thread, till a stud r on the cylinder, striking on the top of the curved piece t, bends the spring e, until that piece rests on q. By bending this spring, the square bar is turned a little on its axis, and pulls the hook f into the teeth on the rachet R; then, the treadle being released, the spiral spring turns back the cylinder, till the piece j is brought under the stop on the ratchet ring b. The parts of a revolution are regulated by setting the number required on the ratchet ring b to the index on the fixed ring a. Each of the teeth answers to the motion of 1-1000th of an inch in the plate, and the number of revolutions, each of which moves the plate 1-20th of an inch, is regulated by setting the piece j on the bar.

Orderic Vital.

HUXLEY'S CALCULATING MACHINE.

[19947.]—I notice Mr. Buttershaw's observations (19909) on the calculating machine (19834), which for ordinary use has a scale not greatly differing in the size of its divisions; but observe the slide-rule with its last division about one seventieth the size of its first division (taking the scale as 100); here it is evident that, in order to invert all the subdivisions, the scale must be considerably lengthened: hence the new machine, which has also this advantage, that the angle made by the arms serves as a pointer for reading the answer.

J. H. H.

MEDICAL REPLIES.

[19948.]—Rheumatism (46610).—"Querist" is probably not suffering from common rheumatism; but she may safely try 10 grain doses of salicylic acid (in place of salicylate of soda) three times a day for a time. Vegetarianism also will be a safe experiment, but not to the extent of avoiding milk, unless she be corpulent. The Turkish, or vapour, or warm bath may safely be pushed and fully tried; but avoid catching cold afterwards. Probably the patient needs more accurate diagnosis as to whether any nervous or blood affection is present, and if so, properly adapted constitutional treatment may be required. Wear flannel, avoid damp houses, and damp climates and night air, especially after hot, badly ventilated rooms.

James Edmunds, M D.
Grafton-street, Bond-street.

HIBERNATION OF ANIMALS.

[19949.]—The author of the article on "Hibernation," reprinted in the English Mechanic of 7th inst., does not mention any instance of hibernation of birds; but as one such instance has come to my knowledge, it may interest your readers to hear of it.

In Chili, and especially in the forests in the south, where the climate is very moist, and many species of the trees flower very abundantly, there is found at least one species of humming-bird which, in the earliest spring, may be seen hovering about the flowers almost as high up the mountain sides as the snow, and one of our surveyors who observed them supposed they migrated from warmer regions, though their powers of flight seemed not equal to the distance.

Having been several years on the coast of Chili, and often made inquiries as to the migration of these little birds, I was told by a friend at Port Montt that he had frequently seen them in the winter in hollow trees hibernating; that if brought into the house they revived, but again became cold and stiff.

The fact of their passing the winters in this condition was spoken of by others as well known, and even at Valparaiso, where there is very little cold, another of my friends told me his servant had found one in that state on the branch of a tree and had brought it in to him.

The information which thus came to my knowledge convinced me that the humming-birds in that country do not migrate, but hibernate, and that they might, with very little difficulty, be brought to England if kept in a cool place.

In the event of anyone making the attempt, I doubt if honey alone would prove a proper food on their revival, as in Chili, and in the tropics, the majority of humming-birds, whose skins I preserved, had insects in their stomachs.

The Chilian species would certainly acclimatise in Madeira, or possibly even in Jersey.

April 13th. **R.**

UNIVERSAL CUTTER.

[19950.]—Noticing the description of universal cutter by "F. W. G.," letter 19908, I trust the author will allow me to say a few words relative to it. In the first place, I can only say that it is a very good instrument; but at the same time it is important that it should at times be capable of being set to any angle, simply because, when being used for cutting spirals, the tool should be set to the pitch of the spiral being cut. I can see no reason why this instrument cannot be made to do so. With regard to the geometric staircase, our correspondent will find that the pattern he describes is totally different from that cut with the eccentric chuck, March 3rd, and that cut by "F. W. G." is what is called the basket pattern, and the result of the variation in division will, as stated, give a spiral appearance to the work.

J. H. Evans.

LATHES AND LATHE-MAKING.

[19951.]—In a letter (19819) under this head on page 35, "Scorpio" says he would like to know how screws were produced in the earlier period of mechanical engineering.

In "Holtzapffel's Turning and Mechanical Manipulation," Vol. II., chap. 26, he will find a good deal of information on the originating of screws, and in the footnotes there are references to several works on the subject.

"Orderic Vital," in a letter (19818) on same page, makes a very practical remark in saying that Mr. Evans would add very much to the value of his papers if he would give such data as would enable a workman or amateur to construct the various apparatus he describes so well, and to make the various parts of proper dimensions.

Of course these appliances will vary in size very much according to the lathe for which they are intended: but if the various apparatus, chucks, cutters, &c., were described for some particular size of lathe, say one of 5in. centre, amateurs could then construct the tools lighter or heavier in proportion to their requirements. When drawings are given might they not be made to scale? This alone would be a great assistance, and would be a guide by which to proportion the different parts of any apparatus. There is nothing more unsatisfactory than to waste time and material in making a tool and to find that it is too heavy and clumsy or too light and inclined to vibrate and make bad work.

The proper proportioning of various parts is a thing that amateurs can hardly be expected to know a great deal about.

On page 11, "F. W. G." describes a very simple and apparently efficient eccentric cutter and drilling instrument; but if he had given us the result of his experience as to the most suitable dimensions for the different parts of the cutter, it would have been a great help to amateurs wishing to make one for themselves.

The same remarks apply to his letter on the combined eccentric and ellipse chuck on page 55. The description and illustrations show very clearly what an ellipse-chuck is like, but it would be difficult to form an idea of the relative sizes of the various parts unless one had some knowledge of the style of chuck.

If "F. W. G." had given the dimensions of the body or face-plate of the chuck, and also all particulars of the ring and the bolts that work the slide, it would have been a great assistance to many amateurs.

He describes a simple and excellent form of "fly-cutter" on page 108, and here he has marked some of the sizes.

The wheel-cutting frame described on page 127 is a very simple and most useful tool.

With reference to the plan for cutting worm wheels, I have tried the following method with some success, and though it is not a very mechanical way of doing work it requires no apparatus, and can be tried by any one having a slide-rest:—

The wheel must be turned with a semicircular groove. In the tool-holder of the slide-rest fix a piece of iron about 6in. long, and ¾in. by ½in. or so thick. The end next the lathe-centre must have a hole to take a vertical stud, which must be turned a working fit for the bore of the wheel to be cut.

On this stud place the wheel, the centre of the groove being exactly the height of lathe-centre. Fix a carrier to a common plug-tap, of a diameter to suit the thickness of the wheel, and run this between the centres. With the top-slide of the rest the wheel may be brought in contact with the revolving tap, and the latter will cut the teeth and carry the wheel round. The wheel can be examined to see whether the number of teeth suit the diameter; but I have never had much trouble on this point.

The wheel must be secured on the stud by a nut and washer above. I have not seen this plan tried anywhere, and would like to have "F. W. G.'s" opinion on it.

No doubt a hub such as he describes for his wheel-cutting frame would be much better than a tap to run in the lathe. The only advantage of my plan is its simplicity. **Tinker.**

ORNAMENTAL SLIDE-REST.

[19952.]—In reply to the objections raised by "M. A." (19230) to my ornamental slide-rest, he says he does not think the tool-box so well adapted to eccentric cutters and drills as to ordinary turning tools. If he looks back to an article of mine on a combined eccentric cutter and drill, he will see that the instrument I use and recommend is perfectly adapted to the tool-box, the driving pulley being in front, and it is set true in the rest by the edge of stem being placed exactly along the margin of upper slide. (The engraver, in illustration, has not made the clamping-screws of tool-box to project apparently far enough towards margin of slide.) "M. A." objects to my plan of taking up back-lash between nut and screw, and like many critics, opposes theory to actual practice. He evidently quotes from Mr. Evans's article on the ornamental rest, and is undoubtedly right in his method of taking up back-lash in square threads, but I adopted my method from its superior handiness of adjustment without having to take the rest asunder. When describing my rest, I probably did not enter sufficiently into the minutiæ of the process of the construction as Mr. Evans in his articles does; as, in the first place, it is very difficult to make oneself intelligible so as to be of any use to a tyro; and, secondly, I take it for granted that anyone who would attempt to make any of the apparatus I describe would be already pretty dexterous at turning and fitting. When making the nuts and screws for my rest, the lathe being a screw-cutting one, they being ½in diameter, are cut 11 threads to the inch, instead of 12, Whitworth gauge; though if anyone wants to fit spiral apparatus 10 threads would be handier; but as I have another self-acting slide-rest, it did not matter to me. The threads in both leading-screws and tap for nuts should be cut deep and sharp, and afterwards the top of threads of leading-screws rounded off, and a reamer passed through the nut, after being tapped, sufficiently large just to take off the top of the threads of nut also. Thus, when the lugs of the nut are drawn together by the little binding-screw, the threads of both nut and screw wedge into each other. Of course, when the nut gets very much worn, you must get a new one, which is easily done. I have my rest in use now for several years for ornamental work only, and have never yet had to put in new nuts. I think it does not matter whether you have the pillar O fastened to the lever or fixed in the hole P, provided it is made a good fit: but it must be capable of being taken out when using the stop arrangement with the leading screw. Next, with respect to the rival merits of the screw ferrule or washers for raising the rest. I have only one washer on mine, as making all my ornamental cutting frames myself, I can fit them exactly to suit the height of lathe centres; but for those who buy their apparatus, perhaps at different times, and of various sizes, I admit that the screw ferrule might be better, provided they do not mind the extra trouble or expense. Lastly, with regard to what "M. A." says about my combined oval and eccentric chuck. He must think that mine is made with the slide and guide-bars, double chamfered at each side, like Mr. Evans' pattern. It is not so; they are made with single chamfers, and the opposing surfaces of under side of slide and bed-plate are true planes, the former being first planed with my planing attachment, which I have already described, and afterwards scraped and tested by a surface-plate, and the latter accurately turned and also tested on the surface-plate, and then ground together with oilstone powder; and they come as close together as a film of oil will allow, so that no clamping screws could possibly bend them. Certainly, if the chuck was made like Mr. Evans' pattern, with double chamfers at each side, his objection would apply, if there were a sufficient space left between the surfaces to admit sheet-brass, however thin. In conclusion, to show how a little inadvertence in a description may expose one to adverse criticism, may I ask "M. A." how, if the four holes for the screws in the corners of his square-threaded nut be drilled and *tapped* before the nut is sawn in half, the binding screws are to draw the halves together—they presumably being screwed firmly into both halves?

F. W. G.

TO "FELLOW-WORKMAN."

[19953.]—When speaking of making the hole to fit pivot, you were not sufficiently explicit for anyone to gather your idea, as you simply said "make the pivots fit jewel-holes; with brass holes, *vice versâ*." As you have in some degree explained yourself here, perhaps my criticism may prove beneficial to the many readers of this valuable paper; if so, I shall be glad to have added my mite towards instructing the ambitious amateur, who would like, I have no doubt, frequently to see such criticisms, for it is through criticising each other that we gain much knowledge.

I quite agree with you about using too much space; but, in some respects, we might not be thoroughly understood with a given space; in such cases we had better beg an extra inch or two than spoil the article for want of it. As I have for some considerable time contributed horological lessons to one of the leading trade journals, I am well aware of the value of space, and therefore always try to be as brief and explicit as possible; but, at the same time, try to give every minute particular regarding the different parts of a watch.

Tempus.

LEGAL REPLIES.

[19954.]—Legal (46565).—As a general rule, one trustee is not liable for the receipts, acts, or defaults of his co-trustee. A clause to this effect is generally inserted in all well-drawn deeds of trust, and is now implied under Lord St. Leonards' Act. But if the co-trustee be guilty of any fraud or negligence, or be at all aware that the money is insecurely invested, or the like, then he would be liable, so that much must depend upon the facts of each case. Lord St. Leonards' handbook on the Law of Real Property is the best I know of; but the doctrine of trusts and the duties of trustees are now subjects so vast that they cannot be dealt with in any little book for laymen.

(46573.)—There is no fine for not proving a will sooner; but if there be a delay of more than three years, this delay must be explained to the satisfaction of the Registrar. In the case put, the widow must prove the will before she can do anything, and by way of explaining the delay, she should make an affidavit as to the property being mortgaged, and that she now desires to divide it under the will. Upon this she will probably be allowed to prove, and then she can carry out the testator's wishes, as she ought to have done twelve years ago. She may, of course, be held liable to render an account of the estate so received by her and paid away.

Legal (46584).—A user of 16 years is not long enough to give a right of way by prescription. There must be a twenty years' enjoyment to do this. In the case put, I think, therefore, that the gates can be hung up again, and the mere fact that they have been down for 16 years will not give anyone a right to remove them as obstructions.

A Ruinous Wife (46586).—The best thing the husband can do in this case is to apply to the magistrate for an order upon the pawnbroker to give up the property pawned by his wife without authority. Such an order should be made, as the pawnbroker would have no legal answer to the case. A husband is not liable to repay money borrowed by his wife without his authority, even though under false pretences.

Legal (46590).—An assignment is necessary to enable a purchaser of any debt legally to recover it, and this assignment is not valid until written notice thereof has been given to the debtor. The assignee of a debt, after notice, may now sue for it in his own name, or if the original creditor allow him so to do, in the name of that creditor. In taking an assignment of a county court debt, by which I mean one already sued for, leave to use this creditor's name should be inserted. The best books are Pitt-Lewis, price 2 guineas, and Heywood's, one guinea, and several shilling books of little value.

Deed of Gift (46592).—As against the father, the deed of gift is, of course, good, whether the houses are freehold or leasehold. But being merely a voluntary conveyance, it would not affect either a purchaser or a mortgagee of the property for valuable consideration in good faith, and without notice of the deed of gift. In other words, the sons could not upset the title of the purchaser or mortgagee at all, if freehold, nor if leasehold, unless they could show that he had notice of the existence of the settlement in their favour, or of facts that amounted to such a notice, because in law the sons would be only volunteers.

Legal (46600).—As far as I can understand this question without further particulars, the legacy rests in the nephews and nieces, from the date of the will, and therefore, each would be able to leave his or her share by will. But in these cases it is necessary to see the will itself, before being certain.

Wife's Liability (46625).—The husband could not be liable, but the wife certainly would, and she should be sued for the debt, and her goods taken in execution if it be not paid. But in the present muddle of the law, it would be safer to join the husband with her in the action, though only asking for an order of judgment against the wife's separate property.

Fred. Wetherfield.

TOLMAN'S BATTERY — GRATIS ADVERTISEMENTS — MR. BENNETT'S BATTERY.

[19955.]—Your correspondent (19902, page 107) states that my *form* of battery has been known to electricians for 15 or 16 years. He evidently means principle, not my particular form, or shape. He then gives us the theoretical action of the manganese cell, of which nearly every word for word we have read before, and winds up with a protest against the exclusion of manganese. His letter would have looked better if he had merely signed his name, and not have used the pages of "ours" to post the name of his *firm* before the readers gratis. As far as manganese is concerned, I made up cells with and without 16 years ago, and they are as good now as the day they were set up, and I defy anyone by tests to select the ones containing manganese. After 10 years' use I have examined manganese: it is not the slightest reduced or discoloured. So satisfied am I with my cell, that I am making up 36 of them for one job alone.

I do not consider that either "W. W. H. G." or Mr. J. H. Anderson has made any improvement on the caustic-soda cell. For the benefit of readers, I may state that I purchased in 1874 a caustic-soda battery—I think the name was Highton; it was identical in form with the old Leclanché, without manganese—that is, the porous cell had a plate of carbon in it, and was packed with broken carbon; a solution of the soda in the outer cell, in which was placed the zinc. In a few weeks, it followed the fate of the Grenet—not the slightest current could be obtained from them.

George Tolman.

MR. BENNETT'S NEW CELL.

[19956.]—The modification I mentioned in letter 19901 is simple and very readily constructed, and will yield a current of 22 hours' duration without rest, so that for those who cannot easily obtain "tins and borings," the following will answer:—An old pot or jar, 4½in. diam., 5in. deep; broken hard coke, previously saturated in a solution of common salt, and well drained, packed around a porous cell inside of jar, and a zinc plate in porous cell. (See page 5.) A lead plate in place of zinc will produce a current slightly weaker than the zinc yields for nine hours without rest. The positive plate may be muffled with cotton rag, and saturated with the caustic soda solution, in lieu of porous cell, for experiments. I may mention that the words "my plan" were only used for a distinction.

J. H. Anderson.

A NEW FORM OF CHEAP BATTERY.

[19957.]—The following particulars of a cheap battery will, doubtless, be of some interest to many of your readers who are interested in the development of the electric light for domestic purposes:—The outer cell is an ordinary quart battery-jar, and contains a small porous pot, which is closely packed round with a mixture of iron boring with peroxide of manganese; the porous jar contains a strip of platinised silver about 1in. wide, with a wooden plug to fit the porous jar closely. To charge the battery, fill the outer space with the ordinary bichromate solution, and the inner cell with one part of nitric acid to ten of water. Six cells of this description gave a good light from a Swan lamp for over eight days without renewing, except making up for evaporation.

Hy. E. Hawkins.

Birmingham, April 14th.

GELATINE EMULSION.

[19958.]—Several queries having lately appeared concerning above, I venture to give a method which gives results equal to the most rapid plates to be bought:—

Coignet's best gelatine....	4gr.
Bromide potassium	30gr.
Distilled water	4dr.

Silver nitrate	42gr.
Distillled water	2dr.

Warm bath: Add silver solution gradually, shaking after each addition; now wrap bottle containing emulsion in piece of cloth; then put them in tight-fitting tin canister, and place in ordinary oven; the temperature reaching emulsion will be about 120° Fahr. Emulsify about 4 hours, or until a warm purple by transmitted daylight, which must be ascertained by removing canister from oven to dark room, after second hour removing stopper and touching piece of clean glass for after examination. Examined by transmitted daylight, the changes which the emulsion undergoes are:—Yellowish orange, when first mixed, then a dirty brownish colour to warm purple. By reflected light the emulsion changes from white to greenish cream colour. If the emulsification is carried much further, coarseness of the image without increased sensitiveness results.

During the emulsification place to soak, water 6 drachms, Coignet's gelatine 70 grains. When emulsion is cooked, add the strong gelatine solution which must be previously dissolved (it requires a good heat), shaking frequently and violently for about a quarter of an hour, during which time it must be kept hot. Pour out to set, squeeze through coarse canvas into water, let it stand half an hour, squeeze through again into fresh water, let stand a little longer, then pour water containing emulsion into calico bag (made of a large piece of calico, elastic band, and wooden rim of sieve), and wash by pouring gradually about 2 gallons tap-water over. Slip off elastic band, gather end of cloth, wring rather dry, dab the ball of emulsion in bag on blotting-paper, untwist, scrape into bottle, dissolve, filter, and coat.

N.B.—1. When emulsion is first mixed, make very hot before putting in stopper; otherwise heat of oven might raise it.

2. For very hot weather, 1 drachm alcohol added to above quantity entirely prevents frilling.

3. Small opaque spots in the film are caused by insufficient shaking, after adding thick gelatine solution.

4. Red or green fog is caused by insufficiently washing the emulsion after setting, and generally shows when development is forced.

I have already occupied too much space, or would describe easily-made rapid drying-box; but should anyone be interested will write again.

Gelatino-Bromide.

EVOLUTION—THEORY AND PRACTICE.

[19959.]—Mr. J. H. Huxley and others interested in the subject will gain much instruction by reading the article "Evolution" (by the late Prof. De Morgan) in the "Penny Cyclopædia," wherein he lucidly expounds the rationale of Horner's method of extracting roots and of solving equations.

W. J. R.

Chelsea, April 8th.

SCREW PROPULSION.

[19960.]—With reference to Mr. Thos. Moy's remarks (19879), I repeat, after looking up the laws regulating the motion of solids in fluids, that it does not appear practicable to go astern with sculls projecting from the stern. I understand the Chinese are adepts at sculling from the side of a boat. I have seen a Collin sailor boy scull from the side. The Fijians scull from the platform connecting their double canoes; they stand up, press the loom of the paddle forward, astride the paddle. "If you want to propel with the greatest efficiency, you must do so by pressing or striking the water back in the opposite direction in which you wish to proceed." I suppose it is a truism that it was hardly worth while to state here. I repeat, Mr. Hooley's, as far as the theory of it is concerned, is the most efficient propeller I have seen; it acts in a direct line, no twist or beating the water in a circular form. Water moves in right lines opposite to the pressure.

Twickenham. **J. C. Curtis, Capt. R.N.**

THE CONTINUOUS BRAKES RETURN.

[19961.]—The table given upon page 109 shows the amount of rolling-stock fitted with brakes which appear to fulfil the conditions of the Board of Trade.

The following list gives—

The total number of engines and vehicles fitted with each system during the half-year ending December 31st, 1881.

Name of Brake.	Engines.	Vehicles.
Westinghouse Automatic....	150	1,431
Sanders—Bolitho Automatic Vacuum..................	155*	691
Smith's Automatic Vacuum..	14	79
Clark, Clark and Webb, Chain	—	320
Smith's Vacuum	75	305
Fay, Fay and Newall	—	41
W. Parker-Smith's	—	3
Total........	394	2,870

The 155 engines fitted with the Sanders brake have steam brakes.

It is certainly to be regretted that the companies should have provided 75 engines and 669 carriages with brakes which do not even appear to fulfil the "conditions."

With reference to the letter of your correspondent "J.," page 130, the table which I published upon page 109, and in my pamphlet, was compiled from the last Brakes Return. "J." considers the Parker-Smith brake fulfils all the "conditions," but the Liskeard and Caradon Railway Company's Return (page 9) states that it can be applied *by guard only*.

It also appears that the company had the brake applied to four vehicles, but not to any engines.

It will be of advantage if "J.," or the inventor, will furnish further details to the English Mechanic to enable the readers to consider its merits and defects, and to see for themselves whether it fulfils the Board of Trade conditions or not.

Clement E. Stretton.

Saxe-Coburg-street, Leicester, April 15.

CONTINUOUS BRAKES — UNIVERSAL COUPLINGS—TO "CENTAUR."

[19962.]—At the Euston Conference very much was heard of "Universal Couplings," and one which can only be used with vacuum brakes was adopted. The Westinghouse coupling possesses very great advantages, as it is perfectly air-tight when used either with vacuum or air pressure. The Westinghouse automatic *vacuum* brake, by the use of a triple valve requires a main pipe of the same size as the automatic air brake; hence it follows that by the use of the universal coupling, carriages having the one system of brake may be introduced into trains fitted with the other, in the same way that vehicles having through pipes only are used to prevent the brake power being cut off by an unfitted carriage.

This coupling, which appears very likely to become the much-desired *universal coupling*, has a tap at the end of each vehicle.

The ordinary Westinghouse pump serves to produce either air-pressure or vacuum, or both at once if required. To obtain and maintain a vacuum by means of *ejectors* necessitates the expenditure of a far larger quantity of steam than when the same work is performed by a pump.

A very important correspondence has recently taken place in the *Engineer* and *Railway Review*, in which it has been repeatedly stated by several of the writers that the use of a small ejector always "blowing" to maintain a vacuum, not only uses a quantity of steam but seriously detracts from the "steaming powers" of the engines, so much so, that drivers state that they have had to shut off the small ejector, and work the train without a continuous brake.

This inconvenience would be entirely avoided by the use of a pump, and this latter would possess the very great advantage of being capable of producing either compressed air or vacuum, and, therefore, supplying the power for either of the two great brake systems.

Clement E. Stretton.

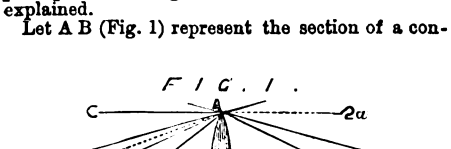
RULES FOR FINDING THE FOCI OF LENSES.—Part II.

Conjugate Foci.

[19963.]—In my previous letter on this subject, I gave rules for finding the principal focus of a lens of any given form. When we wish to compare the powers of any two lenses, the principal or solar focus of each must always be found, either experimentally or by calculation. Rays of the sun are parallel—that is, the circular beam of light falling on the lens has no tendency either to close up or to widen: thus a standard is obtained by which we can estimate the effect of any lens. But supposing we place a candle in front of a convex-lens, we know that, generally, an inverted image of the flame is formed at some point behind the lens; if we know one of these distances, how can we find the other? The place occupied by the light is called the radiant point, that in which the image is formed, the focus; and both these are termed conjugate foci, because they are, as it were, linked together, and are interchangeable; that is, if the light be placed in the back position, the image will occupy the front one. Their distances from the lens have a definite relation to the principal focal length; what this is will now be explained.

Let A B (Fig. 1) represent the section of a convex-lens; and C A, a solar parallel ray, be bent in the direction A D, cutting the axial or unchanged ray in D. Then D E is the principal focal length. Let us bend a piece of wire to follow the path C A, A D; then by moving it about A as a centre, it will show the advancing and receding positions of the conjugate foci. For instance, let the left branch be lowered till it cuts the axis in (1), then the right branch will have receded so as to cut it in (1*a*); and as (1) approaches the front, (1*a*) recedes behind, until we come to position (2), which is the same distance in front as the principal focus is behind. The second branch is then in a line with C A, showing that the emergent rays are parallel. Passing (2) towards (3), the direction of rays coming out of the lens is inclined so as to cut the axis in some point (3*a*) on the same side as the radiant point—that is, the rays diverge on emergence. When we know the principal focal length and one of the conjugate focal distances, we can find the other by a very simple rule. Let F, as before, be the principal focus D E; D the radiant distance from point (1) to the lens, *d* the conjugate or back focus from (1*a*) to the lens; then, to find the value of *d*, multiply F and D together, and divide by their difference. Let D be greater than F; the rays will come to a real focus at (1*a*) behind the lens; but if F be greater than D—that is, if the radiant is behind position (2)—there will be no real focus, and *d* will represent a distance of some point (3*a*) in front of the lens.

FIG. 1.



This rule gives the second congugate focus for diverging rays falling on a convex-lens. Now, if the first rays had tended towards a point, or had been converging, the sum, instead of the difference, would have been the divisor. Thus we obtain the following two rules for a convex-lens:—

1.—Diverging rays, $d = F \,.\, D / (D - F)$.

2.—Converging rays, $d = F \,.\, D / (D + F)$.

For a concave lens, the imaginary focus is on the same side as the incident light, and diverging rays are made still more divergent; hence, rule (1 becomes—

1.—Diverging rays, $d = - F \,.\, D / (D + F)$.

And the second one—

2.—Converging rays, $d = F \,.\, D / (F - D)$.

From this latter rule it appears that D must be less than F, in order that a real image may be formed.

I will illustrate these rules by a few examples:—

Ex. (1).—A candle is placed 12in. in front of a lens of 8in. focus; where will the conjugate image be formed?

By rule (1) for a convex, $d = (12 \times 8) \div (12 - 8) = 24$in. behind the lens.

Ex. (2).—A convex lens of 20in. focus is placed 12in. in front of another convex of 6in. focus; if the sun's rays pass into the combination, where will the conjugate image be formed?

Since the lenses are 12in. a part, the rays from the first really form a converging beam, tending to a point 8in. behind the second lens. Hence employing rule (2) for a convex, $d = (8 \times 6) \div (8 + 6) =$ 3 3-7in. behind the second lens.

If in the first example the lens were concave of the same negative focus, we should have by rule (1) for a concave:—$d = (12 \times 8) \div (12 + 8) =$ 4 4-5in. in front of the lens.

And similarly in the second example:—$d = (8 \times 6) \div (6 - 8) = 24$in. in front of the lens.

It is usual to express the above rules in reciprocal values, which is much more concise. Thus the first two are $1/d = 1/F \mp 1/D$. And for the second pair, the sign of F must be negative, which is all the alteration required.

When two or more lenses are in contact, the reciprocal of the compound focus is equal to the sum of their reciprocals (or difference, if one or more are concave).

There is one property of the conjugate foci, which is useful in finding the principal focus of a small lens. When the radiant point is twice the principal focus distant from the lens, the back focus is at the same distance on the other side. Hence, if we so adjust the conjugate foci that they are equally distant from the lens, its principal focus is one fourth of the distance they are apart.

Orderic Vital.

LENSES AND THEIR FOCI. — TO "ORDERIC VITAL."

[19964.]—In reply to "Orderic Vital," may it not be that the "mistiness" is not only in my brain, but, to a certain extent, in the textbooks themselves? At all events, though I am pretty well supplied with the latter, I have, hitherto, failed to find the information in the simple and convenient form in which "O. V." is himself supplying it in the pages of the English Mechanic. I am, therefore, glad my letters have had such a satisfactory result. The fact is, the textbooks aforesaid assume the reader to want one thing when he may want the very reverse; for instance, when the radii of curvature of the lenses are known, it is easy to roughly obtain the foci by geometrical construction in the way shown by the diagrams, or by the rules given in illustration; but when one wishes to determine the radii (which radii are perhaps desired to bear a certain ratio to each other) in order to obtain a required focus, then the textbooks do not help one.

Again, supposing one has a convex mirror, and it is desired to find the focus, it is not much use to have a formula founded on a diagram in which the radius of curvature is assumed to be known. The method of doing this I came across by chance; but it was not in a book on optics. Or, once again, the textbooks show you how to find the focus of a concave mirror, and give diagrams of the reflecting telescopes; but I have not yet come across a rule to find the equivalent focus produced by the combination of the two mirrors in Gregorians and Cassegrains, or how to fix their distance apart so that the image may be reflected by the small mirror to the right point behind the large mirror. The former I happen to know (no thanks to any textbook); the latter I can only indirectly obtain by trial diagrams. There is also very little information to be found on proportioning curves and lenses for making eyepieces of telescopes and microscopes of any required focus, though one finds diagrams which show very prettily the paths of the rays when they are made.

As to size of "light-spot," I am aware that as a matter of abstract theory this is independent of the size of object-glass or mirror; but as a matter of practice the light-spot seems to be somewhat smaller and of more definite outline when small lenses are employed, or perhaps more strictly when the centre part only of a lens is employed, and this, too, even in the case of lenses which are supposed to be free from spherical aberration. Let me then repeat my query, and ask what will be the diameter of the light-spot produced by a lens or mirror of given focus and aperture. In connection with this I may remind "O. V." that Sir W. Herschel found the apparent magnitudes of the star discs to vary according as he used the central rays, the outer rays, or the whole body of them, though the mirror must have been accurately parabolic. He of course knows that in a large telescope the effect is produced of giving an apparently larger diameter to, say, Saturn than when it is viewed in a smaller instrument. Theory and textbooks don't tell us anything about these peculiarities of practical optics. May I also call "O. V.'s" attention to my query as to photometric measurement of light reflected from mirrors of different foci.

Lens.

Errata.—Evolution (19898).—Page 196, line 19, for "$a^3 \times$ &c.." read "$a^3 +$ &c."; line 6 from bottom, for "83," read "13"; mid. col., line 12, for "by ×," read "by +"; and line 4 above the end, for "$10a^3x^2$," read "$10a^2x^2$."—J. H. H.

REPLIES TO QUERIES

**** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[45869.]—**To Mr. Dresser.**—As a rule I tune every stop from the principal, but it is a rule with exceptions. I tune every 8ft. stop and also every 2ft. stop from the principal, and any mutation stop between those pitches. If there is a 16ft., I tune that from one of the diapasons, either opened or stopped, according to the 16ft. The reeds *should* be tuned from the principal; but much depends on the power of the stops, and the open diapason or principal may be used, as may be found most convenient; but whichever method is adopted, if the organ is properly winded and the tuning correctly done, there should not be any beat. The answer to the question commencing "Why I ask, &c.," is that if such occurs, the tuning is badly done. Again, you say "Then I am told you tune the twelfth, &c." I should say, Who told you so? as it is not generally so done. The gambas, &c., are tuned from the principal. I shall include tuning in my papers on "The Organ."—J. Dresser.

[45959.] — **Bourdon Pipes.** — The Bourdon should not be slow of speech, but if the mouth is only ⅜in. high for a CCC pipe and very little wind admitted, it must be slow. Cut the mouth 1½in. high, and give as much wind as it will take without sounding any harmonic.—J. Dresser.

[45995.]—**Embossing and Gilding on Glass** (U.Q.)—There are two ways of embossing glass: by means of hydrofluoric acid and by the sand-blast. The second method being rather beyond the power of amateurs, I shall not describe it here. In the hydrofluoric acid process, the glass is first coated with some protecting substance, and upon this the design is drawn with a sharp instrument, so as to expose the glass below. The acid is then applied, when the exposed portion of the glass becomes corroded. The wax can be afterwards removed. In practice, the glass should be warmed and coated with molten beeswax (not paraffin, which is too brittle). Superfluous wax should be drained off, so as to leave as thin a coating as possible. Or a composition may be used, formed by melting together 2 parts of beeswax, 2 of asphalte, 1 of black pitch, and 1 of Burgundy pitch, and heating them together until a drop placed upon a cool surface gets hard and tough. Whatever the protecting substance used, it should be permitted to set, and the design should then be traced with some pointed instrument, care being taken to cut right down to the glass. If the design is complicated, it will be found better to trace it first on paper, and then to go over the lines with a pricker. The paper can then be placed upon the wax, and some dark-coloured powder dusted over the holes. On removing the paper, the outline of the design will be found marked on the surface of the wax. It will then be easy to cut away the wax at the desired places. A shallow tray of guttapercha or of sheet-lead must then be taken, and into it be placed about half an inch of the dilute hydrofluoric acid of commerce. The glass must then be placed wax-side down over the tray, and left exposed to the vapour of the acid for some time. On removing it, washing with water, and cleaning off the wax, the design will be found etched in opaque lines upon a bright ground. If required bright upon an opaque ground, the waxed glass, instead of being exposed to the vapour of the acid, should be dipped into the acid itself. After the removal of the wax, the surface of the glass should be ground with very fine emery. Another way is to draw the design on the glass with a pencil and Brunswick black, using as a guide a sketch on paper placed beneath the glass. On exposure to the acid vapour, the whole background will be rendered opaque. The Brunswick black can be cleaned off with turpentine, leaving the design in clear glass. Instead of Brunswick black an ink may be used, made by dissolving asphalte in turpentine, and thickening with beeswax and resin. Where it is desired to produce an artistic effect by the introduction of shading, recourse may be had to Gruene's patent process, wherein the wax or Brunswick black is replaced by substances not altogether impervious to the action of the acid. The design is drawn with oil-varnishes, greasy printing inks, or some such substances (using a good protector for the high lights, a bad protector for the deep shades, and so on), and is then dusted over with finely-powdered metal, copal, &c. When dry, the glass is dipped into hydrofluoric acid and allowed to remain in for a few seconds, and is afterwards washed. If care is taken in the selection of the protecting materials, it is possible for an artistic workman to obtain very striking results. *Gilding.*—Gilding may be done either with bronze powder or with gold-leaf. If the powder is to be used, the design should be traced on the wrong side of the glass with Japan gold-size thinly laid on, which is afterwards dusted over with bronze powder. When dry, a coat of varnish is laid on. In tracing the design, it must not be forgotten that the wrong side of the glass is being worked at, and that when viewed from the front everything will appear twisted round—the right being to the left, and the left to the right. To gild with leaf the glass must be carefully cleaned and laid upon the design. Then a solution of isinglass is put on by aid of a flat camel-hair brush. While still wet, gold leaf is laid on with a gilder's tip (for the sake of economy adhering to the design as nearly as possible). When quite dry, the design, the outline of which has been pricked out as before described, is taken and placed upon the gold. Dark-coloured powder is then sprinkled on as before. The paper is next removed and the outline carefully gone over with Brunswick black. The superfluous gold is cleaned off by the aid of a sharp narrow chisel. The size is made by dissolving ¼oz. of isinglass in a sufficiency of water, adding a quarter of a pint of rectified spirits, and making up to half a pint with water. Note.—If hydrofluoric acid is dropped upon the fingers it is desirable to wash it off without unnecessary delay; but let no one be deterred from using the acid by the dreadful things the textbooks say of it. They don't apply to the diluted acid sold at the shops.—Alfred W. Soward.

[46221.] — **Calculating Watch and Clock Trains.**—I am afraid it would take too much space to reply fully to your query. I would, therefore, recommend you to read a book recently published by Spon, 48, Charing-cross, written by Rev. H. L. Nelthropp. In this work you will find many valuable calculations, which are really copied from Reid's book on "Watch-Work." The book will cost you 6s. 6d. Should you not care to speculate in this, I will try and let you see mine, if you will advertise your address. I can then also recommend other works which would be very useful to you for calculating watch and clock trains.—Father Time.

[46260.]—**Railway Brake Formula.**—To "A Driver."—The resistance due to a brake is the same, deduced from the "distance" run in making the stop, or from the "time," if the brake-power commences to act with full force when the time begins to run, and that it continues to act to the end of the stop. The deviation between the results shows that time elapsed before the brakes came into full operation. Therefore the nearer the results approach equality the more perfect is the action of the brake. The forces acting upon a train are usually expressed in percentages of the weight, or in pounds per ton, while velocities are more conveniently expressed in miles per hour than in feet per second. To find the resistance due to a brake in pounds per ton deduced from distance run, the following formula is used—$R = 74{\cdot}78 \times V^2 / D$; where

R = Resistance in lb per ton.
V = Speed of train in miles per hour.
D = Distance run in feet.

If the resistance is to be deduced from the *time* occupied in making a stop, the calculation is equally simple. By the laws of falling bodies a force equal to the weight of a body acting upon it for a period of one second, will produce a velocity of 32·2ft. per second, and this velocity will vary directly as the force applied and as the period of application. Therefore, to impart in one second a velocity of one mile per hour, or 1·466ft. per second, to a body weighing one ton, would require the application of a force of $2240 \times 1{\cdot}466 / 32{\cdot}2 = 102{\cdot}02$lb. Thus, if we let T = the time in seconds during which the accelerating or retarding force is applied, while R and V are, as before, the amount of the force in pounds per ton, and speed in miles per hour, the following formula is obtained:—$R = 102 \times V/T$. In cases of emergency, a brake is required to bring a train to rest in the shortest possible *distance*, the time being of no practical value. Therefore, it is essential that all calculations should be deduced from the distance run in making a stop.—Clement E. Stretton.

[46295.]—**Turkish Bath for Home Use**—A simple form of hot-air or steam-bath may be made as follows:—To the back of an ordinary wooden or cane-bottom chair fix an upright piece of wood, and to this at the height at which the neck of the sitter on the chair will be fix a hoop of cane or other material sufficiently wide to keep the cloth to hang from the hoop free from the shoulders of the sitter. Place beneath the chair a gas or oil lamp or two, if one does not give sufficient heat. If, now, a cloth be fixed round the ring sufficiently ample to reach the ground and close all round the sitter, a tent will be formed from the top of which the head of the sitter will project. Let the cloth overlap the ring freely, so as to permit of being pulled close to the sitter's neck. Whilst taking this hot-air bath, the feet must be kept in a basin of warm water. If there is danger of a headache, a cold wet cloth on the head will prevent it. If a vapour bath is preferred, place a pan of water over the lamp, so that the water may boil.—Volvox.

[46296.]—**Harmonium or Organ.**—I have been waiting to see if any of our correspondents would notice an objection in the sketch furnished by "Joiner," on page 66 of our present volume, in reference to the above query; but, as no one seems to notice it, I hope "Joiner" will pardon me if I explain what that objection is. In the sketch at B, the tubes or cells are represented in the opposite direction to what they are generally placed. This increases the difficulty of extracting the reeds for tuning, &c., 50 per cent. to that of the general method. Any person at all acquainted with the interior construction of the American organ is aware that the front and back sets of reeds are the easiest to get at for tuning and cleaning. They are also aware that there is always some difficulty to remove or extract the reeds of the intermediate sets, such as the diapason set in large instruments; but the plan suggested by "Joiner" (of having the outer ends of the tubes, where the reeds slide in, inwards) increases the difficulty of removing the vibrator to a considerable extent. I am quite at a loss to conceive how the vibrators at B are to be extracted with a reed-hook. At any rate, in my opinion, it is quite an impossibility to remove them in the usual manner. Had the outer portion of the tubes been represented towards the back of the instrument (in the sketch), the matter of removing the reeds would have presented no difficulty whatever. For the benefit of interested readers, I trust that "Joiner" will clearly explain this, and let us know how he removes the reeds situated in the tubes at B, in the sketch.—G. Fryer.

[46305.]—**Blowing Engines.**—These engines are certainly "suitable," but would they not be rather costly as compared with a fan for each hearth worked from shafting? A smith's fire requires a blast having a density of only about a quarter of a pound on the square inch, whereas iron furnaces require a blast with a density of from 2½ to 3lb. per sq. in. You will find some information on the subject in Spon's "Dictionary of Engineering," but it is a special branch, and notes and formulæ are not published in the usual textbooks.—Nun. Dor.

[46331.]—**Flageolets.**—In all probability you have spoilt the instrument; better take it to a maker and see if he can repair. Doubtful whether any-one can suggest a remedy without seeing the instrument.—T. P.

[46340.]—**Painting on Silk and Satin.**—Did you form a ground with size first of all? I believe that is the secret of painting on silk.—M. P.

[46341.]—**Nickel Plating.**—Is the querist sure he obtained pure materials, and, above all, did he clean the work thoroughly? Make the solution by dissolving double sulphate of nickel and ammonia in hot water, one pound to each gallon, and have a bath large enough to hold about a fifth more solution than is needed. Battery power depends on quantity of solution, but always have plenty and couple up for intensity at the start, changing to quantity when a film has been deposited. The surface of anode should be largely in excess of the surface to be covered—in fact, surround the article with plates of nickel. Beyond thorough cleaning it is advisable to copper steel before placing in nickel bath.—E. C.

[46345.]—**Continuous Brake**—The Henderson system is hydraulic, I believe. A disc-shaped vessel contains a diaphragm, on one side of which is the water in the brake-pipes, on the other steam from the engine. I doubt whether many of them are at work.—T. P.

[46359.]—**Gilding Watch-Plates.**—Frosting is done with the scratch-brush held so as just to touch the metal. It requires a deal of practice. You will find several replies in back numbers; both mechanical and boiling processes. It is not clear which you mean.—Perth.

[46366.]—**Leather for Bellows.**—Ask for best strained sheepskin.—Sabbas.

[46368.]—**Clock**—In the American "Nutmeg" clock, which appears to be the kind alluded to by "Anxious Amateur," the back is secured by two pins, which enter into bayonet-catches at the top and bottom, in the edge of the back. Remove the three screws at the front of the clock which secure the works in the frame: then, using the winder and hand-setter as levers, turn the back to the left as far as the pins will allow, and then pull out the back and works together. To separate them, the winding-handle, which is secured on by a left-handed thread, must be turned to the right (not to the left, as suggested by "Calne"), and the hand-setter pulled off, when the back will be free.—G. C. C.

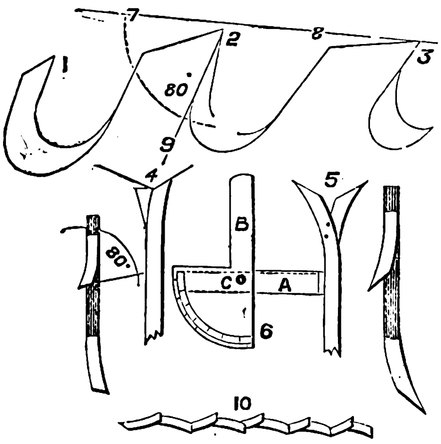
[46381.]—**Three-Legged Gravity Escapement.**—I cannot allow "Alfojoe's" reply to pass without comment. The gravity escapement was invented for the sole purpose of preventing errors of train getting at the pendulum. Now Benson, according to "Alfojoe," says, that "the great advantages possessed by this escapement over all other gravity-escapements are as follows" (paragraph 14): "The angle of the detent-planes can be set so as not only to offer no resistance to the unlocking, but to give an actual impulse." In other words, one of the advantages of this escapement is, that it can be so constructed that errors of train can be applied to the pendulum. One might just as well state that the great advantage of the zinc and steel compensation for pendulums was that it could be so made that the pendulum was not compensated. My reason for only criticising paragraph 14 is, that I saw at the exhibition of scientific instruments, South Kensington, a clock made and exhibited by Cooke, of York. The detents were rounded; so practically it was an impulse-escapement of a very indifferent kind. The erroneous reasoning in the other paragraphs will be obvious to any reader. I believe that the gravity escapement is not suitable for regulators. I understand that it is not used at Greenwich, which is a stronger argument against it than anything I could say. The double three-legged is an undoubtedly good one for turret clocks; at the same time it is equalled, if not surpassed, by a pin-wheel and remontoire.—Edward M. Nelson.

[46396.]—**To "Aldebaran."**—I wish "Aldebaran" would explain how the rays in a terrestrial eyepiece are, as he says, "still divergent" after passing through the second lens, B. In all the eyepieces I have seen, the distance C D is much less than the sum of the focal lengths of C and D, so that in them the rays must have been convergent after passing B. The position of the diaphragm between C and D is wrong; it should be at the point where the rays cross, where the image is formed. Nowhere else can it be clearly seen, and the edges of the field be sharp.—Paugul.

[46402.]—**Cement.**—You will find nothing like a few small silver rivets, which will make your china fit for use.—China Rivet.

[46422.]—**To Mr. Dresser.**—I intend to describe a number of couplers in my articles, both unison and octave.—J. Dresser.

[46424.]—**Circular Saw.**—Your saw should be dished—i.e., tight upon the circumference, to work well, and the hollow part next the fence, for in working, if not sharpened properly, will become hot, and the consequence will be a wobbling saw; but a 64th of an inch would be quite enough; if yours is too much, it may be altered by placing it upon a smooth anvil, and slightly hammering it around the outer edge, and testing it with a straight-edge; your saw, I suppose, from the size given, is the ordinary peg-tooth. There are some who profess to sharpen saws, but can never sharpen one to work without getting hot. A slight sketch will give you a little insight, and perhaps be useful. Fig. 1 is what is called the gullet-tooth, and is how I have seen them filed—1st to an angle forming a needle-point; the 2nd with a very slight angle, and with gullet right; the 3rd square at top, and too much chamfer in the gullet. Now from the face of saw the point of tooth-angle should never exceed 80° for soft wood, and for hard, square the chamfer in gullet about one and a half thickness of plate, and the set not more than two-thirds thickness of plate, the rake of tooth as shown by lines 7, 8, 9, from point of teeth 80°, and clearance from heel to point not more than one-eighth to an inch; the set



should be as shown at 4, not as at 5. Be careful in setting your saw; do not set it down to the root of tooth, or you will buckle it. The same rule applies to hand-saws for wood, that is including tenon saws, panel saws, hand saws, half-rip and dovetail saws (see 10); 6 is a gauge that is easily made; A, a piece of steel or iron hoop, ⅛in. thick, 1in. wide, 4in. long; B, a piece of sheet-iron a sixteenth thick, a quadrant at one end with a tail at the other, and a rivet at C. This is adjustable to apply as shown at lines 7, 8, and 9, and very useful until your eye gets accustomed to the form or work.—Jack of All Trades.

[46456.]. — **To J. C. King, or any Wheelwright.**—To put a new hub or nave to a timber-gig wheel without taking it to pieces. First, take the sizes of the front and back hoops of old hub, and have the new nave turned to suit them, and to the full diameter of the spoke shoulders (if by a rare chance such a wheel has shouldered spokes). Number the spokes from 1 to 14 (the common number of spokes of such a wheel). Take notice for heavy wheels that the spokes are nearly always ¼in. thinner edgeways at the back edge of the tenon than at the front; by neglecting to notice this you may spoil your job. Begin at No. 1 spoke and reverse the width of the tenon, making it a shade narrower by bevelling the tenon towards the front; serve the opposite face of No. 2 spoke in the same manner—this will produce a slightly tapering opening from the front between the spokes. The space between the next two spokes may remain untouched, as they will already be found to taper from the back; thus every alternate opening between the spokes will taper either from the back or front. The purpose of this will be obvious from the illustration Fig. 1, marked M 1, M 2, &c., which is an outspread plan of the spokes of the wheel at the nave. Measure the size of each spoke set out on the nave for mortising, which is done in the usual way, the mortises being duly bevelled to correspond to the "disch" of the wheel. The nave centre is now cut out for the "box" or "bush." I may here explain that the wood left between the mortices in the nave is technically called the "meash." It is round this meash saw-cuts are made to divide the nave into two halves, back and front. These cuts are made with a strong key-hole saw, alternately at the back and front edges of the "meash," as shown by the dotted lines A B C at the front edges of the back half of the nave, and D E at the back edges of the front half of the nave. This is shown by the plan M, 1, M, 2, &c., which by the closing together of the two halves lock into each other, and tightly wedge every spoke in its place. To hold two halves together six bolts are used, reaching from back to front, the same as in the common mail-coach axle-tree. Fig. 2 shows a plan of part of the back of the nave with a rabbet to receive the bolt-heads, so that they may not project, as shown by 1, 2, 3. A front and back face-plate to the nave is necessary for the bolts to go through to prevent them drawing into the nave; the edge of such back plate is shown by the dotted lines H H. Of course, the back and front hoops must be shrunk on the nave before the mortising is begun. A mixture of red-lead and linseed oil is the best cement for the mortise-joints. This is an easy job for an ordinary wheeler.—J. Charles King.

FIG. 2

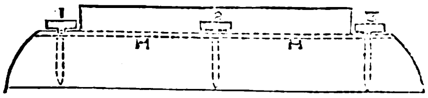


FIG. 1.

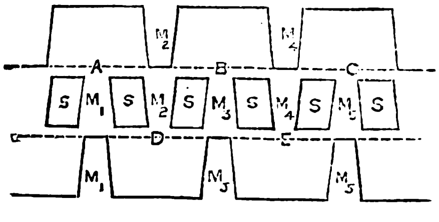

[46489.]—**Bicycle-Making.**—I note that you have bought the forgings in the rough only, therefore, let me help you as best may be. Now, what I should do would be to do the work properly, even at the outlay of time and a little money to make the needful tools, and the most necessary of all would be a drilling spindle. If the holes for the spokes are not drilled properly, so that the spokes, when fitted, stand straight and true, the wheel will be weak, and will be always a trouble with loose and broken spokes. What you need is a drilling spindle. This you can make yourself for a few pence and your own time, and if you will tell me what class of lathe you have, whether it is a single-gear one or with back-gear or not, and if also it has a slide-rest or not, I will then send you a sketch of the drilling-frame and spindle. Without some form of it, you would never be able to drill the hubs properly. In the mean time, you may occupy spare time in getting the hubs turned up to size, and the holes for the spokes pitched off. I need hardly tell you that the holes should break-joint—or, in other words, that alternate spokes should lead to alternate sides of the hub. Get all nearly centred up, as you will have to carry the hub between the lathe-centres when drilling the holes. With a drilling-spindle the spoke-holes are bound to come true. As to the neck and backbone not coming in quite right, as you have fitted it so far, you must rely on the brazing. See my remarks previously. In your case a small pin, drilled through and riveted over, would be an advantage. But get the joint well filled with spelter inside, so that it forms one solid mass. Not only this: but I should, if the fit is very loose, put in a piece of sheet-iron, to take up the slack, and so further solidify the joint. Let me know as to your lathe, and I will put you right on that or any other point, with pleasure.—Sunlight.

[46497.]—**Fortified English Cities.**—To fully answer "Antiquary's" query would no doubt occupy too much space, yet I expected there would have been more interesting information evoked by it than has been. What the query called for was dates, and they have not been forthcoming. Several correspondents refer to Chester as "unique," and "as perhaps the most perfect example remaining in Europe" of ancient walls. Ireland is still supposed to belong to the continent of Europe, and we have yet to hear of a separatist sufficiently rabid to dream of it being otherwise. In it have we not got *the* most perfect specimen of ancient fortifications—to wit, Londonderry? Perhaps the word ancient hardly applies, for the walls only date from the beginning of the 16th century. However, they saw service on more than one occasion, and most people have heard of the last time, when they so successfully answered the end of their being. Since then they have been preserved with the most jealous care. The city has much outgrown them, and to accommodate the increasing traffic, several new gates have been pierced in them; but they have been altered as little as possible. All visitors to the city make it a matter of duty to walk around them. They are a pleasant promenade of about a mile in length. On certain high days they are manned by those who consider themselves the representatives of the ancient garrison; and the thunder of cannon make the surrounding hills re-echo, and call up in loyal bosoms the memory of the good old days when the men of Derry fought and died for true liberty. Are not the walls of Chester much encroached upon by buildings, and when one is walking upon them are they not walking upon the tops of inhabited houses? And are they not quite overbuilt in some places? Are there any relics of the walls of Limerick remaining, or of any other Irish city?—Shan Sholus

[46498.]—**Cement for Glass.**—Isinglass dissolved in common (not glacial) acetic acid, with the aid of a little heat, makes a strong transparent cement for glass. The glass should be slightly warmed by dipping in hot water, after which it must be wiped dry and clean before the cement is applied.—T. A. C.

[46510.]—**Photography.**—Thanks to "W. T. B." and "W. H. S. W." for their replies to above. Will "W. T. B." kindly say what "black varnish" is the most suitable to cover tin developing-dishes with? The plan described for changing plates is just the kind of thing I have been looking for, and will do admirably. I shall be exceedingly obliged to "W. H. S. W." if he will give me full particulars, dimensions, &c., for making a bag as he suggests. The only black stuff I have been able to obtain is not sufficiently opaque without having about four thicknesses. Is black calico the name by which I shall obtain the best opaque stuff sold? Please give explicit instructions for fitting in the arms and elastic. I think that I can feel to do all that is required without the sights, though perhaps these may be an advantage at times.—F. C.

[46512.]—**Boring Horizontal** Bar.—See answer to 46513; but, instead of a drill-point file a three-square point the same as centre-bit, and give it one turn instead of a third.—Jack of All Trades.

[46513.]—**Drill.**—Get a bar of cast-steel, ½in. by ¼in., and make it into a pin-drill about 5-16in. and ½in. long; twist the end about one-third of a turn,

FIG. 3.

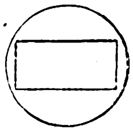

FIG. 2

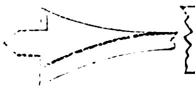

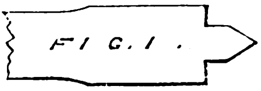

and sharpen the square ends, giving about a 64th clearance from cutting-edge to heel, and harden and temper to a dark brown.—Jack of All Trades.

[46531.]—**Yacht-Deck.**—In my opinion, "Working Tom" does not give sufficient thickness to the deck planking, unless the boat be a very small one. 1¼in. would be less likely to give trouble by leakage; also it would be very injudicious to leave only ½in. of timber for the spike nails to be driven into, as he recommends.—J. J. A., Liverpool.

[46536.]—**Shaft.**—I have fixed shafting the same as you speak of, and have had very little trouble to get them to work properly. If you were in my locality I could show you one at work that I fixed five years ago.—Stratheden.

[46553.]—**Riveting Copper Boiler.**—Apparently it is only reasonable to presume that it is an externally-fired boiler you have in view. If so, and you want to reset the other end in, the only way is to flange up the end plate, and recess it into the shell, which will leave the rivets in view, as sketched in Fig. 1. Or another way is to flange out the shell-plates and rivet a flat end on as at Fig. 2. In either case, I should well sweat the joint with solder, to insure its being steam-tight.—Sunlight.

FIG. 1.

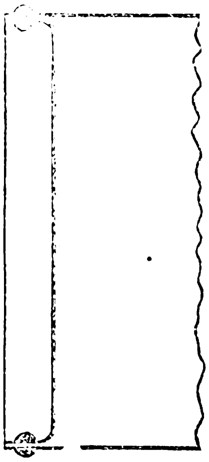

FIG. 2.

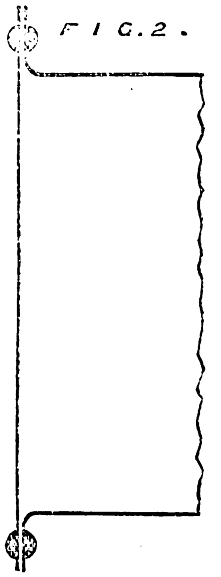

[46556.]—**Skin Disease.**—I was afflicted with a similar disease for 15 years without relief, until I was recommended to try the following by a retired surgeon from the East India Company's service, which completely cured me in six weeks. His prescription was five grains of corrosive sublimate to 1oz. spermaceti ointment, scented with bergamot. I rubbed a small quantity on the part affected two or three times a day, and increased the quantity every day. It made it apparently worse for a few days; but I persevered, and it cured me, and I have not had it since. I have recommended it to many, and never known it to fail. —Jas. Lewis, brushmaker, Swansea.

[46557.]—**Spun Wire.**—No drawings of machine have appeared in this paper since Vol. XVII., page 481, when I sent a plan and description of one I made for my own use. Just previous, a well-known correspondent, the late "H. B.," sent a plan of the method he advocated, but it required the assistance of a self-acting lathe or similar machine. A cotton or silk-covering machine will not do for covering with wire, for in this case it is absolutely necessary that a very great strain should be put upon the covering-wire while it is being wrapped round the under wire, and the principle of covering is different. You can buy covered strings singly or in sets, pretty cheaply, either of Mr. Davies, or elsewhere. In the olden plan, the wire is strained in a framing, carrying a toothed wheel at each end, and these wheels revolve equally by means of a shaft carrying suitable gearing. In the other plan the wire is placed within a tube, having a disc on one end carrying the covering wire; the tube revolving in bearings. —J. C. L.

[46557.]—**Spun Wire.**—The strings should first be prepared for covering by drawing them between two coarse files. This roughens the surface, and by giving the copper wire a hold, prevents its springing loose and rattling. The process of covering is a very simple one, and consists of fastening the steel string between two revolving hooks—properly, they ought both to receive the same motion by means of cog-wheels connected by a long rod; but for covering with copper wire up to about No. 20 B.W.G., it will be sufficient if one only does the work, while the other revolves freely with the string. The copper wire should be fastened to one of the hooks and held, in a piece of slit wood, at about the position the covering is intended to begin; the string will then wind up the wire as it revolves, and at the same time push the holder along. When the covering has gone far enough, a little pressure by the fingers on the copper wire underneath the holder will cause is to break off close to the string. The spare wire at the other end may then be cut off by reversing the movement of the lathe and nipping the copper wire with a pair of cutting pliers, which, to prevent injury to the steel, should previously have been softened. If Mr. G. Fryer will send me his address, I will forward him a holder. For this, though easy enough to make, is not so easy to describe without an illustration.—W. H. Davies.

[46559.]—**Sharpening Carpenter's Saws.**—See answer to query 46424, and for pitch of teeth, fine dove-tail saw, 24 to 32 to the inch; tenon, 12 to 16; panel, ⅛ to 5-32; hand, 3-16 to ¼; half rip, 5-16. Files there are great differences in: the first two a 3in. file will do; the next two, a 4in.; and the last, 5in. or 6in.; but for the first, any 3in. file will not do, as they are not fine enough upon the angles, but with Stubbs', I have cut 40 and 50 to the inch, the while with others that are called tenon-saw files I have had the greatest difficulty to get a tooth within the ordinary tenon-saws or meat-saws for butcher.—Jack of All Trades.

[46560.]—**Tuning Piano.**—To Mr. W. H. Davies.—I should hardly like to advise "R. H." to raise the pitch of his piano two whole tones without knowing something more about it, for I am afraid the tuner must have had some good reason for saying that, if raised, "it would be down the following day," as this would certainly not be the case unless something had given way, although it would be quite true that one tuning would not be sufficient to make up for such neglect, even in the best of instruments. I may, however, tell "R. H.," for his comfort, that the difficulty is quite as likely to have originated in the unwillingness of the tuner to undertake such a job as from any defect in the piano. For if there is one thing more than another a country tuner dreads, it is just such a task sprung upon him when he has very likely parcelled out his work barely to time a certain train, and it must be admitted that, under these circumstances, there is "good reason" enough to warm up the most prosaic of mortals into eloquence on the possible perils of such a proceeding; and it would be easier to blame him for this than to act differently in a similar situation, especially when it is taken into consideration that a very large proportion of these cases is due to simple neglect and to a foolish habit of boasting how much longer one particular piano will stand in tune than any other—pitch and tune being, of course, with such people quite distinct qualifications. "R. H." must not think I include him amongst this class; but the tuner would be almost certain to do so, and would make him suffer for the faults of his neighbours. The fact that the pitch seems to have gone down equally throughout, points to a defect in the wrestplank, if anywhere, and is, taking it altogether, rather an advantage than otherwise; but before venturing to tighten the strings I should remove the backing and notice if the plank shows any signs of pulling away from the bracings. If so, a few good strong screws would be of service, though I have noticed it is peculiar to such pianos that the tuning-pins are placed too near the top of the plank for screws to be put in above them, and it may therefore be necessary to put them underneath, though in this position they will have to contend against the increased leverage. In raising the pitch it will be at first only necessary to rough it up. For an amateur the easiest way of doing this will be to raise each note to unison with the ½-note next above, and proceed upward until finished. It should then be left to settle for a short time, and notice should be taken if there are any signs of giving way, such as loud noises, &c. The proceeding may then be repeated half a note at a time until the strings are all up to pitch. To fine tune it, will, of course, require a considerable amount of practice; but, with care, a passable job may be made with the assistance of a set of 12 harmonium or concertina reeds tuned to consecutive half-notes, —if fixed in a concertina so much the better—when the octaves and unisons may be tuned from the groundwork so laid. To remedy the squeaking, a touch of blacklead on the hoppers is all that is necessary; but the difficulty, in a check action, will be to get at them; perhaps the best way would be to lay the action, face downward, on a kitchen dresser and to scrape a little dry blacklead on to the butts of the hammers and to rub it into the grain of the leather with a camel-hair brush. The escape-buttons at the back of the hopper may also require a similar treatment; but with such difficulties a little careful and intelligent planning will do more good than a whole page of instructions, which must necessarily be mixed up with a great deal of advice given at random.—W. H. Davies.

[46561.]—**Water-Supply.**—"A." can, if he thinks fit, disconnect all pipes passing through his house—that is, if the house is his own property. All information he requires he can get from the water-works of his district.—P. Mooney, Plumber.

[46574.]—**Photo.-Bath.**—I was for some time troubled with these stains like marbling. In my case they were caused by a habit I had of moving the plate in and out of the bath by way of helping the ether and water to mix. A gentle motion within the bath may be useful; but if any part of the plate be withdrawn before decomposition is complete, the ether runs into greasy patches, which are sure to show on developing.—W. A. S.

[46574.]—**Photo-Bath.**—Insert pieces of blotting or filtering paper at the corners of the carriers; upon these let the plate rest. The bibulous paper will carry off the drip, and if plates are kept but a reasonable time before developing, the "oyster-shells" should not appear. An inferior quality of silver sometimes causes these marks; organic matter in the bath sometimes produces them, but glue (or other matter in the wrong place) at the corners of the carriers is very often the cause. Never use glue for carriers; shellac is safe. A prolonged and agonising experience makes me suggest glue as the possible cause.—W. T. Bashford.

[46579.]—**Continuous Brakes.**—The G.N.R. company use Smith's vacuum brake generally, and in some cases the Westinghouse automatic, on their Scotch expresses. The M R. use the Westinghouse automatic on their Scotch expresses, and the Sanders and Clayton modified automatic vacuum brake on the ordinary expresses. The L. and N.W.R. use the "Emergency" chain-brake on their Scotch expresses, which only acts on the train, and is not used except in cases of emergency, when it can be applied by driver, fireman, guards, and passengers (by pulling communication cord). The S.E R. use Smith's vacuum on their Continental, tidal, and other expresses.—Brake-block.

[46582.]—**Pressure on Wheels of Railway Carriages.**—The rule needed seems to be the ordinary one: Multiply the power (in pressure) by its distance from the fulcrum, and divide by the distance of the weight from the fulcrum, and the quotient will be the weight or resistance—in this case, the pressure on the wheels.—Paugul.

[46586.]—**A Ruinous Wife.**—I was for eighteen years labouring under the same misfortune, and found that nothing short of a thorough exposure and separation would cure the disease. If "An Unfortunate Husband" will advertise a name and address (post-office will do, but must not be initials), I will give him the benefit of my unhappy experience, and do my best to assist him.—X. Y. Z.

[46588.]—**Telescope Lenses.**—As a week has passed, and this has not been answered, I suppose it may now be considered open. Apologising, in any case, to the correspondent to whom it was primarily addressed, I may tell "J. L." that what was meant was rather the positions of the lenses themselves than of their tubes. What is essential is that the central ray of the eyepiece shall pass through the centre of the o.g.; whether it reaches it perpendicularly or not does not so much matter. Incline any *one* of the lenses of your eyepiece, and you will see.—Paugul.

[46588.]—**Telescope Lenses.**—To "Aldebaran."—By moving the eye-tube of a three-draw telescope sidewise, it is the centres only that are thrown out of line. This is of very little importance in any but very short-focus lenses, such as are occasionally used in celestial eyepieces for delicate double-star work. For ordinary use it would not have any appreciable effect, and, indeed, in nine eyepieces out of ten, is not thought worth the trouble of attending to at all. But to interfere with the squareness of the lenses to their axes is a very different thing, and would render clear definition impossible. As an illustration of how small an error of this description is sufficient to blurr the definition, I may mention that I have now in my possession an astronomical telescope of 3in. diameter, whose performance was, for years, extremely unsatisfactory. This was attributed all along to a want of achromatism in the object-glass, and perhaps the more naturally, that any bright star appeared surrounded by a blaze of all the colours of the spectrum. I was one day trying to focus the sun on a piece of white paper, and found it impossible to get a clear-cut image at all. This put me on the right tack, and I loosened the three screws that held the cell-cap to the body-tube, intending to adjust the lens to a proper focus, when I found, to my surprise, that it was already done, and that the definition was exceedingly good. I dare say "J. L." has at some time amused himself by reflecting sunlight with a piece of looking-glass. If so, he must have noticed that the slightest turn of the glass in his hand was sufficient to cause the reflection to pass across an immense area, while if he merely moved it bodily it had very little effect. These two motions fairly represent the difference between the truth of the planes and that of the centres of lenses in a telescope.—Aldebaran.

[46597.]—**Toning.**—Any good toning-bath with an alkaline reaction will, in course of time, assume a dark tint. This is due to a gradual reduction of the chloride to the metallic state. I find my bath, which has been in use for years, and toned many reams of paper, is slightly tinted, and I prefer it so; the deposit is once or twice a year collected and saved for reducing again to the chloride. If it is desired to prevent this precipitate, filter the bath immediately after use, and add just sufficient of a weak solution of aqua-regia to indicate acidity, but the bath must then be made distinctly alkaline prior to again using. Again, by adding a faintly acid solution of gold to the filtered bath immediately after using (sufficient for the next toning) will generally prevent the deposit, and the interval that elapses suffices to ripen the bath. Your formula is good, but your acetate of soda may be alkaline, and thus cause a wasteful deposit. A few drops of chlorine water, or of a solution of chloride of calcium—sufficient to make the bath smell of chlorine, will prevent the deposit, but changes the tone from purple to black.—W. T. Bashford.

[46597.]—**Gelatine Emulsion.**—I have had no experience with gum as a substitute for gelatine; and except for special purposes, I have for some time past bought the plates of one maker; they are so thoroughly satisfactory in every way, and so very cheap, that I would rather buy these than go to the trouble of coating the plates, though the emulsion cost me nothing. A few days ago one of the most successful amateurs I know asked me to test some plates he had prepared for a tour in Normandy. They were delightfully sensitive, clean, and easy to develop; the following was the simple plan he adopted—certainly the quickest and simplest I know:—1. Gelatine, 300 grains; ammonium bromide, 300 grains; water, 5oz.; dissolve by heat. 2. Silver nitrate, 400 grains; water, 5oz. To this solution add liquor ammonia drop by drop until the brown precipitate first formed is dissolved and the solution is clear. Make this solution of ammonio-nitrate of silver warm, the same as 1, and add the two solutions together, gradually stirring briskly all the time. Now set aside this emulsion where it can cool very slowly (the slower the better). The next day add 300 grains of gelatine to this emulsion, again set aside to cool very thoroughly, and wash in any way thought best. On remelting the emulsion, if it has not taken up enough water to make the total measure 20oz., add water to make that bulk. Or add water to make 20oz. before washing the emulsion, and coat the plates at once, washing them in running water after the coated plates are well set (personally I prefer the latter plan, and if there is convenience for this rather cumbrous method it has several advantages). Dry the plates thoroughly, and they are ready. There is a special make of gelatine peculiarly suited to this formula by Ch. W. Heinrichs, Höchst-on-Main, but probably equal parts of Nelson's No. 1 and No. 2 will answer almost as well. It is extremely important in all manipulations with this emulsion that very special care be taken to use the dimmest and most non-actinic light, both in mixing, washing, coating and developing. —W. T. Bashford.

[46598.]—**Problem in Plumbing.**—You can stop the water passing through the supply-pipe, by putting in the end a good cork. The cork must be in a few minutes before it will thoroughly stop it, as it will swell with the water. Care must be taken when drawing the cork or it will break. I would advise, if possible, an entirely new pipe, as the old one is dangerous.—P. Mooney.

[46606.] — **Back-Geared Headstock.** — To "Sunlight."—Many thanks for your reply. I beg to state that I have a single-geared headstock, but it is not my intention to alter it. I want to make a new back-geared headstock for the same lathe, with a mandrel running in gunmetal bearing, and kept true by a back-centre; and for this purpose solicit your instructions. I shall be most thankful for your help, and trust you will furnish dimensions, with a rough sketch of parts, &c.—Progression.

[46607.]—**Fuller's Battery.**—The Fuller is a carbon-zinc cell. In carbon division put a saturated solution of potassium bichromate, mixed with 1-12th its volume of strong sulphuric acid, with zinc, one of acid to 20 of water. A good modification is chloride of zinc inner cell, and muriatic acid with the bichromate in the outer cell. He may also refer to Vol. XXIX, pp. 298, 374,416.—Kappa.

[46607.]—**Fuller's Battery.**—This battery is a modified form of bichromate. An outer stoneware cell contains a solution made by dissolving three ounces of bichromate of potash in a pint of hot water to which, when cold, 2 fluid ounces of sulphuric acid is added. An inner porous vessel contains dilute sulphuric acid (1 of acid to from 6 to 20 of water, according to the use to which the battery is to be put). The negative element is a carbon plate, and dips into the bichromate solution. The positive is a zinc block, and dips into the liquid in the porous cell, at the bottom of which and in contact with the zinc is a layer of mercury. This block in the batteries sold by the makers is of a rather peculiar shape—resembling a pillar standing upon a broad flange-like base; but there would seem no reason why an ordinary plate or rod should not be used. The copper connecting wire attached to the zinc should be soldered thereto, and the joint coated with some protecting substance such as guttapercha. This may easily be done by rubbing some warmed guttapercha over the joint while the latter is still hot. This form of battery is more constant than the ordinary bichromate, and the zinc plates being, owing to the presence of the mercury, kept constantly amalgamated, local action is abolished, and a great saving of zinc is effected. The battery is fumeless, and is suitable for the performance of all ordinary experiments where a current is only required for a short time.—Alfred W. Soward.

[46608.]—**Strength of Battery Current.**—Certainly; what you want is a galvanometer. Described frequently in back numbers. It is constructed as you assume, and is the best thing for the purpose of a visual test. If you have not back numbers, or want further information, write again and I will help you.—Sunlight.

[46608.]—**Measuring Strength of Battery-Current.**—"C. M. R." is evidently thinking of a galvanometer. Such an instrument may be readily constructed by winding some insulated wire into a small flattened coil, and suspending within it a magnetic needle in such a way that the needle, when at rest, shall be parallel to the longer axis of the coil, but shall be free to swing to the right or left. On sending a current through the coil, the needle will be deflected. But a galvanometer made in this way is of little use as a measurer of currents. The angle of deflection bearing no calculable relation to the strength of the current, it merely tells us that a given current is greater or less than another. The only way practically of using such an instrument for measuring purposes is by first calibrating it. A current of known strength is sent through the coil, and the deflection noted. A current of twice the strength is transmitted, and the new deflection noted, and so on. "C. M. R." will probably find a voltameter of more use to him than a galvanometer. See description by "Glatton," at page 89.— Alfred W. Soward.

[46609.] — **Monohydrate of Sodium-Carbonate.**—This substance may readily be prepared from common soda crystals (decahydrate of sodium carbonate), by pounding them up and permitting them to effloresce, or more speedily, by melting them (which can be done at a temperature of 34° C). In either case, nine molecules of water of crystallisation are given off, and the monohydrate remains.—Alfred W. Soward.

[46614.]—**Tricycle.**—To "Sunlight."—If the cranks were set at right angles, as with a steam-engine, a different action would take place altogether. With a tricycle, power is only applied on the down-stroke, none on the up-stroke; or, in other words, the rider produces revolution of the wheels by pushing only, and not by both pushing and pulling. With the cranks on a right line as now used, the power is applied all round the revolution nearly. The only time when power is not applicable is at the dead-centres. Now, if the cranks were set at right angles, what would result? For one-half of the revolution there would be no power at all applied—that is, to drive the machine forward. The one crank would be first passing on to the bottom centre, the other one in such a position that no force can be applied to it except to go backwards. And as the second crank follows it past the bottom centre, the same state of things still remains. Hence, if the cranks were so, the machine would be driven by the cranks during half each revolution, whilst during the other half the machine would be driving the cranks, thereby losing just half the power now applied. Set at a triangle would be equally bad.—Sunlight.

[46616.]—**Leclanche Battery.**—What do you call the copper pole? and how is it that the carbon does not form the positive pole in each cell? Have you reversed the middle cell of the three? Perhaps your solution was not pure and clean.—Kappa.

[46616.]—**Leclanche Battery.** — What does "Odd Fellow" mean by saying, "I find that.... the zinc in the cells in which the carbon forms the copper pole gets quite black, whilst the others remain quite bright"? Surely the carbon acts as a copper pole in all his cells. If "Odd Fellow" will write again, saying exactly how his battery is joined up (thus, copper plate of cell No. 1 to so-and-so, zinc plate of cell No. 1 to so-and-so, and so on), I will try to help him.—Alfred W. Soward.

[46617.]—**Sewer-Gas.**—"C. G. N." will find no difficulty in finding out a flaw, either by the drain, sink, or closet, by using what I term a sanitary ferret. This is what I contrived and made, and put in practice, to convince my landlord that the drain was defective, and because he could not smell the gas, he could actually see it, and he was thoroughly convinced. Make a rocket as big as a Roman candle, and of very smoky material, or, if you are any where near Mr. Jas. Pain, the ship-signal manufacturer, No. 1, St. Mary-axe, E.C., or 121, Walworth-road, you could be supplied with the real thing itself. Direction: Temporarily stop external gulley-holes connected with drain, and if you can serve the rain-water pipe the same, do so; have a good fire in kitchen, and close all doors; cause the ferret to fit like a cork in the gulley-hole of front area. Now set fire to the touch, and place it in gulley-hole to fire the powder; go in the kitchen, close the door, and wait the result, which will be, if the drain is bad, the room will be full of smoke; if not, if there is no smoke to be seen, you may consider that part sound. To test the sink, or closet, open the door leading to the room with the fire, and if any escape is there, it will be sure to show itself in the neighbourhood of either. For an out-door closet, I connected a half-dozen of common squibs without a bang, and although I succeeded, it was a clumsy job.—G. B.

[46619.]—**Tricycle.**—Whether you have an intermediate wheel or not does not affect the power. The size you have speeded to is easily found. Multiply the diameter of driver by diam. of wheel on crank, and divide by diam. of wheel on hub. Thus, 44 × 2⅜ / 4⅛ = 25⅓in., in your case.—Paugul.

[46619.]—**Tricycle.** — Did you measure the wheels over the ends of the teeth on the pitch-line, or on the line of the root of the teeth? Supposing that the wheel on the crank is 2⅜in, its circumference would be 7⅜in. The wheel on the hub is, you say, 4⅛in. diameter, therefore it equals 12⅞in. diameter. The intermediate wheel does not need to be considered, as it is a mere carrier of the power. The ratios, therefore, are nearly equal to 2 to 1. So that your 44in. wheel is going equal to about a 20in. one.—Sunlight.

[46619.]—**Tricycle.**—"Ex." has speeded down his driving-wheel to 25⅓in.:—4⅛ : 2⅜ :: 44 : 25⅓. The dimension of the intermediate wheel is immaterial. "Ex." has sacrificed speed to power—*i.e.*, with the same rate of treadling he will cover only 25⅓ miles in the same time as he would formerly have travelled 44 miles; but he ought now to overcome an external resistance of 44lb. with no more exertion than would formerly have been needed to overcome 25⅓lb.—W. H. S. W.

[46620.]—**Pantelephone Transmitter.**—Size of diaphragm 6in. square. Have not tried cork. The inventor recommends that material. The coil fuse is 2½in. long and 1¼in. diameter; primary wire, three layers No. 24; and secondary, ¼oz. No. 36, silk-covered copper wire. One Leclanché cell. Have tried carbon and platinum in contact, but find contacts of carbon only much the best. Size of carbons, on diaphragm a disc ½in. diameter and ¼in. thick; on spring, a short rod ½in. long and ⅛in. thick, rounded at the end in contact with disc. Receiver, Bell's Telephone. (See English Mechanic, Vol. XXXII., page 56.) In the sketch accompanying my answer to query No. 46353, a line has been left out by the draughtsman connecting the top right-hand post of switch with left-hand post of bell. Supply this by a pencil-line, and the thing is complete.—John C. Frank.

[46628.]—**Watch-Escapement Pendulum.**—Put the plates together with the escapement; now paint the ruby-pin with whiting and oil (this should be thin, and ground fine); while it is wet, put in balance so that roller-pin does not touch the fork; now place the lever against the banking, with its fork in right position to receive the roller-pin; now swing the balance on the other side, and back again; now remove balance and escapement. If you look at the fork you will be able to see if the roller-pin touches the bottom. Is the guard-pin (*i.e.*, the little pin in the lever) free of the roller? You can try this the same way. Not as a rule; if you cannot stop the balance without touching it, there is not much the matter with it; some light balances, when the watch is fresh cleaned, cannot be stopped.—A Fellow Workman.

[46631.] — **Somerset House Analysts.**—A certain number of gentlemen, members of the Inland Revenue Department, are selected yearly to receive a chemical training in the laboratory. The most promising are retained as temporary assistant analysts, and as vacancies occur in the staff they are filled up from the assistants. Salaries of the analysts vary from £200 to £600.—Somerset House.

[46631.] — **Somerset House Analysts.** — "South Kensington" will find it is not an easy matter to obtain one of these situations. The way they are obtained is as follows:—Appointments are only given to persons in the outdoor branch of the Inland Revenue. A candidate must, therefore, present himself at one of the examinations held half-yearly by the Civil Service Commissioners for the post of second-class assistants of Excise. If successful, he must serve as an assistant for at least twelve months, to obtain practical knowledge of the laws, &c., of excise. At the end of that time, on petitioning the Board of Inland Revenue, and receiving permission, he may be examined for the position of student in the Somerset House Laboratory. This examination is held yearly, in August, and is open to all first and second-class assistants, provided they have received permission, as above stated, and appointments are given to the first six or eight on the list, according to the number required. The examination includes chemistry, physics, and mathematics, and the competition is pretty severe, a much larger number of candidates presenting themselves than are required. The successful candidates have a year's instruction in theoretical and practical chemistry, after which they become assistants in the laboratory. At the end of about three years they return to the outdoor service, ready at any time to perform chemical work, and by their scientific knowledge, act as a deterrent to fraud in a service in which chemical analysis is often the only effective check. The staff appointments of analysts are made as vacancies occur from amongst those who have passed through the above course. These appointments are very rare, the last occurring, I believe, about seven years ago. The salaries given range from £130 to £500 per annum.—Somerset House Laboratory Assistant.

[46634.]—**Fixing Electric Wires.**—(1) Wires for electric bells or telegraphs do not need to be tightly strained, except when carried on posts and insulators. This is rarely needed for domestic purposes. (2) I prefer that all joints be made by twisting the wires one over the other, so that a joint, say, 2in. or 3in. long is made, and then sweat them together with solder. Always, if possible, solder the joints, and this is easy done with a spirit-lamp flame, such as gasfitters use. (2) The length of wire must depend on the size.—Sunlight.

[46634.] — **Fixing Electric Wires.** — 1. Straighten the wires by drawing them tightly through the fingers, and fasten them to the walls with double-pointed American steel tacks, driven about 5ft. apart, the slight tension which can be given with one hand whilst the tacks are driven with the other will be quite sufficient to keep them taut. 2. Twist the bared ends together, solder them, and afterwards cover with guttapercha, using a small spirit-lamp for these purposes. 3. Entirely depends upon the quality of bell, cells, and wire. Two improved Leclanché cells will ring a good bell efficiently through at least 500 yards of good wire.—R. T. Lewis.

[46637.]—**Mount-Cutting.**—I have witnessed "one in the trade" and to the manner born performing this operation, and he didn't spoil the point of his knife on glass, but used a cutting-board of beech wood; also cast-iron patterns got up smooth to any desired shape and bevel. I may observe that, requiring at one time an unusual size of oval mount bevelled, I made a wooden (oak) template, which fully answered the purpose.—J. J. A., Liverpool.

[46640.] — **Electric Dancing or Working Figure.**—Construct figure of cardboard, paint with water-colours, and gum it to give it stiffness. Joints to be made with very fine catgut. Rig overhead a lever contact-maker and breaker. Hang the figure by a horsehair, and it will dance deliriously. Let its feet rest upon a tambourine, and all you have to do is to whistle. — J. J. A., Liverpool.

[46642.]—**Drilling Fluid.**—It will be difficult, I opine, to beat soap and water for cheapness; but I would suggest the trial of urine as regards efficiency and economy. It will be all the better is the user "nose" nothing about it, though. For anything hard I would suggest the use of paraffin-oil.—J. J. A., Liverpool.

[46643.] — **Division-Plate.** — To "Kismet." To do what you say you want will require 180 rows of holes, beginning at 181 up to 360. The average number of holes in a row will be about 270, and the total number of holes will be 48,690. Suppose you put twenty rows on one plate, you will require nine separate plates. Anyone who gives a little consideration to the subject, soon perceives the immense advantage obtained by using a train of wheels for counting; there is no making mistakes, no straining your eyes to count the holes, and no fumbling with the division-peg. To show the enormous advantage the wheels possess, I have drawn up a little table to show what can be done with four wheels only—viz., those of the following numbers of teeth, 60, 40, 48, and 120:—

Number of Teeth.	Wheel on Tangent screw.	Wheels on Stud.	Driving-wheel.
32	48	60 40	120
40	40		120
48	48		120
50	60	48 40	120
60	60		120
72	60	40 48	120
200	120	60 40	48
240	120		60
288	120	40 48	60
300	120		48
360	120		40
450	120	40 60	48

One Turn of Winch-handle in every Case.

The worm-wheel into which the tangent-screw works has, in this case, 120 teeth; wheels of half the above number of teeth only require two turns of the handle, instead of one turn, giving thus 16, 20, 24, 25, 30, 36, 100, 120, 144, 150, 180, 225, and three turns of the handle give in addition, 80, 96, 100, and so on; and for double the above numbers half a turn instead of a whole one. I am now engaged in reconstructing an old-fashioned wheel-cutting machine, of which I will send the drawings some day, and I have entirely rejected the dividing plate on account of its great inconvenience as compared with a worm-wheel and tangent-screw, and a small set of change wheels. I have all the numbers up to 150, and the set of wheels to produce them are only about 46 in number, including several duplicates, and several that might be dispensed with. Another fault of a division-plate is, that supposing you have a circle of 360 holes, and you want to drill or cut 240, you cannot do it. Then, if you obtain a row of 240, the only additional gain thereby is the power of drilling 80, as you already have 40 and 20 in your 360 row; whereas with wheels you can obtain any aliquot part or any multiple whatever of any one that you already have.—J. K. P.

[46645.] — **Astronomical.** — J. Atkinson is making needless difficulty for himself. The value of 1″ of an arc, in *time*, is the same, no matter what latitude he is in. If he wishes to know what the value of 1″ of arc in *space*, say, feet or yards, he will find a table giving this in Simms's book on mathematical instruments; or I could send him a copy, should this be what he requires. The quantity decreases towards the Pole, where it becomes *nil*. It is easily calculated by multiplying the equatorial value by the cosine of the latitude.—David Simms, Limavady, Co. Derry.

[46649.]—**Mounting Micro. Lenses.**—Premising that I am only an amateur, I may say that if "Micro." will make known his address, I will give him instructions. I fear they would be too voluminous for the "E. M."—Paugul.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Since our last, A. W. Soward has replied to 45995.

QUERIES.

[46651.]—**Problem in Mensuration.**—In Nesbit, p. 120, is the following:—"A gentleman a garden had, five score feet long, and four score broad; a walk of equal width half round he made, that took up half the ground: Ye skilful in geometry, tell us how wide the walk must be?"—Ans. 25·96876ft. The walk must run parallel with two adjacent sides. If taken from the middle of one long side round by the short side to the middle of the opposite side, the walk would occupy the whole of the lower half of the garden. Will some mathematical correspondent favour me with a solution in an arithmetical form, or without using quadratics?

$$(100 + 80)\,W - W^2 = \frac{100 \times 80}{2} = 4{,}000.$$

$$W^2 - 180\,W = -4{,}000.$$

$$W - 90 = \sqrt{(4{,}000 + 8{,}100)} = \sqrt{4{,}100}.$$

$$\text{Whence } W = \pm\sqrt{4{,}100} + 90 = 25, \text{ \&c.}$$

But this is not the form of solution which I want.—John N. Dufty.

[46652.]—**To "Clerkenwell Clockmaker."**—I fancy you promised us particulars of a hall chiming clock once or twice in August last and before. Could you kindly say when you think you will give it?—W. N. B.

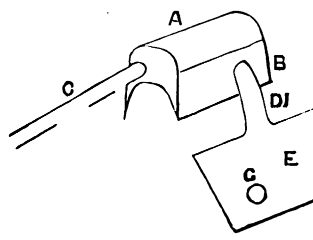
[46653.]—**Finishing Flax, Twine, and Cord.**—I will thank some of our readers to give a recipe for making up a good gloss or dressing with which to finish flax, twine, and cord?—Esquirer.

[46654.]—**Storage Battery.**—Will someone tell me how to make a small model storage battery? Could it be charged with a Bunsen?—Dix-Huit.

[46655.]—**Astatic Galvanometer.**—I wish to make an astatic galvanometer. In the directions given in science and art textbooks, I am told to make the needles as far as possible astatic, and that an astatic system consists of needles of equal power. Now, in Ganot's "Physics" (an old edition) I find that it is an advantage if the needles are not of equal power. Is this latter correct, and why? Any other information on this subject will oblige—Dix-Huit.

[46656.]—**Pitch of Propeller.**—I should be glad if any reader could inform me of an accurate and ready method of ascertaining the pitch of a screw propeller, or what forward moving distance one revolution would make?—Propeller.

[46657.]—**Turkish Bath.**—A B is a semi-cylindrical vessel (like a little boiler) placed over a furnace. Its object is to supply hot air to hot-room, E. And C is a pipe leading from garden intended to supply this vessel with fresh cold air. D. is a pipe to carry the air as it becomes heated into heated chamber, E. But, strange to say, the direction of the current of air is out through the pipe into the garden, thereby lowering the temperature to 80°, and spoiling the bath. How shall I remedy this?—J. H. M.



[46658.]—**Date Mark.**—Will someone kindly say how the age of silver plate can be determined further back than 1796, from that time to the present? I know the date marks. Any information on the subject will oblige—Alpha.

[46659.]—**Spongy Platinum.** — How can I obtain spongy platinum? I have failed in my attempt, though I followed minutely the process as given in Francis's "Chemical Manipulations." No difficulty in either making the solution of chloride, or in precipitating with chloride of ammonium; but upon washing the precipitate, as directed, it was entirely redissolved, leaving a clear deep yellow solution. How can I treat this so as to again obtain a precipitate? Upwards of two dwts. of the metal was dissolved, so that I am unwilling to lose it.—G. F.

[46660.]—**Sutton's Secondary Battery.**—I have just constructed a cell as follows:—A sheet of "lead," (about 120 sq. in.), a sheet of copper (about 100 sq. in.), each drilled with several holes, and bent into a spiral with indiarubber between top and bottom of the plates to prevent contact; the whole inserted into a stone jar containing about three pints water, in which was dissolved 1lb. sulphate of copper. It took about nine hours to charge with two quart Bunsens—the liquid in that time being almost colourless. Upon disconnecting the battery and connecting the lead and copper plates, I could get but a very feeble current. It has now been connected for over three days, and the solution is still nearly colourless, showing that no return action has been going on. If some reader can tell me the cause of failure, I shall be much obliged. The lead was amalgamated with mercury.—W. Stutchbury.

[46661.]—**Watch Balance-springs.**—Will some practical person give information as to what is the cost of a watch balance-spring of the best quality? If any better than the "tempered" ones (6d. each) are generally used?—the common ones costing 2d. and 3d. each. Also, if the balance-springs of M. Lutz, of Geneva (secret make), of whose extraordinary merit mention is make in Encyc. Brit. (art. Clock), have been adopted into use.—Hour-Glass.

[46662.]—**Electric Tell-tale Clock.**—I shall be glad to receive a few hints respecting the construction of the above. Diagrams will be esteemed by—Amateur Clockmaker.

[46663.] —**A Street Nuisance.** — Will Mr. Wetherfield advise?—I work six days per week, from 5 a.m. to 8 p.m. Unfortunately, a lamp-post is fixed opposite my street-door. On arriving home, my much-needed rest is denied me by a band of 15 to 18 preachers who are connected with the "Salvation Army" (and by singing hymns to the tunes of ribald songs, collect the blackguards from a radius of a mile), whose "performances" are conducted round the lamp-post until ten o'clock at night, and all day on Sunday. The police refuse to interfere, and the preachers to move on, although requested by the residents to cease their persecution, there being a number of sick people in the neighbourhood—16 miles from London. How can I stop the annoyance?—Ajax.

[46664.]—**Resistance of Electric Lamps.**—I have seen it stated that the resistance of a Swan lamp being 50 ohms, the resistance of four ranged in series will be 200 ohms; but if the four are arranged in multiple arc, the resistance is only 12·5—presumably for each lamp. If that is so, what is the resistance of a lamp when there are 50 in multiple circle?—Nun. Dor.

[46665.]—**Discolouration of Paint.**—Will some courteous correspondent of "ours" kindly explain the cause, and, if possible, suggest a remedy for the following?—In my business I use a great quantity of white paint, the bases being either white lead or zinc white. After painting and rubbing smooth, this white is varnished. Now if the article so painted is exposed to the light, as, for instance, in a shop-window, it changes to a dirty grey colour, and as long as it is so exposed, the tint continues to grow darker. If the article is then taken into a dark room, or is covered up, it gradually returns to its pristine whiteness. A plate of iron coated as above, and one-half covered over, and the other half exposed to the light would, in two or three days, be half grey and half white. I have tried varnishes of all kinds, and consulted every varnish-maker I know, and it still remains a mystery to us all. I have also tested the whites for adulterations, and have found both pure and impure are affected alike.—Achromatic.

[46666.]—**Organ.**—Can anyone inform me whether (when using the suction principle in a two-manual organ harmonium) the same effect is obtained by varying the air supply as by using a venetian swell-box and the pressure principle?—E. F. G. G.

[46667.]—**Medical.**—Will Dr. Edmunds kindly advise in my case?—Age 47, weight 10st. 4lb., and inclined to lose weight; have symptoms, I think, of "Bright's disease"; water very frothy, and remaining so for a long time; great feeling of lassitude and aching of limbs after any unusual exertion, and sometimes without; water clear when plenty of soda-water is taken—otherwise generally turbid. I have always lived freely, and smoked considerably. I also frequently suffer from heartburn after meals. This I have found relieved to some extent by hop-bitters.—B. D.

[46668.]—**Household Dyes.**—Having a few articles which I wish to dye a fawn colour, and not finding that shade in the household dyes, I should feel obliged if any of your correspondents could tell me what colours to mix to produce a fawn colour? Also, a few hints as to colours to mix to produce various shades.—J. C. B.

[46669.]—**Patterns for Engine.**—Will someone tell me how to set out the proportionate sizes in making working drawings for engines? I want to get out drawings before making the patterns. In one case the cylinder is 1⅜in. bore, with a stroke of 3½in.; in the other, 4in. bore by 8in. stroke, horizontal. Will "Sunlight," or some other reader, give the proportions of other parts, and state the nominal horse-power.—T. Hendry G. Brown.

[46670.]—**How to Gelatine Paper, Show-cards, &c.**—Could any reader kindly give any information about gelatining or the preparation which is applied to the glass to cause the gelatine surface to leave the glass easy? I have tried to gelatine some showcards, but I cannot get them off the glass properly.—H. Williams.

[46671.]—**Brown Marks on Skin.**—Like many others I should feel grateful to Dr. Edmunds if he would kindly give me his advice. I have had a yellowish-brown mark which covers nearly half my forehead. Also two or three smaller ones (varying from the size of a threepenny bit to that of a sixpence) on other parts of my face. They came suddenly about two years since, when suffering from weakness, a bad bilious attack, and cold. From those I have long recovered, and am now enjoying average good health. But the marks remain, and as they quite disfigure me, I should feel most thankful if Dr. Edmunds would advise me how to get rid of them. I am most careful as to diet, &c., and have taken several bottles of Camomile pills to see if they would have any effect; but if they have it is so slow as hardly to be noticeable. I am 26 years of age.—Sister of a Long Subscriber to the English Mechanic.

[46672.]—**Binding Screws.**—As these are an expensive item in electrical apparatus, can anyone suggest a ready substitute or mention a cheap form of them, and at what price they can be procured?—Crux.

[46673.]—**Varicose Veins.**— Will Dr. Edmunds kindly say, could a person afflicted with above reside in a hot country—such as Australia or India—without injury to health?—V. V.

[46674.]—**Telephone.**—I have noticed that one or two writers question the advantage of using the secondary current for the telephone. Will someone kindly point out where and how the advantage does come in, the only obvious disadvantage being the cost of induction coil, which is, however, a large item?—Crux.

[46675.]—**G N. Engine, 48.**—Could any reader of the English Mechanic inform me the cylinder size and stroke of the G.N. engine, No. 48? Also, dia. of driving-wheel and any other dimensions connected therewith? I believe she took the first prize at Darlington in 1876; but of this I am not sure. Who were the builders?—Amateur.

[46676.]—**Focus of Lanterns.**—Can any of "ours" tell me the best way to produce the largest picture with a 4in. focus lantern, 4in. condensers, using the safety limelight jet? Any directions would be acceptable to an—Amateur Exhibitor.

[46677.]—**Musical Box.**—I have lately purchased a second-hand musical-box, playing six tunes, and although the tunes are perfectly played, still there is (to me) a disagreeable screeching like the whistling of a bird all through the tune, something like the peculiar noise a fork would make when pushed in an upright position across a plate. Could any of "ours" tell me a remedy, or is it intended to be so to imitate a bird?—J. Acsird.

[46678.]—**High Temperature Fluid.**—Would any correspondent be good enough to name any oil, or other fluid which will not boil nor rapidly deteriorate at about 600° Fahr., nor corrode cast iron? Required for some peculiar hydraulic work.—S.

[46679.]—**To Mr. Lancaster.**—Thank you for noticing my query (46297), but I am afraid there is a misprint somewhere, and I have not made my meaning plain. I want to know what should be the thickness and resistance of the wire on the magnets to produce the maximum effect on the armatures which are already wound with 18, and have a resistance of about ·625 ohms. I am sorry to trouble you again.—Clôture.

[46680.]—**Horizontal Escapement.** — Would "Fellow-Workman" kindly tell me how to put a horizontal escapement in beat? It is very much out.—A. H. K.

[46681.]—**Windmill Pump.**—I shall be grateful to brother-readers for advice, with diagrams, if possible. I want to lift 100 gallons of water per hour by a 2in. force pump to a height of 30ft. from surface of water in well by means of a windmill, which shall automatically present its face to the wind.—O.

[46682.]—**Hydrometers.**—I have been at a loss for some time to know the difference between Baumé and Twaddell's hydrometers. Perhaps some of your intelligent correspondents will kindly give me a comparison of the two, so that I can work with Twaddell from Baumé.—Carrick.

[46683.]—**Magneto-Electric Machine.**—To Mr. Lancaster.—I have made a magneto-electric machine, but can get no current from it—a 5in. permanent horseshoe magnet, bobbins 1¾in. long, with ⅜in. turned iron cores and copper bobbins wound with two layers of 26 cotton-covered wire; the cores are joined at the end furthest from the magnet with a piece of iron, and the other end with a piece of brass One wire goes to spindle which has two flats filed on it, against which a spring makes and breaks contact. The other wire goes to washer insulated from the spindle, against which another spring rubs. I cannot get the least current from it. Thinking that there was not enough wire on it, I connected it on to an electric bell with the same result. Do you think the magnet is strong enough? A machine I saw the other day had cast-iron cores and bobbins with a double magnet, which was only bright on one pole. The spring at make-and-break of contact had two small holes in it—what were they for? Also, can I make a magnet of some pieces of square steel clamped together and joined by a piece of iron at the top, as the magnets in the machine I saw were bright only on one pole. Would not a straight magnet do as well? I revolved my machine at a very high rate by connecting it on to the lathe.—A. W. C.

[46684.]—**Photo. Background.**—I want to paint a plain background for outdoor photography—one that will take dark. The one that I have is a dark grey, and when the light falls on it it takes white at the bottom end. Could anyone give me a good colour and say how I am to prevent it from shining?—Dark Background.

[46685.]—**Piston.**—To "L. O. V."—A few weeks back you answered a query about taking out piston to clean it. I went by your instructions—put in the eyebolts in piston-end, then tried to pull off piston-cover, but found it would not come; then I put a long bar of iron through eye-bolt across end of cylinder, then turned round engine; but the eye-bolt broke at screw, leaving screw in piston. How should I proceed to get piston-cover off? There is very little room at back end of cylinder, as the condenser stands close to it.—Stoker.

[46686.]—**Organ Reeds.**—I have an organ of two manuals. In the Swell were two reeds—Cornopean and Oboe. In the Great there were no reeds, but an objectionable mixture of two ranks. I took out the Oboe from the Swell and put it into the Great in place of mixture. Pressure of wind little more than 2½in. The Oboe went only to Tenor C in the swell, but I put it all an Octave lower, so as to make it a 4ft. reed. The holes for the wind were too small for the boots, so I first enlarged them, and then found that the holes in the slider and wind-chest were also too small, and not wishing to take off the soundboard, I burnt the holes larger with iron wire. I doubt if there is wind enough now, as the reeds are (*a*) very slow in speech. Further, they are continually getting out of order. When in the Swell they seldom required anything but tuning. Now, sometimes, I find two or three (*b*) altogether dumb. In attempting to put them right I find a great number of difficulties. Some (*c*) will sound a note which gradually gets less in volume until it arrives at the right pitch and then goes off altogether. I try them with my mouth and they seem all right. Directly they are put into the organ they are dumb. Some (*d*) grunt—intolerably coarse. Some (*e*) vibrate well until near pitch, and then become hard and horny, having little of the tone of a reed. Will some of the "cognoscenti" kindly tell me the causes of these various defects? And a few hints on the mysterious subject of reed-voicing will, I am sure, interest many besides one who is nearly at his—Wits' End.

[46687.]—**Lifting Water by Motion of Ship.**—I want to put pipe through bottom of ship to lift water by the motion of the ship passing through the water. Would any reader kindly give me the height at different speeds (from 1 to 20 miles) that the water will rise?—R. W.

[46688.]—**Intensity and Quantity.**—In Jenkin's "Electricity and Magnetism," p. 88, there is the following par.: "Cells joined in series are sometimes described as joined for intensity, and cells joined in multiple arc as joined for quantity. These terms are remnants of an erroneous theory." In my electrical days we used to join all the similar plates of a battery in the expectation of getting quantity, and couple the plates alternately if we desired intensity. Is there really no difference between intensity and quantity now? Or is the above not the way to develop either? And if not, how do you do it?—B. H.

[46689.]—**Focal Length of Photo. Lenses.**—In the last paper on dry plate photography (p. 124), should it not be $\frac{f}{16}$ instead of $\frac{f}{14}$, as there given? $\frac{1}{16}$ is afterwards squared in reference to same lens, and ¾ is certainly 1-16 of 12. Will anyone please explain to me if, in calculating rapidity of a lens used with different stops, you have to take into consideration the varying focal length when nearer and more distant objects are focussed? Take for instance a lens of 12in. focus. Now in using this lens, the focal length will be slightly more or less at times—according as near or distant objects are focussed. Is the exact focal length at the time of using the lens to taken as 12in. always, or to measure the length on each special occasion, and then get at rapidity? Thus, with the lens I use, the focal length varies more than 1in., according to what is being focussed. I hope you will be able to understand what I mean. When a lens is spoken of as being 12in. focus, at what distance is the object supposed to be to make 12in. the exact distance between diaphragm and ground glass?—F. C.

[46690.]—**Waterproof Cloth.**—If any of the readers of the "E. M." could tell me of a cheap light material suitable for making a cover for my tricycle, I should feel obliged. Could I render canvas waterproof by oiling it or otherwise?—M. L. R. S.

[46691.]—**Retouching Photos.**—Will someone please give instructions for retouching negatives? What pencils to use, &c., and how to set about it? How can the tiny holes and thin cracks which make their appearance at times in gelatine negs. be avoided or repaired (they, of course, give dark tiny spots and thin lines on the prints, which are very objectionable)? In retouching, is it only the face that is usually done, or are flaws and holes, &c., made good by the retoucher? Are landscapes retouched? Any information will be thankfully received by—F. C.

[46692.]—**Scotch Bagpipes.**—Can some kind reader give me any information respecting the above? Should like to introduce them in a second part of a minstrel entertainment—but am rather in the dark regarding them. Are they difficult to learn? Could I get a book to instruct me, and music suitable for a solo?—Cosmo.

[46693.]—**Staves.**—Would someone versed in the timber trade state how Baltic staves are reduced to Petersburg standards? The writer can work out deals, &c., correctly. Any references to former replies touching timber calculations would be also valued.—H.

[46694.]—**Brick-Kiln with Down Draught.**—I shall be glad if any of your readers can give me, through your paper, a sketch of one such as are used at Stourbridge and in Staffordshire—either round or square, and to hold about 30,000 bricks.—Brick-Kiln.

[46695.]—**Spark Condenser.**—To Mr. Lancaster.—Thanks for former reply about induction coil. Will you kindly say construction of Browning's spark condenser to be used instead of Leyden jar? Also, what length of spark-coil would be required with a condenser of this kind to give spectra of the metals?—Volvox.

[46696.]—**Bichromate Battery and Intensity Coil.**—A month ago I constructed a bichromate battery, (containing 12 pint cells) to obtain a light from a toy-lamp, but found that it did not answer very well. I then resolved to try C. C. Cory's electric lamp (a description of which I saw in No. 723 of the "E. M."). Having got everything ready, I found that the solution had nearly lost all its power, having been used only twice. Can any kind reader inform me whether it would be best to strengthen the solution, or throw it away and make a new one? Also, how I could construct an intensity coil equal to 60 such cells?—Jack in a Fix.

Nearly 3,000 tons of charcoal iron are still made annually in the United Kingdom. There are, according to the report of the British Iron Trade Association, six charcoal furnaces in existence, all of them belonging to one firm.

ANSWERS TO CORRESPONDENTS.

◆◆◆

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, April 19, and unacknowledged elsewhere:—

R. A. Lee.—Foxdale Institute.—R. Mills.—Rev. N. S. Godfrey.—A. Ledger.—F. Bartleet.—S. E. Peal.—Sir P. Radclyffe.—G. H. Cawthorn.—H. Maxted.—Jumbo.—E. R. M.—Grapho.—A. M. G.—G. W. Dunn—Philolectron.—H. B.—Anxious.—Minim.—A Captain's Wife.—Arc.—A. B D.—Semper Fidelis.—Foundry.—Amateur.—Orderic Vital.—Switch.—Gauge.—E. Gobert.—W. H. B.—Electric Light.—A. W. Soward.—E. Williams.—F. W. G.—Mottershead and Co.—Steel.—Prismatique.—A. Manock.—Practical Amateur.—Vega.—Working Blacksmith.—Mathew.—B. M.—C. S.—What Can't be Cured Must be Endured.—Tormented One.—H. R.—Wm. Johnstone.—Blackwater.—Circular Saw.

Expulsion. (The cause is having eaten the scolex of the worm in the shape of measly pork or infected beef; the best remedy is male fern, which any druggist will make up for you; but you will find other suggested remedies in back volumes.)—B. H. (Yes, a new edition is being prepared, but when it is coming out we do not know.)—D. Williams. (We cannot give the date, as the translator is away, but it is in the *Comptes Rendus* of the meeting of Feb. 20.)—Young Hand. (See p. 480, No. 800, and a series of papers on Soldering in Vol. XXXIII., pp. 170, 264, 334, 455. 2. With a needle drill.)—Reflector. (One of the silver powders sold by the makers of Bessemer's paint may answer your purpose; but looking-glass is made by coating with an amalgam of mercury and tinfoil, or by depositing silver. See indices for processes. For prices, you must ask at the dealer's.)—Silurian. (The process is described in the cyclopædias, but is rarely used nowadays. See p. 231, Vol. XIII., for the improved process, or p. 606, Vol. XXIX.)—Sanitary Inspector. (We do not know the address of the Institute; but their examinations, &c., are periodically reported in the *Building News*.)—Jacques. (Try the "Vulcan" cement, mentioned on p. 115.)—Georgiana. (What do you mean by a "provisional" will? If the wife was appointed sole executrix, and all the property devised and bequeathed to her absolutely, she can, of course, dispose of it as she pleases.)—J. A. Smith. (You had better advertise for it in the "Sale" column. Our pages would be altogether inadequate for a full-size working model, even if we could spare the space.)—Surgeon. (The odour is usually sufficient; but a method of ascertaining whether sewer-air can find its way into the house is to pour some essence of pennyroyal down the drain. Care should, of course, be taken that the odour of the pennyroyal reaches the house only through the suspected inlets.)—J. S. (No one can tell you without examining the apparatus.. You should take it to an optician.)—Charles Newton. (Unfortunately, the transference takes the form of a notch, which goes on deepening until the connection is broken. Edison has endeavoured to overcome it by making the bridge as a whole revolve very rapidly. Merely changing the direction after a given interval would simply prolong the life, as the carbon would not be deposited in the notch.)—An Amateur in Electricity. (You will need 30 quart cells of Bunsen form. They consist of an outer jar or porous pot, a piece of zinc bent to surround the porous pot, and a rod of gas carbon in the latter. Nitric acid is placed in a porous pot, and dilute sulphuric acid in the jar; but for practical instructions in the making of batteries, see pp. 321, 373, 395, 419, 468, 539, 630, Vol. XXVIII., and pp. 65, 137, 312, 362, Vol. XXIX. See also the indices of more recent volumes.)—Grateful. (No, it must have been erased before the silvering was done, or it would still appear—that is, if the coat was put on by electro-deposition.)—Steam Rubber Tube. (The size is rather small, but we should advise you to try another maker. Look through our advertisement columns.)—Dealer. (It is a police regulation, full particulars of which can be had from the superintendent in your district. We know of no other license, except in the case of the precious metals.)—J. M. B. (No advice worth anything can be given in such a case without examination of the eyes. If you reside in London, and cannot afford to pay fee, take him to University College Hospital, or one of the special hospitals.)—A Cornchandler but Old Subscriber. (If you have your old volumes you will find your questions answered many times. For instance, p. 229, Vol. XXX.; pp. 273, 296, Vol. XXIX.; pp. 342, 388, Vol. XXVI., &c.)—Oil. (See p. 511, No. 775, and elsewhere. Full particulars would require too much space, but the principles are to be acquired, and the rest is easy.)—Wensley. (Do you mean the cases of the pens? It is vulcanite or ebonite, made by mixing sulphur and rubber, and subjecting to heat and pressure.)

The English Mechanic

AND

WORLD OF SCIENCE AND ART.

FRIDAY, APRIL 28, 1882.

PHOTOGRAPHY OF OBJECTS IN MOTION.

THE art of photographic representation of the successive phases of a phenomenon which occurs with considerable rapidity, has of late been remarkably advanced by the labours, more especially, of Mr. Muybridge, and MM. Janssen and Marey. We propose here to indicate some recent achievements by the French physicists in this interesting art.

It is known that the principle of M. Janssen's "photographic revolver," employed during the Transit of Venus in 1874, consists in rotatory movement of a sensitised plate, on which images of different phases of the variable phenomenon are successively produced. In that instrument, the sensitive plate is stopped mechanically each time that an image has to be taken, and it only moves to allow of a neighbouring unimpressed part receiving a fresh image. Notwithstanding those stoppages, a certain number of photographs can be obtained in a second, and the method has been successfully applied by M. Marey to the flight of birds (in a way already alluded to in our "Scientific News," and to be described more in detail presently); but it will be readily understood that this condition imposes a limit soon reached after exceeding about a dozen images per second. The reason is, that it is extremely difficult to stop suddenly, and for a very short time, a body animated with rapid motion.

For example, the study of the flight of insects requires that images be taken at extremely small intervals, probably much less than 1-100th of a second. Now it would be impracticable to give a plate motions and stoppages following one another with such rapidity. Thus the applications of the revolver, which would be the most interesting and fruitful of new facts, would be impossible if this condition of successive stoppages were absolutely indispensable.

M. Janssen has long been of opinion, however, that it would be possible to take photographic images on a plate in motion. If we analyse the question, we find that there is a relation, according to the delicacy of the elements of the image, between the motion that may be given to the plate, and the time of the luminous action. To give an experimental demonstration of the principle, M. Janssen chose solar images. It is known that the solar surface is one of the most difficult objects to see in telescopes, and that its reproduction by photography has only been accomplished quite recently. Now, M. Janssen proposed to obtain this granulation on a plate which had a motion of 0·15m. to 0·20m. (say 6in. to 8in.) in a second.

The result was quite satisfactory. M. Janssen has exhibited to the French Academy plates on which two similar portions of the solar surface were reproduced. One of these portions was taken on the plate while the latter was at rest, and the other while the plate was moving about 6in. in a second. A comparison shows that the motion did not at all hinder the manifestation of the granulation, that is to say, of one of the most delicate phenomena of astronomical photography.

The ascertainment of this fact doing away with the requirement of successive stoppages, it will be understood that, in some sort, nothing limits the number of images which the revolver might furnish in a given time. It is only necessary to establish a right relation between the delicacy of details of the image, the velocity of the sensitive plate, and the time of luminous action.

In the new arrangement, the support of the sensitive plate, and the slitted screen, have each a continuous rotatory movement, and it is the magnitude of these movements and their relation that determine the rapidity in the succession of images and the conditions of their formation. By some simple calculations, M. Janssen has convinced himself that it will be easy to obtain images of a phenomenon, following one another at intervals of 1-100th of a second, and even to go beyond that.

The results of M. Janssen's further studies will doubtless be looked for with much interest. Let us now turn to the photographic rifle (based on the principle of the old photographic revolver), which M. Marey has now described, together with some of his experiments with it on birds' flight, to the French Academy. He constructed an apparatus of the size of a fowling-piece, which photographs the object at which it is pointed twelve times in a second. Each image requires an exposure of only 1-720th of a second. The following is the author's account:—The barrel of this rifle is a tube which contains a photographic object-glass. Behind, and solidly mounted on the butt end, is a large cylindrical breech, in which is a piece of clockwork. When one presses the trigger of the rifle the clockwork is set in motion and imparts to the different pieces of the instrument the necessary motion. A central axis, which makes twelve revolutions in a second, commands all the pieces of the apparatus. There is first an opaque disc, pierced with a small aperture. This disc forms a screen, and only admits the light from the object-glass twelve times a second, and each time during 1-720th of a second. Behind the first disc, and turning freely on the same axis, is another which has twelve apertures, and behind which is applied a sensitive plate, of circular or octagonal form. This perforated disc has to turn in an intermittent manner, so as to stop twelve times per second opposite the beam of light that penetrates the instrument. An eccentric placed on the axis produces this jerky motion, giving a regular to-and-fro motion to a ratchet-rod which, at each oscillation, catches in one of the teeth forming a crown on the perforated disc.

A special screen stops finally the penetration of the light immediately the twelve images have been obtained. There are other arrangements to prevent the sensitive plate exceeding, by its acquired velocity, the place where the ratchet brings it up, and where it should be perfectly motionless during the time of luminous impression. The adjustment to focus is done by lengthening or shortening the barrel, with the effect of displacing the objective forward or backward. The right position is verified by observing through an aperture in the breech the distinctness of the image received on ground glass. A conjuror's box (*boite à escamoter*) of circular form served as holder for twenty-five sensitive plates, and for passing them into the rifle without exposure to light. Before applying the apparatus to birds' flight, M. Marey tried it on a rotated arrow and on a pendulum. A chronographic apparatus was adapted to the rifle. M. Marey photographed a gull in flight. As the bird gave exactly three strokes of the wing in a second, the twelve figures show four successive attitudes reproduced periodically. By enlarging the figures, images are got which are visible at a distance. They were somewhat indistinct, owing, as the author says, to his small experience in photography. Reproduction of the images by heliogravure gives dark silhouettes (see *Comptes Rendus*, April 10th). With exact focussing, details of form (imbrication of the feathers, &c.) could be made out in the microscope. If the protographs be arranged in a phenakistiscope, the appearance of movements of flight is, indeed, reproduced; but the images corresponding to each revolution of the wing are still too few to allow of analysis. Their number must be augmented. This can be done by doubling the velocity of the plate and the screens. M. Marey did so with the same rifle, and still had enough light for production of the images. The time of illumination of the plate was only 1-1400th of a second, yet the objective used was not a very rapid one. By photographing a bird under various conditions—*e.g.*, when withdrawing from the observer or approaching, when seen from above, and when seen from below, &c.—various information may be acquired as to the mechanism of flight. M. Marey found his principal results with the graphic method confirmed by the fresh data, and he anticipates a considerable further elucidation of the subject of flight by the new method. He gives a brief account of observations on a bat's flight, which is difficult to photograph. The photographic rifle, of course, lends itself to observation of the movements of other animals as well as birds.

REVIEWS.

Railways and Locomotives. By JOHN WOLFE BARRY, M.Inst.C.E., and F. J. BRAMWELL, F.R.S., M.Inst.C.E. London: Longmans.

THIS volume contains the lectures delivered by the authors at the School of Military Engineering, Chatham, in 1877, and is published in its present form because it was thought to be a useful book for the general reader as well as for those who wish to study the constructive details of railways. It contains six lectures by Mr. Barry, three of which are mainly extracts from his well-known textbook on "Railway Appliances," and three by Mr. Bramwell, the latter dealing with the locomotive exclusively. The volume is freely illustrated with engravings, most of them taken from actual constructions, where such a course was possible. Although specially intended for military engineers, the lectures form in reality an excellent treatise on railways, and a useful textbook for students going up for technological examinations. The whole minutiæ of signalling, with the details of interlocking arrangements, are set forth in tolerably full description, while the construction of rolling stock is explained by the aid of diagrams and tables of dimensions. In the lecture on rolling stock, &c., Mr. Barry says that the best theoretical arrangement of buffers, &c., would be to concentrate the buffing arrangements at the head and end of the train, and to couple-up the intermediate carriages tightly—the buffing carriage to be of sufficient length to take up the momentum of the blow before any serious damage is done to the rest of the carriages. On the question of supplying signalmen with speaking instruments at all boxes, Mr. Barry takes up the chief objections, and points out that the advantages enormously outweigh the alleged disadvantages, the chief of which can, however, be easily removed. The idea that speaking instruments would encourage a lax working of the block system is somewhat like the notorious objection to the general use of a continuous brake on a certain railway, for at least others besides the two signalmen would be aware of the breach of rules, and where the latter are really enforced, railway employés do not exhibit an absorbing desire to break them. It is rules that are not enforced that they disregard—too often to their own destruction. As to the objection that if speaking instruments were provided they would be used for idle conversation, it could easily be arranged that the instruments should record the number of times they were used, or even the messages sent; but in the absence of such devices the signalmen could not be certain that an inspector was not in the other box. At any rate, the advantages are so great, as some companies have lately learned to their cost, that it is probable before long all boxes will be furnished with speaking instruments of some kind. What is generally held to be the most perfect system of electric interlocking of signals and points, is briefly referred to in a note, whereas an appendix or a separate chapter might well have been devoted to an explanation. Sir Frederick Bramwell's portion of the volume is devoted to the engine, of which it is a popular explanation, though scarcely entering so minutely into details as might be wished. The movements of the slide-valve and the use of the indicator are explained at some length, and the diagrams help to make the matter very clear, and bring it within the comprehension of the average intelligent reader. Hence, this book might find an appropriate place on the bookshelves of all public libraries, and those of mechanics' institutes. One of the most interesting portions of these lectures is that in which Sir Frederick Bramwell describes the methods of reversing the engine prior to the introduction of the link.

Modern Metrology. By Lowis D'A. Jackson. London: Crosby Lockwood and Co.

This manual of the metrical units and systems of the present century shows very clearly the necessity that exists for some reform in the systems of weights and measures used in various parts of the country; and it is, therefore, natural that the author should append to his work a proposal for a systematic and uniform English scale of weights and measures. To alter the measures of a country by any arbitrary act is felt on all sides to be a difficult and harassing undertaking, for customs of the kind are often looked upon as part and parcel of the national life—that is, in the respective districts and the trades interested. A knowledge of the way in which produce or articles of manufacture are bought and sold often constitutes the sole secret of trade, and it is not surprising that a conservative feeling should predominate amongst those immediately concerned. Nevertheless, a strong feeling has always existed, and is steadily gaining strength, that weights and measures should be put on a uniform basis throughout the kingdom, and that the diversity in custom, which we now find even in adjoining counties and neighbouring market-towns, should cease to perplex the uninitiated. In the work before us, Mr. Jackson has laboriously compiled tables of the various weights and measures used at the present day by civilised nations, or at least by those of commercial importance, and opposite to the figures he gives the proposed English scientific equivalent and the existing French weight or measure, as the case may be. The basis of the English scientific system was laid down by the Warden of the Standards in his work on the "Science of Weighing and Measuring" (Macmillans, 1877), and Mr. Jackson points out that an English scientific system, to suit all purposes, must be either strictly decimal, or mixedly decimal, centesimal, and millesimal, at the same time being in some accord with the English trade units. The proposed system would, for measures of length, divide the foot into ten tithes, a rod would be 10ft., a chain 10 rods, a cable 10 chains, and a mile 5,000ft. The square foot would be 100 square tithes, and similarly the square rod 100 square feet, the square chain 10,000 square feet, and the acre 40,000 square feet, the square mile being 25 million square feet. The cubic foot would be divided into 1,000 cubic tithes, and for wet capacity the cubic tithe would equal a fluid ounce (= 1,000 fluid mils), while 16oz. would equal a fluid pound. For measures of weight there would be a uniform "foot weight or talent," equal to 1,000oz., or 62½ pounds of 16oz. each. The ton would be 40 foot-weights, or 2,500 pounds. There is, we think, small chance of any reform of the kind, but those who are interested in the subject of metrology will find much valuable information in this work.

The Scientific Basis of National Progress. By G. Gore, LL.D., F.R.S. London: Williams and Norgate.

The author in his preface says that there exists at the present time in this country a considerable degree of uneasiness respecting our ability to maintain our position in the race of progress, and he thinks it desirable, as our future success as a nation depends largely upon science, to call attention to the great public importance of scientific knowledge, and to the means of promoting its development. Such "uneasiness," as did unquestionably exist a few years ago, has been quieted by the efforts made to give technological instruction to the industrial classes; and though we are amongst the first to acknowledge the value of original research, and that human welfare depends, to a great extent, upon scientific progress, we cannot admit that it is the business of the Government to establish a fund for the Endowment of Research—though it might appropriately enough interfere with some existing endowments to the extent of seeing that the money is not absolutely wasted. As Dr. Gore points out, progress is the result of new ideas, and the chief source of new ideas is original research, and he happily suggests that probably one of the most satisfactory ways of rewarding scientific discoverers and serving national interests at the same time, would be to create salaried professorships of original research, and appoint discoverers of repute to fill them. Further on, he says that the money paid to young men in Oxford alone now amounts to about £80,000 or £90,000 a year—funds which were originally intended for promoting knowledge, "but vested interests prevent their being used for discovering new truths." It is obviously to the national advantage to elicit new ideas in science—that is, to obtain new knowledge; but we suspect it will be a long while before the nation will consent to the endowment of State laboratories. Dr. Gore's little work will, however, be read with much interest, and the probable effect will be that the laboratories he desires will be established by private munificence—certainly not by the State, or by corporations out of municipal funds.

Vibratory Motion and Sound. By J. D. Everett, M.A., F.R.S. London: Longmans.

In this volume Prof. Everett treats the subject of vibratory motion in a manner suited to the capacities of students who have mastered the elements of dynamics. Simple harmonic motion, which is the key to the whole subject, is treated in chapter I., and the two succeeding chapters contain explanations regarding the composition of motions, with some novelties in the shape of geometric proofs of propositions usually established by trigonometry. The method of treating the subject involves a knowledge of mathematics; but, though the book is mainly intended for students, it will interest many who will read it as a popular treatise. For instance, while in one chapter we find the mathematics of Lissajous' curves, in the next, we have some mechanical illustrations of simple harmonic motion, which include the tide-predicter of Sir W. Thomson and Donkin's harmonograph. Other chapters discuss in a popular way the theory of sound-waves, while accurate investigations of the rapidity of stationary vibrations of strings and columns of air, the velocity of propagation and the energy of undulations are treated in a very readable manner. Finally, to render the treatise complete, there are a couple of chapters which treat sound from the point of view of the student of musical intervals.

We have also received *The Sphygmograph*, by R. E. Dudgeon, M.D. (Baillière, Tindall, and Cox), a description of the instrument devised by the author, with examples of its use. We illustrated Dr. Dudgeon's sphygmograph on p. 104, last volume, and his little book gives a history of the development of the instrument, and of the important part it plays in diagnosis.——*Chess Players' Annual and Club Directory*, edited by W. R. Bland (Bemrose and Sons), is the vade-mecum for the regular player, and will be found of much interest to those who only indulge in a game occasionally. The lists of clubs and chess resorts in this country and on the Continent will be useful to many, while the papers and problems will serve to amuse the reader.——*Plane Geometrical Drawing*, by F. E. Hulme (Longmans), is a volume of worked examination questions for the use of students at the military and engineering colleges, and also for those who are endeavouring to teach themselves. The preface contains instructions for using the book, and some sound advice; but the drawings which form the great bulk of the volume are drawn of such a size that they cannot be merely blindly copied for examination purposes.——*Homes and Farms in America*, by G. H. Everett, M.D. (Dickie), is a readable little guide to those desirous of emigrating to the United States. It recommends Kansas to the agriculturist.——*Half-holiday Handbooks* (T. Fisher Unwin). We have eight of these useful guides to the country around London, all of them referring to districts south of the Thames. One of the guides is entitled "geological rambles," and will be found useful by the amateur geologist. Most of the books are provided with a clear map, and a distance guide for the road from London.

ASTRONOMICAL NOTES FOR MAY, 1882.

The Sun.

Day of Month.	Souths.	At Greenwich Mean Noon.

The Method of finding the Sidereal Time at Mean Noon for any other Station will be found on p. 390 of Vol. XXXIV.

Spots, faculæ, and prominences continue to testify to the activity of Solar disturbance. On and after May 22nd, there will be no real night in England; the Sun never descending as much as 18° below the horizon, even at midnight.

There will be an

Eclipse of the Sun

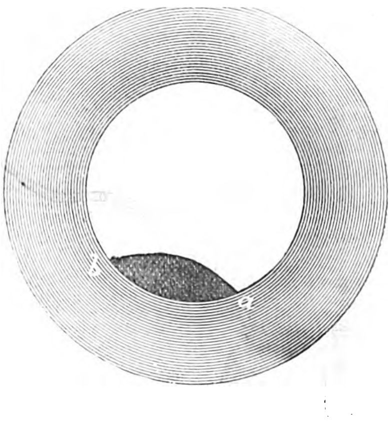
During the early morning of May 17th, which, seen as a total one in Northern Africa and

Arabia, and Central Asia, will be visible as a partial one at Greenwich. Its magnitude there, however, will only be ·186 (that of the Sun's diameter being = 1). It

Begins May 17 6h. 10·5m. a.m. }
Greatest Phase 6h. 46·0m. ,, } Mean Time at Greenwich.
Ends .... 7h. 23·0m. ,, }

Viewed with the naked eye, the angle from the Sun's North Pole of first contact, 158° towards the West; angle from the Sun's North Pole of last contact, 130° towards the East; angle from the Sun's Vertex of first contact. 118° towards the West; angle from the Sun's Vertex of last contact, 172° towards the East.

Our figure represents the Sun as seen at Greenwich at the instant of the greatest Phase. The Moon will enter on his disc at the point we have marked *a* and pass off at *b*.



The Moon

Is Full at 8h. 30·8m. a.m. on May 3rd, and enters her Last Quarter at 34·7 minutes past noon on the 10th. She will be New at 7h. 32·6m. a.m. on the 17th, and enter her First Quarter at 12h. 41·0m. p.m. on the 24th.

Day of Month.	Moon's Age at Noon.	Souths.
	Days.	h. m.

† A near approach. ‡ Star below the horizon.

Mercury

Comes into superior conjunction with the Sun at 7 a.m. on May 2nd, after which he, of course, travels in the order of the signs through the sky and becomes an Evening Star. The end of this month will be as favourable a time as the student can possibly embrace for seeing this planet with the naked eye, as he will not set until past 10 o'clock at night. His North Declination during the last third of May is about as great as it can be. His angular diameter, which is 5″ at the beginning of May, increases to 7·8″ by the end of it.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	2 30·8	14 33·1	11 53·6 a.m.
6	3 13·1	18 33·0	0 16·1 p.m.
11	3 56·3	21 50·3	0 39·5 ,,
16	4 38·0	24 7·0	1 1·4 ,,
21	5 15·8	25 20·2	1 19·5 ,,
26	5 48·4	25 37·9	1 32·4 ,,
31	6 14·8	25 12·3	1 39 0 ,,

The above Ephemeris shows that Mercury will travel from Aries, right across the entire width of Taurus into the confines of Gemini. He will pass to the North of σ Arietis on the 3rd, and somewhat to the south of δ in that constellation two days later. On the 9th he will be some 3° south of η Tauri. He will be about as much south of β Tauri on the 21st and 22nd, and North of η Geminorum on the 29th. He will be in conjunction with Saturn at 7 a.m. on the 4th; with Neptune at 3 o'clock in the afternoon of the same day; and with Jupiter at 9 a.m. on the 13th.

Venus

Is an Evening Star during the entire month, but presents no particular features of interest for the telescopic observer, her departure from a circular form becoming only just now at all noticeable. Her angular diameter increases almost imperceptibly from 10·2″ at the beginning of May to 11·2″ by the end of it.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	3 45·0	20 2·8	1 7·5p.m.
6	4 10·5	21 29·7	1 13·3 ,,
11	4 36·4	22 41·9	1 19·5 ,,
16	5 2·7	23 38·1	1 26·0 ,,
21	5 29·2	24 17·4	1 32·9 ,,
26	5 55·9	24 39·2	1 39·8 ,,
31	6 22·6	24 42·9	1 46·8 ,,

Starting thus from a point to the South and somewhat to the East of the Pleiades, Venus, like Mercury, will cross Taurus into Gemini. She will be some 4° South of β Tauri on the 19th and 2° North of η Geminorum on the 28th. She will be in conjunction with Jupiter at 8 a.m. on the 5th.

Mars.

Is visible from dusk until about midnight, but is wofully shorn of his glory now, and appears very little more than a very large and misshapen red star. His angular diameter dwindles from 7″ on May 1st to 6″ on the 31st, and scarcely any amount of optical power suffices to show any details of interest on his surface. After this month we shall take leave of him for the year.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	7 55·6	22 41·9	5 17·5 p.m.
6	8 6·5	22 6·7	5 8·7 ,,
11	8 17·5	21 28·5	5 0·0 ,,
16	8 28·6	20 47·3	4 51·4 ,,
21	8 39·7	20 3·2	4 42·9 ,,
26	8 50·9	19 16·2	4 34·4 ,,
31	9 2·2	18 26·3	4 25·9 ,,

The whole of the arc indicated above is described in Cancer. On the 14th and 15th Mars will be just to the North of η Cancri, and in the same telescopic field of view with that star; and on the 19th and 20th somewhat to the South of Cancri.

Jupiter and Saturn

Have both left us us until the autumn, the former coming into conjunction with the Sun at 9 a.m. on the 30th, the latter at 8 a.m. on the 6th.

Uranus

Is approaching the West, and should be looked for as soon as ever it is dark enough to be seen to any advantage at all. His angular diameter remains sensibly constant at 3·8″.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	11 4·5	6 48·0	8 25·9 p.m.
6	11 4·2	6 49·6	8 5·9 ,,
11	11 4·0	6 50·7	7 46·0 ,,
16	11 3·9	6 51·4	7 26·2 ,,
21	11 3·8	6 51·5	7 6·5 ,,
26	11 3·8	6 51·1	6 46·9 ,,
31	11 4·0	6 50·2	6 27·4 ,,

Hence Uranus will travel slowly in a northwesterly direction from that curious little variable star S Leonis.

Neptune,

Like Jupiter and Saturn, has left us until the autumn.

Shooting Stars

Are rare in May, but may be watched for on the 2nd and about the 18th.

Greenwich Mean Time of Southing of Nine of the Principal Fixed Stars on the Night of May 1st, 1882.

Star	Souths. h. m. s.
α Ursæ Majoris	8 17 52·61 p.m.
β Leonis	9 4 20·68 ,,
β Corvi	9 49 22·58 ,,
α Canum Venaticorum	10 11 37·81 ,,

α Serpentis	12 59 7·44 ,,

The Method of determining the Local Mean Time of Transit of either of the Stars in the above List, as also that of ascertaining the instant of its Meridian passage at Greenwich, on any other night in May, will be found on p. 392 of Vol. XXXIV.

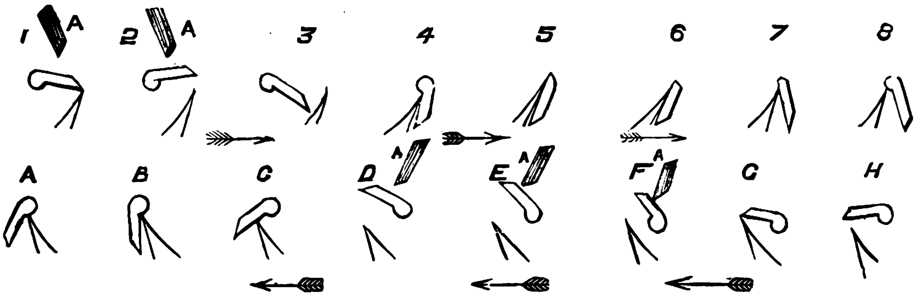
WATCH-CLEANING AND REPAIRING.

By "A Fellow-Workman."

(*Continued from page* 119.)

THIS week we will take the escapement. The verge should be escaped as shown Fig. 1, 2, 3, 4, and A, B, C, D. Fig. 1 is the top pallet, which has just got high enough to let the escape-tooth free, the bottom tooth A is just about to drop on to bottom pallet. A are the bankings, which are fixed inside the potence. Now (Fig. 2) the verge has travelled nearly to the banking, the bottom pallet (B) has also travelled with the bottom tooth resting on the angle made by the body of the verge and the face of the pallet; Fig. 3, the tooth, has got out of top pallet's way, but bottom tooth (C) is hard at work; which has driven pallet D, from some cause, right home to the banking. This gives us position of top pallet (Fig. 4). Now you see what the bankings are for. If they were not there, the balance would go on, if it were given the power, until the top pallet had got sufficiently far up the face of the escape tooth to bite and hold, and where the pallets are at right or acute angles, would go far enough to rest on the top of the tooth: the same with the bottom pallet. It is necessary, then, for us to see that the banking pins are of sufficient length to prevent the balance from "throwing over," but not long enough to interfere with the "play" of the balance; if you put the balance back so that the pallet rests against the banking pin, as shown at E, Fig. 5, and it will swing of its own accord, then you will know that the banking pin is long enough; but if it hangs, then you must lengthen the pin. If it then "hits the banking," *i.e.*, swings too far, or as we should say, has got too much play, then you must draw the follower a little; this will give it more "drop" and less "play"; but the more uninterrupted play you can get, the better time your watch will keep.

Fig 36.



Then again, you must not get the balance wheel (or escape wheel) too near the verge, *i.e.*, "too deep"; if you do the tooth will, if the pallet is short, drop on the body of the verge (see Fig. 8), or if the pallet is long enough, it will catch against the top or back of the escape tooth. On its return journey, if sufficiently deep, it will stop dead; if only a little too deep it will "catch"; therefore, if it drops on the body of the verge you must, if there is sufficient substance in the potence slip, fit a bush which protrudes beyond the face of the potence, then put the escapement together and try it; if it has then got too much drop, you must keep shortening this new bush with a piece of oilstone until you get the proper drop; but if it drops on the face of the pallet (B, Fig. 2), then by easing the follower, after the watch is together and going, with a pair of long-nosed pliers, and be careful of the contrate wheel, then if you put the blade of your screwdriver against the plate of the watch and the handle in your ear, you will easily hear if it catches—the catch is very easily distinguished from the beat of the watch; but if the potence slip is not of sufficient substance to hold a bush, you must fit another—there is wire sold for this purpose at 2d. per piece; if you have to fit a new potence slip first get height of hole with tool, Figs. 16 and 17 (page 25), and mark position as shown Fig. 18 (read "To put a Hole in Potence Slip," page 25). The bankings in the cock plate are treated in the same way, and are much easier.

You will understand better what I am telling you when you have had a little practice. It is not to be supposed that you will read what I say and then sit down and do a job. You might just as well read a music-tutor, and after you have read it fancy you can play a tune. Practice alone will teach you.

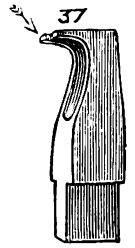
It is often the fault of some jobbers to file the pallets too short: therefore, they get too much drop and no play, and if they put the escapement closer to get less drop, they find the escapement in the position as shown, Fig. 8. Then, to remedy this, they cut away half of the body of the verge to give more face to the pallet. If you do this you must be very careful that the point of the escape wheel tooth cannot reach the centre of the body of the verge or go beyond. If it does, you will find it in the position as shown, Fig. 6, and the tooth will not begin to work until the pallet has gone too far for it to be of any use as a propeller. The tooth will remain in its position on the centre of the verge until the pallet has travelled sufficiently far to allow it to leave its position. There will not be any catching or dead stopping to show you what is the matter—only an unequal swing, sluggishness, sometimes stopping, very irregular as a timekeeper; in fact, a regular nuisance to the owner.

The Frenchmen cut their verges this way; but then they have complicated potences, so that the escapement can be put to any depth when the watch is together, by means of screws. Their escape wheels, too, have such small teeth that they are obliged to have short pallets. But, it is not so with our escapements, they must be escaped, as shown Fig. 1, 2, 3, and 4.

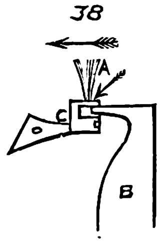
You must see that the bottom pallet does not touch bottom of potence; that the bars of the balance do not touch the curb pins in regulator or hairspring stud; that the collet does not touch top of escape wheel; that the hairspring does not ride in regulator; that hairspring stud is not loose; that hairspring does not touch balance or plate; that the collet is not loose on the verge; that the pallets of the verge do not touch anywhere inside the potence; that the front pivot of escape wheel does not go beyond the points of the teeth; that the escape wheel runs freely when all other wheels are removed; that the cockplate does not touch the inside of the case; that the escape wheel is not loose on its pinion.

If the bottom pallet touches the bottom of potence, or the bars of the balance touch curb pins, or hairspring stud or collet touches escape wheel, you can alter them by raising the balance as follows:—Make a stake out of an old file, Fig. 37. There should be a piece filed out where the arrow points, so as not to stop the bush; put this stake in your vice, place potence (C) as shown Fig. 38; take a punch (A, Fig. 38) and drive the bush towards the inside of potence; offer it until you get balance clear; if the bush is too far gone for this treatment, then you will have to fit another. On no account shorten curb pins or stud, or interfere with the collets; if your verge is not long enough you had better put another. If it is only the balance that is in fault, you can bump that.

37



38

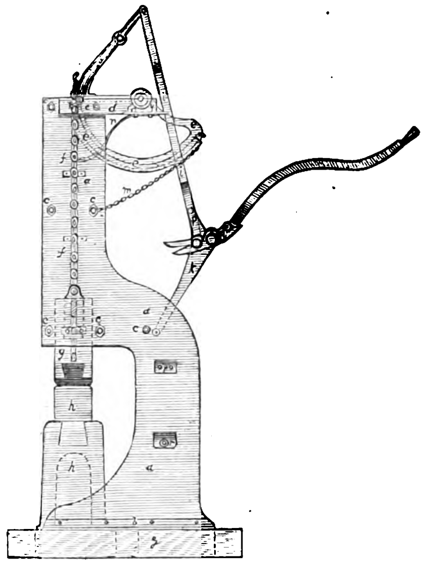


Now, with a little practice, you ought to know how to put an escapement in order, and always bear in mind that if the verge is wrong *alter the verge*, if the escape wheel is wrong, *alter the escape wheel*, &c., do not alter the part that is *right*, to remedy the part that is wrong.

(*To be continued.*)

CUTHBERT'S COMPOUND LEVER-HAMMER.

THE lever-hammer, illustrated in the annexed engraving, has been recently patented in this country by Mr. J. Cuthbert, of Landport. It is intended for use in shops where steam-hammers are either unobtainable or inconvenient, and its capabilities are said to be from 20 to 25 blows of 1000lb. per minute, or an increased number of lighter blows according to the nature of the work. The frame *a*, consisting of two vertical side-pieces, secured to a base-plate *b*, is held together by stays *c*. At the top they carry a cross or head-piece *d*, on which is centred the eccentric-shaped quadrant *e*. This quadrant at its upper corner is connected by a chain *f* with the hammer-head *g*, shown resting on the anvil block *h*, which stands within the vertical sides,—at this part curved out for its reception. By the motion of the quadrant, which is operated by the lever *i*, having a movable linked connection or other suitable connecting-rod *k*, the hammer-head is raised to the required height, and is operated by the lever-handle shown. A recoil-chain is seen at *m*, and springs at *n*, which are compressed in contact with the hammer when that is raised to its extreme height. The portion of the angular-shaped lever represented by *i* is forked or slotted to allow of the working of the quadrant through it. The radius-pawl is indicated by *p*, and the lever-pawl by *q*. The weight of the hammer and frame is about 700lb., and it is said to be capable of giving as many as 60 quarter-ton blows a minute.



AUTOGRAPHIC TRANSFERS FOR PRINTING PROCESSES.

AN improved autographic transfer process for lithographic and zincographic printing has been patented in this country on behalf of J. J. Magne, of Paris. The process consists in writing or drawing upon unprepared paper with inks or crayons having an affinity for fatty lithographic ink, then moistening the paper with a liquid having a repellent action for such ink, then inking up the writing or drawing with a lithographic roller, and finally transferring to the stone or zinc. The fatty lithographic ink is retained by the ink or crayon, but repelled by the liquid that moistens without attacking the cellulose of the paper, and the transfer is thus made without injury to the original manuscript, which may be preserved for an indefinite period. For the reproduction of printed matter by lithography or zincography, the same liquid is used, inasmuch as ordinary printing ink has the same properties as the inks of this invention. By moistening a printed paper with the liquid, and rolling up with lithographic ink, the typographic or other impression may without injury to the original be transferred to stone or zinc. The composition of the liquid is as follows:—water, 1000 parts; acid (preferably sulphuric), 150 parts; alcohols (or their congeners), 350. These proportions may be varied, but it is essential that the proportion of alcohol should be high, in order to avoid injury to the original.

The formula above indicated gives good results; but it must be understood that the process is not limited to the employment of the precise ingredients herein mentioned, as this part of the invention consists essentially in the protective intervention of a substance (alcohols or other) in an acid liquid for the purpose of repelling the fatty ink. Under the term "acid liquid" is included not only acids properly so called, but also combinations of these acids with substances which, as they do not neutralise the acids, permit the combinations to act in the same manner as if the acids were pure. The patentee is thus enabled to use salts which by reason of their acid nature repel fatty ink; we may also add to the composition which fulfils the double purpose of preserving the paper and of repelling fatty ink, certain substances of a hygroscopic nature, which will retard the evaporation of the composition and keep the material impregnated therewith at a suitable degree of moisture. These substances may be briefly stated as being either of organic origin, such as gelatine rendered soluble, either hot or in the cold, soluble gluten, starch, dextrine, mucilages, gums, sugars, and glucosides, &c., or of inorganic composition, such as deliquescent salts, &c.; and, in short, all substances capable of retarding the desiccation of materials impregnated with the composition. These substances may either be mixed directly with the composition, or they may be applied upon the originals to be reproduced either before or after impregnation with the composition.

For the production of autographic transfers any kind of paper of medium thickness, sized or not, or other material may be used. The inks employed are composed of protein substances (albumens, caseins, fibrins, &c,), and of bichromates, prussiates, alums, &c., forming liquid compositions capable when dry of retaining fatty inks. The following is the method of preparation:—dissolve in a quantity of water 2 to 3 times greater than the quantity of albumen (or other protein substance) a mixture of 2 parts of bichromate, prussiate, or alum, &c,, to 1 part of ferrocyanide of potassium, by which a limpid brown solution is obtained. Beat up separately a certain quantity of albumen and its equivalent of water. The proportion of the mixture of salts relatively to the albumen employed should be about 6 per cent. The two liquids are intimately mixed together with the addition of a suitable quantity of colouring matter. The ink thus made is unalterable, remains constantly fluid, and drawings or writings may be executed in it with a pen, brush, or drawing pen upon any paper of medium thickness, avoiding cardboard and tissue-paper.

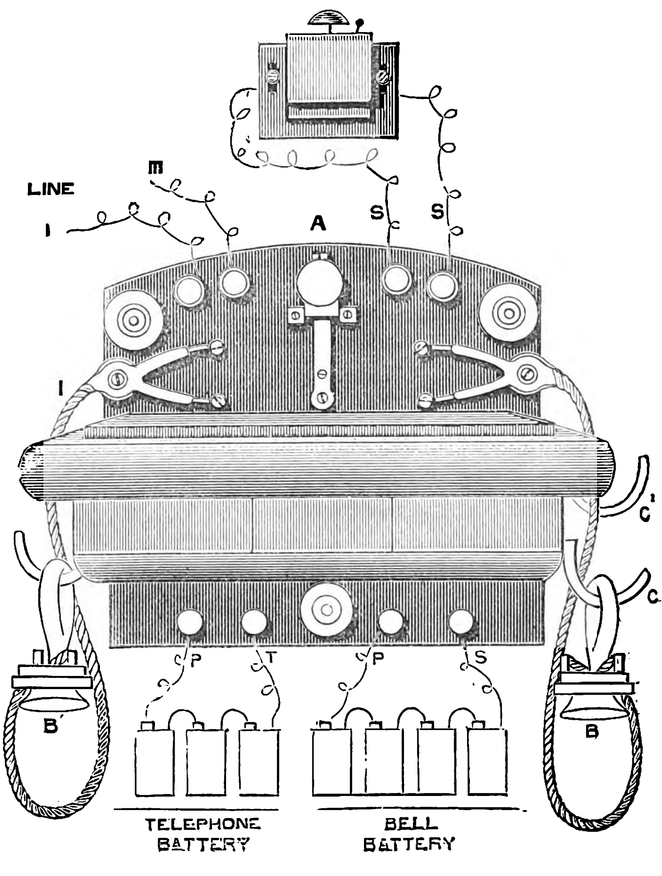
The crayons to be employed for the same purpose are of paraffin or its congeners and lampblack, bone-black, ivory-black, &c., or other impalpable colouring matter, so as to form crayons marking like those of blacklead, red chalk, or charcoal. The proportions for lampblack crayons are about 100 parts of paraffin to 16 parts of lampblack, but may be varied according to the depth of colour desired. To produce crayons of different degrees of hardness there should be melted with the paraffin before mixture with the colouring matter a certain quantity of common or other resin, regulated by experience, but which should not in most cases exceed 10 per cent. The melted mixture is run into moulds, and after cooling the crayons are cut into lengths and either inclosed in stiff paper or cased in wood in the manner of ordinary lead pencils. If the drawing has been executed with ink alone it may be used as soon as it is dry, but if executed with ink and crayon, or crayon only, the face of the drawing should be held for one or two seconds over a vessel containing boiling water. The paper is then allowed to dry by exposure to the air, more especially if the drawing be done both in ink and crayon, after which the paper is placed face upwards in a bath of water, acid, and alcohol, as before specified, and allowed to remain until it is thoroughly saturated, which is known by a sort of exudation of the liquid through the pores. The paper is then carefully spread out upon a glass plate or on a board, and an inked lithographic roller passed over it, whereby all the lines of the drawing are coated with fatty ink. When sufficiently inked a damp sponge is passed over those parts of the paper which have retained any of the ink, taking care not to blur the drawing, which is then washed and placed to drain upon a slab of plaster, and when brought to the proper degree of humidity it is laid down upon the stone or zinc plate, and the transfer pulled in the ordinary way. In order to preserve the drawing in an unaltered condition it is necessary (1), to wash it with a solution of carbonate of ammonia or of soda filtered; (2) to rinse it in pure water; (3) to drain upon a plaster slab or blotting paper; (4) to dry it by strong pressure between blotting paper.

The process of reproducing printed matter is as follows:—The mixture of alcohols and sulphuric acid, before referred to, is applied with a brush either upon the front or back of the printed matter to be reproduced. The paper becomes instantly saturated with the liquid, and the surface is then immediately washed by applying or plunging in pure water. The sheet is then spread very carefully upon a glass plate or board previously wetted, and a lithographic ink roller passed over the print, taking care if the roller is passed more than once over the print to moisten the surface of the latter with pure or slightly acdiluted water to prevent the paper adhering to the roller. If this operation, which is very simple, has been performed by a skilled hand, it is only necessary to lightly wash the print to remove the excess of acid, which would otherwise bite the stone too deeply, then to drain upon a slab of plaster, and when brought to the proper degree of humidity to lay it down upon the stone and pull it through. The transfer is then complete, and the ordinary lithographic process proceeded with in the usual way. When it is desired to reproduce both sides of a sheet, one side is inked and transferred first, and then the other side is inked and transferred. For the reproduction of typographic printing the transfer would be made upon a polished zinc plate, and then bitten in with acid in the ordinary way.

THE APPLICATIONS OF ELECTRICITY.*

(*Continued from page* 145.)

THE telephone is certainly one of the most important recent applications of electricity, and formed one of the greatest attractions of the Exposition. The telephone was invented by Professor Bell, and consists essentially of three parts: a vibrating plate, a magnet, and a coil of insulated wire wound round one of its poles. This is the simplest form of telephone; we have only to connect the coils of two such instruments by means of two wires, in order to be able to converse at a distance.



The working of the telephone is easily understood. When we speak in front of the iron vibrating plate, we cause it to vibrate in unison with our voice. The plate vibrating to-and-fro in front of the magnet, causes fluctuations in the strength of its magnetism, and these fluctuations suffice to induce small electrical currents in the coil wound around the magnetic pole. These currents are transmitted along the line wires, and received in an exactly similar instrument, where they cause the receiving plate to vibrate in unison with the sending plate. In Bell's instrument only one pole of the magnet is utilised, but in Gower's and Ader's telephones both poles are made use of by bending the magnet. In connection with the telephone, we have to describe another important piece of apparatus, the microphone. Hughes' microphone is certainly one of the simplest electrical apparatus. It merely consists of a pencil of carbon pointed at both ends, and supported by two pieces of carbon, which have each an excavation to receive the ends of the small pencil. Let us make up a telephonic circuit, and insert in it a battery and a microphone. If we touch the microphone or speak before it, we move or set in vibration the carbon, which, by pressing more or less against its carbon supports, allows more or less of the current to flow through the circuit. We can thus set up important variations in the current, and the iron plates of the telephones in the circuit will vibrate in accordance with these variations. Prof. Hughes's microphone, when properly regulated, is an extremely sensitive instrument, and you may easily judge of it by applying the telephones to your ear, when you will easily hear the ticking of my watch which I have placed upon it; by listening attentively, you will distinguish the noise which the different parts of the watch make in moving. If I stroke the microphone but very lightly with a feather, you will hear a perfect roar in the telephone. Such an instrument is much too sensitive for practical purposes, for it converts articulate speech into a continuous roar and buzzing, altogether unintelligible.

Let us now turn our attention to the practical and every-day applications of the telephone for transmitting articulate speech to a distance. I think I can do no better than to show you the instruments most frequently employed for that purpose, on the lines of the Société générale des Telephones, and which have been kindly installed here for this lecture by Messrs. Lencksewski and Co., the constructors. (See annexed figure). We have here a complete Ader telephonic post. The transmitter has the form of a desk, the sender speaks in front of this thin plank of pine, to which are fixed six carbon microphones. The number of microphones is thus increased to avoid sputtering noises. This compound microphone is connected with the telephone battery, but is not connected directly with the line wire. An induction coil is made use of, the primary being in connection with the microphoneand the secondary in connection with the line. The reason of this will easily be seen. Suppose we have a line three or four miles long, the resistance of the line wire will be considerable, and the variations of resistance caused by speaking to the microphone will be insignificant when compared to it. When, however, we use an induction coil, the microphone is in a short circuit, and its variations of resistance have a great relative importance. The secondary current sends them along the wire without diminishing their relative importance. The receiving instruments are Ader's telephones (B, B′). When we wish to call attention we do so by means of this push (A), which rings a bell; our correspondent answers by ringing our bell. We then unhook the two telephones from their supports and apply them to our ears. The act of doing this releases the automatic commutator C, which springs up to position C′, this unconnects the bells and puts the telephones and microphones into circuit ready for use. We have only to speak in front of the desk and listen in the telephones. In order to show you the delicacy of these instruments, I will converse with my assistant, who is in another part of the building, in so low a voice that no one around me will be able to catch anything of our conversation; on the contrary, I will now ask some one at the other end to sing in front of the instrument, and to play a tune on a brass instrument, and you will be able to hear from your respective seats. These were the instruments used for the auditions of the opera at the exposition. Several microphones were placed near the footlights, and were put into communication with the telephones at the Palais de l'Industrie, and you had only to apply these to your ears in order to hear the music as well as if you were at the opera.

---

* Lectures delivered by C. Detaille, at the Palais du Trocadéro, Paris.

We will now turn our attention to another kind of electrical phenomena—the decomposition of chemical substances by the electrical current. Water is thus decomposed into two gases—oxygen and hydrogen. Metallic salts are also decomposed, the metal going to the negative pole. Copper, silver, and gold can thus be deposited on to metallic surfaces by dipping them in the bath and connecting them with the negative pole of the battery; a plate of the metal to be deposited is hung in the bath opposite the object to be plated, and is connected with the positive plate. The applications of this to silvering and gilding are known to all. In recent times another metal, nickel, has been added to the list of easily-deposited metals, and you see here a brass object, which we are now going to cover electrically with nickel by M. Gaiffe's improved process. Nickel is a brilliant white metal, which does not oxidise in air, and can be easily deposited on to metals by electrolysing ammoniacal sulphate of nickel. We shall see further on that these experiments have been reversed, and that electrolysed substances can be utilised for giving back the current which has been required to decompose them.

(*To be continued.*)

IMPROVEMENTS OF THE GAS BATTERY.

UNTIL water-power has been successfully pressed into service it is clear that the electric light will depend for its existence as a means of illuminating on the consumption of fuel through the medium of steam, gas, or hot-air engines. If the coal could be used directly in producing current, the question of Electricity *v.* Gas would be settled at once. Mr. G. E. Dering, of Lockleys, Herts, has recently obtained a patent for a method of generating dynamic electricity on the principle of Grove's gas-battery, by which he asserts that 85 per cent. of the energy contained in the gas may be transformed into current. Gas-batteries comprise five elementary parts, viz., two different gases answering to the positive and negative metals in an ordinary galvanic couple, two conductors consisting of metal or carbon in contact with the two gases respectively, and an electrolytic conducting liquid in contact with the two gases and two conductors. The negative gas may be oxygen or atmospheric air, and the positive gas carburetted hydrogen or "generator gases," or water gas, or carbonic oxide. The gases are conducted from holders or retorts to the battery cells, and are kept by automatic means at such a pressure that the level of the conducting liquid is constant. When other elements than oxygen or hydrogen are employed, an escape is provided for the gases that will not enter into combination with each other. As the electromotive force of a gas-battery increases in a high ratio with the degree of compression of the gases, it is advantageous to work the cells under pressure. The solid material in contact with the negative gas is coke. When this gas is atmospheric air the coke may be freely exposed, or may be alternately exposed and submerged. It must, of course, be provided with means for collecting the current, such as plates of retort carbon. The same conductor may be used in contact with the positive gas; but it is preferred to employ lead or tin, or alloys of these metals; or sheet metal coated with lead or tin in a dense condition, or moulded carbon, the surfaces of all these to be electro-plated with platinum or other non-oxidisable metal in a spongy condition. In every case it is most important that a large surface of metallic conductor should be exposed by bending it into an open coil like a watch-spring. The distances of the several surfaces of metal should exceed that at which capillary attraction would draw up the conducting liquid, or not less than one-sixth of an inch. Another method of forming a battery is to employ for the positive and negative conductors a disintegrate mass, such as broken up gas-retort carbon, or granulated lead, platinised when in contact with the positive gas, the whole being pervaded throughout by the conducting liquid, and to cause the gases to bubble or percolate upward through the interstices. The effect of a gas battery may also be augmented by bringing the solid conductors in contact with the gas and liquid alternately by mechanical means. Another part of the invention relates to substituting the negative metal and associated liquid of a Daniell battery for the negative gas and its conductor in a gas battery.

WHAT TO OBSERVE, AND HOW TO OBSERVE IT.*

THE greatest difficulty, next to getting a good telescope, is, it seems to me, what to do with it; and though there are a great many first-class instruments in England, yet the amount of valuable contributions to astronomy in the country is steadily on the decrease. The reason is, I believe, that a man reads the exaggerated accounts in popular works of what a telescope will do, and then he is disappointed when he looks through his own. Now, just as we must learn to walk before we attempt to run, so in astronomy the beginner must be content with doing only a little at first. The eye must be trained, and trained long and carefully; and probably no one is competent to give his opinion on the performance of a telescope before he has had five years' practice at least. Now, the question arises at once—How is the eye to be trained? Well, as a preliminary trial, the ordinary sight-seeing of the heavens is as good as anything. The beginner will thus quickly see which of the two great branches of telescope work his eye is best suited for. It is quite absurd to imagine we can see all celestial objects equally well; on the contrary, he who sees faint stars best will generally see planetary markings worst. A few years ago Mr. Webb and myself were observing Saturn together in his 9⅓in. reflector. The night was superb. A very curious thing happened. Mr. Webb saw distinctly the division in the outer ring, which I could not see a trace of; and I picked up a faint point of light, which turned out to be Enceladus, and of which Mr. Webb could not see a trace. As a rule, I find I can do little with planetary markings; hence I have devoted myself of late to stellar work. I purpose then to confine myself chiefly to stellar work, and this reminds me that I would advise each beginner to make up his mind as to which branch he will choose, for planetary and lunar work quite ruins the eye for stellar work, and I don't think he will be able to do them both. I believe that planetary work, to be valuable, will, on the whole, require larger apertures than stellar work; but I shall dismiss the planetary work with a very few remarks, because having directed my attention more particularly to the other branches, I feel but ill qualified to enlarge upon it. Firstly, to my eye, planetary markings are deeper in a refractor than in a reflector. I have compared a 12in. refractor and a 13in. reflector side by side, and have observed the planets with all sizes of aperture under 12in., both with reflectors and refractors, and my impression has always been that refractors give the planetary detail darker than the reflectors. Secondly, I have found a light shade of green or blue glass deepens the markings very much. Again, the belts on Jupiter I always see better with a terrestrial eyepiece than with a celestial one. This is due, I imagine, to some peculiar absorption in the extra two lenses; for, reducing the aperture of the object-glass has not the same effect. Thirdly, I find it well to begin with a low power and gradually increase the magnifying power till it has reached the highest point the night will bear. Now, if this high power be suddenly changed for a low power, the markings on the planet will stand out in a wonderful manner. Lastly, the different satellites of Saturn I see best with a low power. If the power is too high the satellites disappear. As regards the apertures they may be seen with:—Titan is visible in a finder of 1½in. aperture; 2½in. should should show two, 3½in. four, 4½in. should show five, and 5½in. should show six satellites. I have never seen more than five with my 5in. refractor; but I think it would reach Enceladus, which would make the sixth, if the air and the eye were in the best condition. To turn to stellar work. The beginning is here beset with two dangers—first, the endeavour to see impossible stars with small apertures; second, the splitting of double stars inseparable with his aperture. But as this kind of thing is necessary for testing a telescope, a few remarks may be of service. If you know the distance of a faint star from its brighter companion and its approximate position, you are sure to see it; therefore, when testing a telescope, never look at the position angle of a test object, but look at the distance and then estimate the position angle for yourself. If your estimation is nearly right, there can scarcely be a doubt but that you have seen the object. As to mere sight-seeing, you can never have too low a power. I have an eyepiece the field of which is nearly a degree in diameter, and I cannot conceive a more glorious, and at the same time awful, sight than to sweep with this through the constellation of the Swan. Stars of every shade of colour defile through the field, from orange and bright blue to the pure white of Deneb and the two deep yellow suns of 61 Cygni. More ideas will thus be obtained of the structure of the heavens than in any way I know, and it will be found impossible to resist the conviction that the juxtaposition of two stars of the same magnitude, colour, and glory implies a real connection. Now, here is work for all apertures; and it would be as well to make notes of such pairs for subsequent publication through the columns of the English Mechanic and kindred scientific journals. I will here take exception to Mr. Burnham's limits of the distances of double stars. That the closer two stars are, the more probability of their binary or physical character being discovered I allow. But when we come to think of what time is in astronomy, that thousands—nay, millions—of years can in this science be reckoned but as moments, and that the accurate measures of most of our double stars are scarcely 50 years old, we must admit that it is premature to put "relatively fixed" to systems of which we can know but little. It is, for example, a singular fact that no deep blue star is ever found alone. A blue star has always a big neighbour. Surely this implies a real connection. But perhaps in variable stars lies the true work of the amateur, and the one which is likely to lead to the greatest results. There are nearly 400 stars which have been suspected of variation. Many need only an opera-glass to watch them, and scarcely one of them a telescope of more than 2½in. aperture. The short-period variable will be found generally among stars visible to the unassisted eye, and their distribution is probably pretty even all over the heavens. The stars of long periods will be found in a zone inclined to the equator at about an angle of 15° or 20°, and crossing it, to pass southwards about R.A. 12 hours. To sum up. Telescopes of 5in. upwards may be employed for planetary work, and the search for new double stars. Telescopes under 5in., and down even to an opera-glass, may yet do good work amongst the variable and coloured stars. No aperture is too small. Some of the most valuable work has been done with small apertures—for instance, Argelander's N. Zones, made with a telescope under 3in., and Beer and Mädler's great map of the moon was made with an instrument equally small in size. In conclusion, my object to-night has not been to repeat what may be found written in the excellent works, such, for example, as "Celestial Objects for Common Telescopes," and many others that have been written especially for the guidance of amateurs, but rather to put forward some original notes of my own, which nearly a decade of years has furnished me with, in the hopes that they may be found useful to brother star-gazers, and also provoke some discussion and suggestions from others.

PROFESSOR TYNDALL ON KOCH'S THEORY OF TUBERCULOSIS.

IN a letter contributed to the *Times*, Professor Tyndall has called attention to an address delivered by Dr. Koch, before the Physiolegical Society of Berlin, on the etiology of Tubercular Disease, or in colloquial phraseology, the cause of consumption.

Koch first made himself known by his reseaches on the contagium of splenic fever. By a process of inoculation and infection he traced this terrible parasite through all its stages of development and through its various modes of action. This masterly investigation caused the young physician to be transferred from a modest country practice, in the neighbourhood of Breslau, to the post of Government Adviser in the Imperial Health Department of Berlin. From this department has lately issued a most important series of investigations on the etiology of infective disorders. Koch's last inquiry deals with a disease which, in point of mortality, stands at the head of them all. If, he says, the seriousness of a malady be measured by the number of its victims, then the most dreaded pests which have hitherto ravaged the world—plague and cholera included—must stand far behind the one now under consideration. Koch makes the startling statement that one-seventh of the deaths of the human race are due to tubercular disease, while fully one-third of those who die in active middle age are carried off by the same cause. Prior to Koch it had been placed beyond doubt that the disease was communicable; and the aim of the Berlin physician has been to determine the precise character of the contagium which previous experiments on inoculation and inhalation had proved to be capable of indefinite transfer and reproduction. He subjected the disease organs of a great number of men and animals to microscopic examination, and found, in all cases, the tubercles infested with a minute, rod-shaped parasite, which, by means of a special dye, he differentiated from the surrounding tissue. It was, he says, in the highest degree impressive to observe in the centre of the tubercle cell the minute organism which had created it. Transferring directly by inoculation, the tuberculous matter from diseased animals to healthy ones, he in every instance reproduced the disease. To meet the objection that it was not the parasite itself, but some virus in which it was imbedded in the diseased organ, that was the real contagium, he cultivated his *bacilli* artificially, for long periods of time and through many successive generations. With a speck of matter, for example, from a tuberculous human lung, he infected a substance prepared, after much trial, by himself, with the view of affording nutriment to the parasite. Here he permitted it to grow and multiply. From this new generation he took a minute sample and infected therewith fresh nutritive matter, thus producing another brood. Generation after generation of *bacilli* were developed in this way, without the intervention of disease. At the end of the process, which sometimes embraced successive cultivations extending over half a year, the purified *bacilli* were introduced into the circulation of healthy animals of various kinds. In every case inoculation was followed by the reproduction and spread of the parasite and the generation of the original disease.

---

* A paper read by Mr. T. E. Espin before the Liverpool Astronomical Society on April 19.

It is not necessary to give an account of the actual experiments made by Dr. Koch—suffice to say, they leave no opening for doubting the correctness of his conclusions. The important question is, knowing the cause, can a remedy be devised? That remains to be seen. Koch determines the limits of temperature between which the tubercle-bacillus can develop and multiply. The minimum temperature he finds to be 86° Fahr., and the maximum 104°. He concludes that, unlike the Bacillus anthracis of splenic fever, which can flourish freely outside the animal body, in the temperate zone animal warmth is necessary for the propagation of the newly-discovered organism. In a vast number of cases Koch has examined the matter expectorated from the lungs of persons affected with phthisis, and found in it swarms of bacilli, while in matter expectorated from the lungs of persons not thus afflicted he has never found the organism. The expectorated matter in the former cases was highly infective, nor did drying destroy its virulence. Guinea-pigs infected with expectorated matter which had been kept dry for two, four, and eight weeks respectively, were smitten with tubercular disease quite as virulent as that produced by fresh expectoration. Koch points to the grave danger of inhaling air in which particles of the dried sputa of consumptive patients mingles with dust of other kinds.

BURNISHING.

By burnishing the roughness of an object is flattened down until the surface is smooth and polished like a looking-glass. Burnishing is an important operation for electro-deposits, which consists of a multitude of small crystals, with intervals between them, and with facets reflecting the light in every direction. The deposited metal is hardened, and forced into the pores of the underlying metal, and the durability is thus increased to such an extent that, with the same amount of silver, a burnished article will last twice as long as one which has not been so treated. The instruments employed for burnishing are made of different materials, and must be of great hardness and a perfect polish. Such are hardened cast steel, agate, flint, and blood stone. For metallic electro-deposits steel and blood-stones are especially employed. There are several qualities of blood-stone; its grain should be close, hard, and without seams or veins; it should leave no white lines on the burnished parts, nor take off any metal, and its colour should be of an intense black red. The steel must be fine and close grained, and perfectly polished. Should the polish of any burnishing tool alter by use, it is restored by friction upon a skin or leather attached to a wooden block, which is fixed to the bench. The leather is covered with polishing rouge in impalpable powder, or, preferably, with pure alumina, obtained by calcining ammonia alum in a forge fire. Venetian tripoli, rottenstone, tin putty, emery, or many other hard substances finely powdered may be employed. The burnishing tools are of various shapes, such as a lance, a tooth, a knife, a half sphere, or a dog's tongue, and a considerable stock is necessary. The burnishing is divided into two distinct operations. The first consists in roughing, and the second is finishing. The tools for the first have a sharp edge, while for the second operation they have a rounded surface. The tools for the hand or the lathe are fixed by copper ferrules into short round wooden handles, so that the hand is not influenced by their weight. The tools for the arm or vise are fastened to wooden handles sufficiently long to rest their slender part upon the arm or shoulder. The stouter lower portion is grasped by the hand. The burnishing tools and the objects must be frequently wetted by certain solutions, some of which facilitate the sliding of the instrument, or with others which have a chemical action upon the shade of the burnishing articles. Of the first are pure water, solutions of soap, decoctions of linseed, and infusions of the roots of marsh mallow or liquorice. The second includes wine-lees, cream of tartar, vinegar, alum in water. When burnishing gold applied upon electro-deposits of copper, as in gilding with a dead lustre by that method, use pure water, for fear of producing a disagreeable red shade. A solution of green soap is sometimes preferred by operators, although when old, it imparts an unpleasant tinge, owing to the sulphides of the liquor. When the burnishing is completed, the surface is wiped longitudinally with a soft and old calico rag. The polish obtained by burnishing is called black when it reflects the rays like a mirror, and should the presence of mercury or a bad deposit prevent the tool from producing a bright surface, the object is said to be greasy. Articles which have been previously polished, and which generally receive a very trifling deposit, are not burnished, but rubbed with chamois leather and the best polishing rouge. Too thick or too rapid electro-deposits cannot be burnished, but must be polished by rubbing with a leather and a mixture of oil and powdered pumice-stone, tripoli, or tin putty. Coarse powders are used at the beginning, and impalpable ones at the end of the operation. Polished silver deposits are more agreeable to the eye than burnished ones, but the hardening of the latter renders them more durable.—*Scientific American.*

ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.—VII.*

The Management of the Camera in the Field.

We cannot have transcribed by the camera the broad contrasts which are frequently brought out by colour alone. We must trust to form and to light and shade apart entirely from colour. Very frequently a scene will make a most perfect picture on the camera ground glass, when the experienced photographer knows it will make nothing in the print. Alas! the colour which makes the picture cannot be reproduced. This fact makes it the more necessary in the camera picture to have the form and light well balanced. The picture must not be all on one side, nor must there be running through it in any direction long uninterrupted lines. For the rest, there is wanting to a perfect landscape picture—be it painting, drawing, or photograph—a foreground, a middle distance, and a distance. It is in the latter that photography fails. What to the eye appears a definite distant landscape, the distance, but lending enchantment and softness, comes out in a photograph so dim and faint that it would seem to be almost hidden by a thick mist. The slight haze which, in this country at least, always stands between us and the distance, is exaggerated so as almost to obscure those things which are quite clear to the eye. A certain amount of haze covering distant objects is necessary to give the idea of distance, but the exaggeration of fog, mist, or haze, which the camera always gives, must be allowed for.

Perhaps the greatest difficulty in photographing, however, is that the sky is not, as a rule, rendered at all. An exposure which will suffice to bring out all the detail in a landscape is such that the sky will be so over-exposed as to show no trace of clouds. It is necessary, to get the sky, to make a special exposure, perhaps about one-tenth of that required for the landscape, and to resort to a "double printing" process, which it is without our province to describe.

The subjects best suited for the camera are of the nature of the following: Any landscapes having, apart from colour, broad and well marked contrasts of light and shade, and decided outline of form, are specially suitable. Trees of all kinds are well rendered, both with and without their leaves; in the former case, the difficulty is to get them motionless. A quiet windless day is necessary. Architectural subjects of all kinds are most perfectly reproduced by the camera.

The most charming effects of all are, perhaps, produced in a scene in which there is water—a quiet pool with reflections of trees, for instance.

We will suppose our pupil has determined on some locality where he is sure to find some subjects such as those we have indicated. We shall follow him, indicating how he should act as he proceeds. First, he has to fill his slides. We will suppose he has three of these; they must be packed into a case which should be made to hold them and the camera. Besides these, he must take his lens, his tripod—and let him be most careful not to leave the screw behind him—his focussing cloth, and possibly a "focussing magnifier." This is a small eyepiece to magnify the ground glass image, and enable him to focus with precision. It is useful mostly because it increases the light. When a small stop is used the ground glass image is frequently so dull that it can barely be seen.

Arrived at the scene of action, the photographer must select his point of view most carefully. Let him be in no hurry. Frequently a picture will be made or spoiled by altering by a few yards the position of the camera. When he is quite sure of his point of view, let him unfold his camera, erect it, and place it opposite the scene to be depicted.

Let the stand be placed on the ground with its three legs about equally apart, and with one of them pointing towards the middle of the scene to be photographed. There will be room for the photographer to focus comfortably standing between the back legs. To tip the camera up, all that is necessary is to draw the forward leg towards him; to tip it down, he need only push it from him. He may still further tip it up by spreading the back legs apart; and down, by bringing them together.

When the camera is fixed, and the view focussed, it will probably be found that there is too much foreground and too little sky. Now, one of two things may be done. The camera may be "tipped" up. In this case, if there be any parallel vertical lines in the picture, they will be made to converge at the top, and it will be necessary to bring the swing-back into play, so as to make the ground glass more vertical. If there be no vertical parallel lines, the camera may be tipped a little without appreciably modifying the result. The camera front and lens may be raised. This is usually the best course to adopt. The use of the swing-back always strains, so to speak, the lens, and necessitates the use of a very small stop. Raising the lens also strains it, but to a less degree. Tipping the camera does not at all. Most cameras are made so that either a vertical or horizontal picture can be taken, and judgment must be used to determine in which position it shall be. All the points above indicated having been considered, and the picture being all on the ground glass—proceedings so far having been conducted with open aperture or a large stop—the final focussing must be done. The principal object—generally in the middle distance—must be made absolutely sharp. Now, stops smaller and smaller must be tried till the distance is just sharp.

We described fully in the last chapter the means of comparing the rapidity of different lenses and stops. The student ought, therefore, to be able to make the necessary estimation for the particular stop he is using.

With a good spring or summer light and "open landscape" (that is, a view having no objects with very heavy shadows in the foreground), and with the average of rapid commercial plates, the exposure with $\frac{f}{20}$ will be from one to two seconds; with river scenes or seascapes, it may be reduced to one-quarter of a second—about the shortest possible to give by hand. With heavy shadows or dark-coloured trees it may run up to four or five seconds, and, in the shades under trees, even up to minutes. In interiors, such as churches and cathedrals, it is very much longer, even when they appear well lighted. Four or five minutes is a short exposure for an interior with $\frac{f}{20}$, and even when the eye can penetrate to every corner of the building, exposures of several hours may be necessary. We should say that, for a landscape, the most pleasing lighting is usually a side-lighting. The lighting looking towards the sun is sometimes very pleasing, but care must be taken not to include the sun itself. This must be either to one side or above the picture, or may be kept out of it by the camera being placed in the shadow of a tree or some such object.

SCIENTIFIC SOCIETIES.

THE METEOROLOGICAL SOCIETY.

THE usual monthly meeting of this Society was held on the 19th inst. The papers read were:—1. "Barometric Gradients—Wind Velocity and Direction at the Kew Observatory," by G. M. Whipple, B.Sc., F.R.A.S., F.M.S., and J. W. Baker, F.M.S. For the purpose of investigating the subject of the relation of the force and direction of the wind to the distribution of barometric pressure, the authors have discussed the Kew Observations for the five years, 1875-79. The results show that the rate at which the wind blows increases almost directly with the inclination of the gradient in an arithmetical proportion, the mean rate of increase being 1·85.mile per hour for each additional ·0025in. of difference in the barometer readings at each end of the slope. The authors find that the angle at which the wind crosses the line of gradient at Kew does not vary with either the steepness of the gradient or the velocity of the wind to any material extent, and also that the angle is found generally to lie between 40° and 60°, the average of the whole series of observations giving a deviation of 52°.

2. On "Difference of Temperature with Elevation," by George Dines, F.M.S. In this paper the author gives a summary of his observations made at Walton-on-Thames during the last six years. Two stands, almost identical in size and construction, were used, one being placed on the ground and the other on the top of the tower of the house, the bulbs of the thermometer in the former being 4ft., and in the latter 50ft. above the ground. The results show that the average maximum temperature for every month is always greater, and the average minimum lower, on the ground than on the tower.

SCIENTIFIC NEWS.

THE news of the death of Darwin has brought expressions of profound regret from all parts of the civilised world. Already in quarters where we might least expect to find a just estimate of his work a fitting tribute has been paid to his memory; but the exact value of his labours, and the important services he rendered to science, cannot yet be fully appreciated. The distinguished naturalist happily lived long enough to find his views adopted almost universally; and even before he was buried, much of the objectionable criticism to which his earlier works were subjected was practically withdrawn and atoned for by those who represented his, at one time, bitter opponents. Of the many sermons delivered last Sunday, in which Darwin and his theories were mentioned, there was none more truly appreciative and none in which they were more accurately delineated than in that preached by Mr. W. R. Dale, at Carr's-lane Chapel, Birmingham. Charles Robert Darwin was born at Shrewsbury, on Feb. 12, 1809, and died at Down, near Beckenham, Kent, on the 19th inst., in his 74th year. He was buried on Wednesday, at Westminster Abbey.

The Darwin medal, founded by the Midland Union of Natural History Societies, bears a likeness of Mr. Darwin on one side, and on the other an inscription relating the history of its foundation, surrounding a branch of coral—the subject of one of the deceased naturalist's most important researches.

Dr. J. Palisa has discovered another small planet, his fourth for the present year, making 224 in all. It was discovered on March 30th, whilst seeking for Callisto, and is described as very faint—less than the eleventh magnitude.

The lecture arrangements for the Friday evening meetings of the Royal Institution are as follows:—To-night (April 28th) Prof. Abel, "Some Dangerous Properties of Dusts"; May 5th, Prof. R. Grant, "The Proper Motions of the Stars"; May 12th, A. G. Vernon Harcourt, Esq., "The Relative Value of Different Modes of Lighting"; May 19th, a paper by Sir Frederick Bramwell; May 26th, Sir Henry S. Maine, "Sacred Laws of the Hindus"; June 2nd, H. H. Statham, Esq., "The Intellectual Basis of Music"; June 9th, Prof. Burdon Sanderson, "The Excitability of Plants."

On Thursday last week the Rev. W. H. Dallinger delivered, at Firth College, Sheffield, an interesting lecture on the origin of epidemic diseases, in which he briefly described the advances which have been made in recent years in our knowledge of the causes of such diseases as splenic fever, chyluria, elephantiasis, madura foot, chicken cholera, &c., with especial reference to the part played by the microscope in their discovery.

It is stated that M. Henry Giffard, the inventor of the injector and distinguished aëronaut, who died recently at Paris, has left the whole of his large fortune to the French Government, to be employed in the promotion of scientific research. M. Giffard was not married.

From America we learn that Bell's claim to be the first to invent the magneto-telephone is disputed by another rival in the person of Mr. Daniel Drawbaugh, of Cumberland county, Pennsylvania. Over a hundred witnesses have been examined, and their testimony shows that Drawbaugh invented at least half a dozen telephones before Bell conceived the idea. So long ago as 1867 he had invented an apparatus which conveyed sound by means of a battery, and in 1871 he made the magneto-electrical instrument which is said to embody the principles of Bell's telephone. What he has been doing all this time is not stated, but the People's Telephone Company have taken the case up, and there is consequently a lawsuit to be tried shortly, at the instance of the American Bell Telephone Company.

The Board of Trade have sent round a circular asking for suggestions as to the standard to be adopted for wire-gauge. A proposed (or suggested) scale accompanies the circular. It is quite time that something was done, for complaints have lately been rather loud as to the loss and inconvenience of buying by a gauge which turns out to be based on the private opinion of the maker of the wire.

The Naval and Submarine Exhibition was a success, not only from a popular point of view, but also financially to all concerned. The great majority of the exhibitors are, we understand, more than satisfied. Some had to decline orders—and the only regret expressed appears to have been that the exhibition was not open longer.

During 1881, nearly 16,000 patents were granted in the United States, the largest total ever known. No marked increase is observable in any particular class except one—viz., electricity. The greatest increase in the subdivisions of that class is found in connection with telephones and electric lighting apparatus.

Mr. John Perry, M.E., has been elected professor of Mechanical Engineering in the City and Guilds Technical College, Finsbury.

The secondary battery question, so far as patents are concerned, appears to be complicated by a paper by J. B. Oster, which appeared in a German serial in 1881. He covered a sheet of lead with a coating of peroxide, wrapped it in flannel, soldered on an anode of copper, and rolled the whole tightly in a cylinder; sheet-lead was then put round, and the whole introduced into a porous pot, containing dilute sulphuric acid. That was placed in a glass cell containing a similar solution, with amalgamated zinc plates. The author found it to be a powerful and constant voltaic cell, which he now proposes to modify and convert into an accumulator.

During the scientific cruise of the *Travailleur*, last year, measurements were made of the density and saltness of the water in different parts of the Atlantic (near Europe) and the Mediterranean. The results, tabulated by M. Bouquet de la Grye, in a paper to the Paris Academy, prove clearly the increase of those two qualities, on passing from the ocean through the straits. Thus, while the density in the Bay of Biscay is represented by 1·02718, it rises to 1·02964 off Nice. The less dense of two connected liquids (as in two vessels communicating with each other) is, of course, the higher; and it is estimated that the mean height of the Atlantic is about 1 metre (say 40in.) higher than that of the sea near Marseilles. This accounts for the surface-current through the Straits of Gibraltar; a constant current, inasmuch as the cause which maintains the differences of saltness is a permanent one. The measurements by the *Travailleur* savants verify those of M. Bourdaloue; and a good example is presented of the important bearing of a study of water-density on the constitution and general movements of seas.

The emigration last year from Switzerland was the highest yet known. The number of emigrants after 1872, when 4,957 left the republic, diminished till 1877, then rose to 2,608 in 1878, to 4,288 in 1879, to 7,285 in 1880, and last year it was 10,935. The emigrants are almost exclusively German Swiss.

The instructive results obtained by M. Spring in strong compression of various powdered substances he has lately supplemented by applying the method to mixtures of metals. A coarse powder of filings of bismuth, cadmium, and tin, in proportions the same as those of Wood's alloy (which is known to fuse about 65° C.), was subjected to a pressure of 7,500 atmospheres. The block obtained was powdered by filing, and the powder again compressed; and a metallic block with properties quite like those of Wood's alloy was produced. Put in water at 70° it melted directly. Next, a mixture of lead, bismuth, and tin, as in Rose's alloy (which melts about 95°) was twice compressed. The block melted in boiling water. A mixture of zinc and copper filings, after five or six pressures, yielded a block similar to brass, only a little darker. M Spring believes it may be generally affirmed that matter takes the condition corresponding to the volume it is compelled to assume.

A piece of iron, in being magnetised, is appreciably heated. This phenomenon M. Pilleux finds to be rendered very apparent, when alternating currents are used to produce sudden inversions of magnetisation in a core of iron or steel. Thus with a Meritens machine, he was able to heat a piece of iron to more than 200° C. How is this production of heat to be explained? M. Pilleux sought the cause first in induction currents produced in the core; but having replaced the iron core successively with cores of red copper, brass, and tin, he got no heating. Steel was considerably heated. Using iron more or less annealed, he found the heating to decrease as the amount of annealing increased. The coercive force of the magnetic cores seems to play the same *rôle* as the resistance to passage of electricity in the case of heating a metallic wire with a battery current.

Two Italian physicists, Srs. Cantoni and Gerosa, have lately sought to determine the mechanical equivalent of heat by sudden stoppage of a mass of mercury, let fall from a given height, and measuring the increase of temperature. The mean of the results closely agreed with that obtained by Joule.

French soldiers have in recent years taken part, to some extent, in the operations of haymaking, harvest, and grape-gathering. In the circular in which the Minister of War expresses his consent to this arrangement for the present year, he allows thirty days to soldiers going to join their families at a distance in harvest work, and twenty to those who go to work for farmers near their garrison town. The number so permitted will be such as is judged strictly indispensable for the requirements of each district. The soldiers will be mostly taken from those in their second, third, or fourth year of service, and from all corps of the army; but in the cavalry, artillery, and engineers, the number will be very limited (on account of the care of horses, and the special instruction given to the men).

The provincial assembly (or Zemstvo) of the Government of Simbirsk, and several others in Russia, give prizes for the destruction of wolves—viz., about 15s. for each young wolf taken in its lair, and 7s. for each wolf-skin (the ears and tail are kept as evidence, and the skin is returned). If it be proved that the wolf was rabid, a prize of about £7 is paid. In 1879 the Zemstvo above named paid some £290; in 1880, only £75. While Russian law guarantees to the proprietor the rights of the chase on his domains, any one may generally hunt any kind of game in forests. The officials who pay the prizes make no inquiries as to where the skins, &c., were obtained.

Herr Kalischer, who lately arrived at some instructive results concerning the influence of heat on the molecular structure of zinc, has examined various other metals (in the rolled form), and finds that (besides zinc), cadmium, tin, iron, copper, brass, tombac, lead, silver, gold, platinum, and german-silver, are crystalline, or become crystalline through heating. On the other hand, nickel, aluminium, magnesium, and cobalt, are uncrystalline; also zinc containing bronze, (a fact which probably has a bearing on formation of patina). The author is lead by his researches to the following general result: The crystalline is the natural state of most metals, of which state they may be deprived by mechanical action, some easily, some with difficulty, some perhaps not at all, and into which many of them may be brought back under the influence of heat. The assumption of the crystalline structure of some wires under this influence explains, at least in part, the greater electric conductivity they acquire though heating or incandescence.

In a pneumatic-rotation indicator, lately brought out by the German makers, Schäffer and Budenberg, and especially meant for ships (indicating on the captain's bridge the speed of the engine), motion is imparted by the engine to a rotatory blower, by which, with the engine working in the direct sense, air is compressed into a wind-chest. When the engine is working in the reversed direction, the blower acts as an air-pump, sucking the air from the chest. The variations in the chest are transmitted to an indicator on the bridge, as also to one in the engine-room. These are like the ordinary steam-pressure gauges and vacuum-meters. The air presses on a diaphragm which affects a pointer, or it acts by suction on the diaphragm, moving the pointer in the opposite direction. The indicators are empirically graduated, so that the pointer indicates directly the number of revolutions.

There are several objections to the method of cleaning out old oil and dust from the axle-beds and grease-boxes of railway-waggons by burning. These evils have been avoided in various German railway workshops during the last 1½ years (according to Herr Garbe), by lixiviation, the axle-beds being hung in iron vessels filled with cold water, containing 5kg. soda per cubic metre. Steam is led into the liquid, and after two hours' boiling, the axle-bed is thoroughly clean. The soda is renewed every day. The oil and fat boiled out are collected in holders and sold to soap manufacturers; every four days the vessel is cleared out, the water being let off, and the residue collected. The method proves one-third cheaper than the old one.

It has been lately proved by Herr Schuller, that when hydrogen is burnt in oxygen, or oxygen in hydrogen, under certain conditions, some peroxide of hydrogen (H_2O_2) is produced. An essential point is the rate at which the burning gas penetrates the other; when this is slow, very little peroxide is formed. The presence of sulphurous acid prevents or hinders the formation. Experiment further proved that in explosion of mixtures of H and O peroxide of hydrogen is produced, and in still larger quantity than in ordinary combustion. One deduction from the data is, that in precise determination of the heat of formation of water, regard should be had to the H_2O_2 produced.

Hardening and Tempering Steel.—The following preparation for imparting to steel great toughness and improving its quality, was the subject of an application for a patent. It consists of 200 parts resin, 120 parts liver oil, 60 parts sheep's tallow, 30 parts paraffin, 40 parts colophonium, 20 parts yellow prussiate of potash, 10 parts chromate of potash, 10 parts refined borax, 15 parts powdered ox's hoof, 15 parts tartaric acid, 10 parts alum, 10 parts soft soap, 20 parts charcoal powder from lime-tree wood, 15 parts burnt ivory, 5 parts dry cooking salt, 10 parts gum arabic, 5 parts aloe powder, and 5 parts gentian powder, the whole being mixed and boiled together for an hour.

Areas of Circles.—One is able mentally to compute the area of a circle by simply remembering that the area of one is to the area of another as the squares of their diameter. The application of this is thus suggested by the *American Manufacturer*:—"For instance, if we happen to remember that the area of an 8in. circle is 50 square inches, it is easy to mentally calculate the area of 1in., 2in., 4in., 16in., 32in., or any other binary diameter. Thus we say: area of 2in. circle : area of 8in. circle : : 4 : 64 or 1 : 16; or, in other words, the 2in circle has an area of one-sixteenth of that of the 8in. circle, that is to say, 50 : 16 = 3⅛ square inches approximately."

LETTERS TO THE EDITOR.

[*We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the Editor *of the* English Mechanic, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. Passmore Edwards.

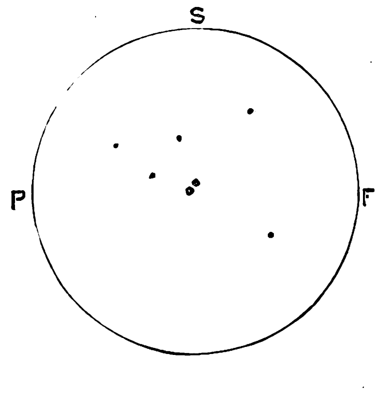
⁂ *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."
—*Montaigne's Essays.*

◆

P VII. 173 CANIS MINORIS.

[19965.]—P VII. Canis Minoris, described by Mr. Webb ("Celestial Objects") as an admirable "test," and, following a little south of Procyon, is a very interesting double, and the field around well worth examining. On the night of the 20th April I perceived, besides the 13th mag. *comes* mentioned by Webb, a much fainter but more distant *comes*, which at first I picked up with averted vision, but which, when once seen, I could keep steadily in view. It is in the north following field, about as far again as the *comes* of "Amici" from 170. Has Mr. Webb noticed it? It will, I think, severely test the light-grasping power of a good instrument. I give a drawing of (170) with these two companions, and a few of the other stars, which make the whole group very beautiful, as seen with my 12¼ mirror. As Procyon is fast getting out of good position, this field should be examined as soon after dark as possible.



S. Mills.

A REMARKABLE SUNSPOT—TO "F.R.A.S."

[19966.]—The disturbance you describe on p. 150, on the Sun's surface, was well seen here, and was one of the most remarkable I have observed during a long course of observations. An aurora borealis seems to have accompanied it.

East Molesey. H. Peacock.

DR. HASTINGS' METHOD OF MAKING FLAT SURFACES—TO MR. WASSELL.

[19967.]—In my English Mechanic just received I note Mr. Wassell's query in regard to the colours referred to in the test for flat plates. I presumed that this was well understood by optical students; but I must agree with Mr. Wassell in his excellent articles on working specula, that while some may know what we happen to know, it is the best rule to presume nothing of the kind. In this way things will always be made clearer, and not one of us should be ashamed to ask a question when in the dark, no matter how simple it may seem to *some*. I was once told by an honest man "that it would take a big book to hold all *I did not know*." And he told a truth that takes considerable of the conceit out of us that was left us as a legacy by father Adam. But enough of this pleasantry. However, I would say that if we amateurs do not endeavour to make things clear, that we have in a measure mastered, for the benefit of those who have had less or probably no experience, from whence are they to get any light? Generally, when a question is asked of one who should give a clear and lucid answer, we get it "as clear as mud." It is, therefore, a most pleasant task to pick up and read the excellent and exhaustive articles of Mr. Wassell and "Orderic Vital." I move a vote of thanks to them. In reference, then, to what is meant by colours of the first or second order. The phenomena is indissolubly joined with the name of the great Sir Isaac Newton, as he first measured and established the phenomena and laws of the appearances presented when a slightly convex lens or piece of glass, or other transparent substance is laid on a flat reflecting surface. We are all familiar with this beautiful experiment, and it is only a modification of it which serves us for a test for reflecting surfaces that are flat, or approximately so. When a piece of glass of very slight convexity is laid on a flat reflecting surface, say a piece of plain polished glass, a series of bright and dark rings will be seen, which are more and more closely approximated from within outward, and are gradually lost. The centre of all the rings is black, and the *colours* from the centre to the first dark ring, Newton called, colours of the first order. From this to the second dark ring colours of the second order, &c. The colours of the first order are black, pale blue, white, orange, yellow, red. Second order: violet, purple, yellowish green, yellowish red. To explain why these colours are seen would be a big undertaking, and as the explanation may be found in any advanced work on optics, I refer those of "ours" who have not studied it to these works. Probably one of the most excellent works on the subject is found in the International Scientific Series, "On the Nature of Light," by Eugene Lommel, of the University of Erlangen. I might say briefly that the colours are formed by the interference of the two reflected rays; one starting from the under surface of the top plate, and the other from the upper surface of the under plate. Now, in regard to the phenomena we should see in our flats, it is evident that if the thickness of the film of air were exactly the same thickness throughout, or, in other words, if the two surfaces were exactly flat, then the two rays of light would suffer identically the same interference from every part of the reflecting surfaces, and as a result we should have a single colour, deviations from the rigorous flat in one plate or the other would produce wave-length interference, determined by the errors of the surface, and as a consequence we would get other colours and other arrangements of them. The phenomena of interference is a study enchanting indeed, clearing up as it does many of nature's "mysteries." I hope this explanation will make the matter clear. I hope Mr. Wassell, with others who may try this process, will note the correction I made in regard to the size of the polisher, in a letter I wrote to the Editor, but which I have not yet seen, though no doubt it will come in due time. I note an error which I am not sure whether I corrected in my last or not, under the head "Advantages of this Method," the types make me say "*not* much less than 1-10 wave-length," when it should read "*out* much less," &c. I hope our friend "W." will succeed in making as good "flats" as he has specula.

Pittsburg, April 8th. J. A. Brashear.

ABERRATION OF MIRRORS.

[19968.]—It would seem that the rule used by Mr. Wassell in calculating his zonal errors, is in exact agreement with the one I gave in these pages some time ago. I feel certain it is correct both theoretically and practically, as it was confirmed in the first respect by two other correspondents using a different method of analysis, and in the second by the "Optical Bricklayer." Since the central error is quadruple the focal aberration, the corrective process seems even easier to apply than Dr. Draper anticipated; but for diaphragms decreasing by single inches, it requires delicate measurement, and presumably considerable practice. Mr. Wassell's aberration values differ by little more than 1-100th of an inch, which is certainly a very small quantity, and not easily distinguishable unless there are definite points to measure from. I am not practically acquainted with these matters, but should think that the main point is to keep the central and marginal parts in proper relation; then if the whole surface be free from rings and uniform, the intermediate parts cannot be far from the truth.

Mr. Wassell is doing good service in so thoroughly elucidating the subject of mirror testing. To enable anyone to understand the character of a surface from the appearance of the shadows, long experience must be required; but if Mr. Wassell can show the amateur where to start from, and what to expect, he will have removed the great stumbling-block to the serviceable use of the Foucault test. A parabolic mirror is in relation to the primitive sphere—an over-corrected spherical one—that is the marginal rays are thrown beyond those from the central parts; consequently there is no definite focus, and a variety of shadows may be produced by a very slight change in the place of the shutter. Hence the problem is to give just so much error at the centre. as shall be destroyed at the focus. Now it mus necessarily happen that the nature, regular grada tion, and extent of this error is not an easy matter to deal with; but I believe Mr. Wassell's plan is as good as any that can be devised for ascertaining what to do, where to begin, and when to stop.

Has Mr. Wassell discarded the use of the eyepiece in testing the quality of a mirror? I would also ask what considerations have led him to adopt the quadruple ratio of aberrations instead of the duplicate given by Draper? He appeals to the mathematical readers to settle the question, which is correct; but the best plan is to refer it to some of our practical friends. There are very many who possess specula of Calver or With's splendid workmanship. Will any of these oblige by testing his mirror for the difference between the central and maginal foci, at the centre of curvature? I feel certain that if this meet the eye of Mr. Calver he will say which rule agrees best with practice.

In connection with telescope matters, I may observe that there is an interesting article in the March number of *Harper's New Monthly Magazine*. The writer says that the Clark's always work a lens (a large one, I suppose he means) *on* the polisher, not the polisher on the lens, and this by hand, not by machine motion. What advantage is this particular process supposed to have over any other?

I am sorry to miss Mr. Lancaster's articles on practical telescope work. I believe he said they did not seem to interest many readers, but surely he was mistaken. The non-appearance of queries is not a sign that little interest is excited, for the simple reason that the articles would probably render the asking of many queries unnecessary. Considering that he has made many promises, may I ask him to favour us with the fulfilment of at least some of them? **Orderic Vital.**

GRINDING AND POLISHING GLASS SPECULA.

[19969.]—Owing to great pressure in other matters I have not been able to write quite so frequently just now. However, our readers have been well supplied in the interesting, instructive, and in many instances original plans described in the letters of our friend, Mr. H. A. Wassell. I am sure, as those results are the outcome of many years of application, most amateurs will have occupation sufficient for a few weeks in getting by heart the modes of working, testing, &c., described by him. In whatever way these modes differ from the usual practice in the trade, the fact remains, that good specula can be produced by the means he employs. With regard to polishing on paper, dry, I feel sure that with proper management and study of the working, stroke, grooving, &c., of the polishers, as Mr. Wassell has done with the pitch, it will be possible to pitch our old and useful, but tricksey and tenacious, friend out—I have not certainly tried actually with *glass specula* to finish off with paper, but I have got it so completely under control from the production of perfect flats and o.g.'s of over 3in. diameter, that I do not despair of getting much larger. One great advantage of dry polishing over wet is the entire absence of capillary attraction between the surfaces; this is the reason why I advocate its use as an intermediary. This at once brings us to face a difficult matter. Amateurs complain that they do not grind their tools to perfect contact with the surfaces; this is owing to the capillary attraction going on between them when *wet* abrasives are used. The right degree of moisture is only got by practice; the last emery in smoothing should be worked down to a *greasy* consistency at least. I have by practice got to work off dry; a dozen or so of dry rubs works wonders. This must not, however, lead any to suppose that dry emery to begin with is the thing. I know dry emery has been advocated as a cure many years ago, by no less an authority than that great master of the art, the late Andrew Ross. It has, however, never been much used on account of the fault he saw in it—viz., the continual cloud of dust of emery produced in the workshop. Thus, the remedy was productive of greater trouble in other ways. The ring caused by this capillary attraction is a depression equidistant between centre and edge, to speak roughly, and if plain tools are used amateurs will certainly get it to a less or greater extent as they approach the proper form of smoothing. The advantage, however, of having a finer surface to polish from than can be got from facetted tools, is great; the very small quantity of fine emery plain tools use, and the comparative freedom from scratching in the smoothing process, commend the plain tool to the amateur as well as the workman. He must however, not expect, without experience, to smooth his surface or fit his tools like a workman. It took me years to master the ring in flat surfaces, both in tools and work; even now with very soft glasses, such as the very dense flint used for spectroscopic prisms, I find it easier to correct with paper polishing, if the surfaces are large, than to dwell on the smoothing too long. Tools, however, should fit, although the work does not fit them; the error is lessened, and the tool (forming as it does the base for the polisher) should have no error, as it does not grind away anything like so fast as the glass. So that a palpable error on the glass is no proof that it is also present on the tool. In grinding a pair of tools it is easy to rub down the emery to a degree of fineness that cannot be done with the glass, and this is necessary to make the tools fit. The emery also requires to be moist—not wet. When a pair of tools fit, the emery is black and greasy in appearance. The stroke in rubbing is straight, or very narrow in the minor axis of the ellipse. I find it a good plan, when tools are very refractory, to use for a few minutes, with all varieties possible of stroke, a little No. 2 emery, and then wipe the tools perfectly dry, and with long straight strokes rub them together; this invariably has the desired effect. The coarse emery gives a sort of file-like surface to the tools, and they file each other up by mutual abrasion to perfect contact, unless the error be very considerable, when a continuation of rubbing with very fine emery is required, and *must* reduce the error. I find I must leave my promised pitch tests for my next, as I have got to the end of my tether.

Prismatique.

OBJECT-GLASSES AND EYEPIECES.—TO "LENS."

[19970.]—As most of the queries have been ably answered by "Orderic Vital," I will just say to "Lens" that the o.g., paradoxical as it may seem, may be absent in measuring its power, or rather the power of an e.p. on it. By using a hole of the exact aperture of the actual or presumptive o.g., placed at its focal distance from e.p., measuring from the diaphragm or stop in the latter, the spot of light will give, by simple proportion, the power of the o.g. So "Lens" can measure off fabulous apertures. Or he may closely arrange lenses if he uses a 3 to 1 proportion by deducting ⅓ from the power of first lens if of Huyghen's form, and adding ⅓ if of Ramsden's, supposing the lenses to be arranged at proper distances—viz., one-half their sum for Huyghen's, and one-third for Ramsden's. Although I have seen many arrangements of the Huyghenian, including crossed convex and meniscus lenses, in proportions of 2½ to 1 and 2 to 1, I still adhere to the opinion that 3 to 1, especially for high powers, is the best, all things considered. The 2½ to 1 proportion has a very questionable preference on account of its nearer approach to aplanatism, but is not so well achromatised. The 2 to 1 proportion is generally used for the microscope. In this case illumination of the field needs such a form. Plano lenses are the rule, I think; nothing has ever been gained by the other forms. **Prismatique.**

FINDING DISTANCE BETWEEN THE MIRRORS OF A CASSEGRAIN.

[19971.]—I do not know whether the following rule for finding the distance between the mirrors of a Cassegrain will help "Lens" (letter 19964, p. 156); but if so he is welcome to it. It was set as a rider to the construction of the Cassegrain in the Cambridge Mathematical Tripos for 1881:—

"Construct a right-angled triangle having the radius of the "concave" for one side, and twice the radius of the convex for the other; add to the hypotenuse the algebraical excess of the first side above the other, and the result will be four times the required distance; the first real image being supposed to be formed at the aperture in the large mirror." Perhaps "Orderic Vital" could prove it for us. **E. C. A.**

ORNAMENTAL LATHE-THREADS.

[19972.]—As no answer has been given in the last issue of the "E. M." to Dr. Edmunds's question, No. 19830, in March 24th, I inclose the calculated pitch and depths of Holtzapffel's deep and shallow screw-threads in thousandths of an inch:—

		Depth of Thread.	
No.	Pitch.	Deep.	Shallow.
1	152	163	132
2	121	131	106
3	106	114	92
4	76	81	66
5	61	64	52
6	50	54	43
7	45	47	38
8	39	41	33
9	35	37	29
10	28	30	24
11	25	26	21
12	18	19	16

The actual measurement of the screw tools I possess being Nos. 3, 4, 5, 6, 8, and 10, of the above series, differs slightly from that calculated. The angles of the teeth are given, however, of "about" only as 50° and 60°; and a small error in this may account for the difference. **B.**

[19973.]—Thanks to Mr. Holtzapffel, we are now in possession of all the data of the celebrated screw-threads which have so long clung to our ornamental lathe apparatus. Much of this information might have been arrived at in other ways, but Mr. Holtzapffel's letters to the English Mechanic (letters 19712, 19731, 19768, and 19874) have put these data upon record in authentic form.

In the table given herewith, I have collated Mr. Holtzapffel's data, and have arranged them so that all the relationships of any one element may be realised by passing horizontally along the line in which it stands. To the right will be seen the nearest element in the Whitworth and Sellers standards. The complication of the Holtzapffel screw-threads is such as to make it difficult to present them in intelligible form. But, starting from the numerical denotements by which Charles Holtzapffel strung them together, I take, as their second classifying character, their screw-rates in pitch sequence; afterwards, I take their alphabet denotements and diameters. Should there be any plan by which these screws might have been exhibited more clearly, I trust that Mr. Holtzapffel, while correcting me with academic severity, will believe me to sympathise with the vexation of spirit with which he will contemplate this collection of screw-tools when set out side by side with the systems of screws which, for a whole generation, have been agreed upon by mechanical engineers. *Omne ignotum pro magnifico*; but now that these screws are tabulated and comprehended, Mr. Holtzapffel will have no difficulty in inducing his clients to adopt the advice given so long since by his father, and, in all new apparatus, to supersede these screws by aliquot threads. No one will be fatuous enough knowingly to prefer a screw 39·83 threads to the inch in place of one of 40; 36·10 in place of one of 36; 19·89 in place of one of 20; or a mandrel-nose of 9·45 to the inch when he can have one of 10.

Sir Joseph Whitworth's screw-rates below the ¼in. are generally thought to be too coarse. The ¼in. screw, when used in mechanical engineering generally, has to take its hold in cast-iron, and therefore has 20 threads to the inch. But for other purposes in which the exigencies of cast-iron are superseded by those of steel, nickel, bronze, or brass, the ¼in. screw should have 24 or more threads to the inch. The fine threads for watch and instrument-makers are now under consideration by a committee of the British Association, and the report of that committee will probably settle the standard threads for screws whose diameters are below a ¼in., and for which the uses of cast-iron as a material scarcely need to be considered. Pending the report of that committee, the spaces in the table of standard screws are left blank below the ¼in., while in the aliquot screws, which I have ventured to indicate, it will be seen that Holtzapffel's incommensurable threads have been simply replaced by aliquot approximations. The screw-rates of Whitworth and Sellers are identical except in the ½in. screw, in which Whitworth cuts twelve threads, while Sellers cuts thirteen. But the advantage of keeping down the number and variety of screw-tools is so great that, unless some adequate reason is given for thus differentiating the rate of the ½in. from that of the 9-16th, the Whitworth is the better. The woodcuts seen below represent profiles of the threads as obtained by sectional planes containing the axes of the screw-bolts. In angle, the American thread is 60°, the English thread 55°, and the Holtzapffel thread 50°. The profiles are all contained in isosceles triangles. The Holtzapffel thread is a full triangle of 50° whose height is greater than the length of its base. In cutting this thread, the point of the tool is just smoothed down to prevent fracture, and the apex of the thread is similarly smoothed down after the screw is completed. The American thread is contained in an equilateral triangle whose height is ·866 the length of its base. The height of this triangle is divided into eight portions; by horizontal planes one-eighth is cut off from the apex of the thread, and another eighth is cut off from the bottom of the channel, leaving two flats. The truncated angular thread thus formed is in height three-fourths the height of the full triangle, or ·65 of the pitch. The Whitworth thread stands in an isosceles triangle of 55°, whose height will be ·96 of the length of the base. This height is divided into six portions, of which one is rounded off from the top by an arc of a circle, centered at the point where the perpendicular and the second horizontal line intersect, while another sixth is rounded off similarly from the depth of the channel. The height of the thread is thus two-thirds the height of the full triangle, or ·64 of the pitch. Taking the triangle drawn in a square, as given by "J. K. P.," page 83 "E.M.," the height of that triangle will, of course, be exactly the length of its base. Here we get an angle of 53° 8′—nearly 2° sharper than that of the Whitworth thread, and, therefore, approaching somewhat more nearly to that of Holtzapffel. If now we divide the height of this triangle of 53° 8′ into eight portions, as in the American thread, and then round off at top and bottom, as in the Whitworth thread, by an arc of a circle—but rounding off the eighth part instead of the sixth—we get the Steinlen thread

FIG. 1

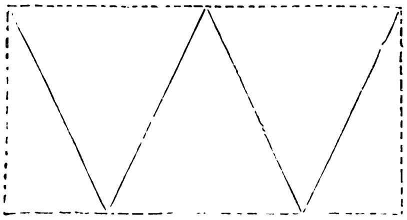

FIG. 2

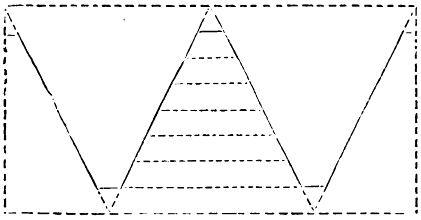

FIG. 3

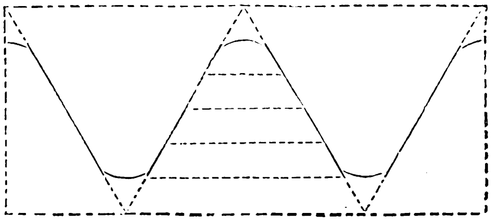
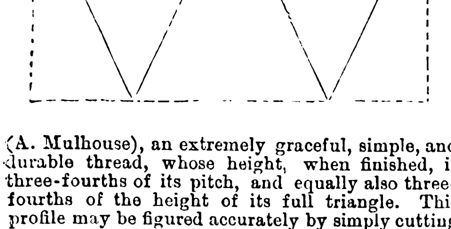


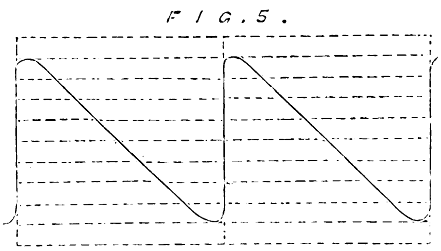
(A. Mulhouse), an extremely graceful, simple, and durable thread, whose height, when finished, is three-fourths of its pitch, and equally also three-fourths of the height of its full triangle. This profile may be figured accurately by simply cutting out a square of paper, folding it in half, and drawing across the two parallelograms diagonal lines meeting at a point. On dividing the surface into eight bands by horizontal lines, and rounding off at top and bottom by arcs of circles* centred upon the intersections of the perpendiculars and second lines from top and bottom, the profile of the Steinlen thread is complete. The Holtzapffel thread, if rounded off one-eighth both at top and bottom, would be much more generally useful than it now is, and its shaft would be much stronger; but, if a model thread were to be adopted for scientific or ornamental lathe purposes, the Steinlen thread is probably the most simple to strike and to verify, as well as the most useful and durable. Sir Joseph Whitworth has done an incalculable service by introducing and accurately manufacturing his standard threads; but he had to make a compromise with the then existing systems, rather than to devise a theoretic thread. The following diagram explains the Steinlen thread:—

FIG. 4.



If the triangle in the square, instead of being isosceles, as in the Steinlen thread, be made a right angle by dividing the square diagonally across, and then rounding off the thread at top and at bottom to the extent of one-tenth, we get a right-angled thread. Here, from a well-known property of triangles drawn upon the same base and between the same parallels, the area of the profile is the same as that of an isosceles triangle; but the material of the thread is disposed so as to be extremely solid in resisting deformation, while its vertical face minimises friction, and relieves the nut of bursting strain. It is, in fact, a square thread, of half pitch, *i.e.*, of a double number of threads per inch, and, therefore, practically twice as strong as a full square-thread screw. Mathematically, this right-angled thread is the strongest and best thread by which a screw-bolt can be held, and it would answer excellently for the mandrel-nose and its chucks. Its cutting by hand-screw tools would be more difficult than that of isosceles threads, but less difficult than that of square threads. In cases where extreme durability is of more consequence than strength, the full height of the thread might be left as in a square thread, and the rounding off would be limited to the sharp edges, as in the Holtzapffel thread. This right-angled thread is shown in Fig. 5.

FIG. 5.



Among the three angular threads which are before us, the full Holtzapffel thread is by far the most difficult of all to cut. It is by far the most liable to injury and deformation. It is entirely unsuitable for taking hold in cast iron, and the sharp deep V-thread weakens the shaft and endangers its safety if ever so placed as to have to take real strain or sudden jerks. The thread, being higher than the width of its base, is also liable to deformation wherever strength is called for. Considering the depth of its thread, its pitch, screw for screw, must be finer, or the shaft is dangerously weakened. Its best position is probably on a steel bolt holding in a steel nut. For brass, cast iron, and wood it is the most unsuitable. The large bearing surface offered by its thread makes it more durable under very frequent fixing and unfixing, as long as no real strain falls upon it.

The Whitworth thread is said to be the easiest of all to cut by ordinary screw tools, but needing much care to cut accurately in the screw lathe. The full rounding of its thread and channel leave the shaft at its maximum of strength, the thread the most difficult to deform by injury or by strain, and for holding in cast-iron most excellent. For durability, when frequently fixed and unfixed, it is said not to equal the Holtzapffel thread. In cutting the Whitworth threads, it should be recollected that the rule is to "keep down the pitches," *i.e.*, to put as many threads on intermediate sizes as the table allows. Thus, for ¾in., and up to ⅞in., the threads are 10 to the inch; for ⅞in., and up to 1in., the threads are 9; for 1in. the threads are 8.

The American thread is very difficult to cut by ordinary screw tools, but very easy to cut in the screw lathe. Its thread is a simple one to figure and to verify, and it is cut with a minimum of waste material.

The aliquot pitches suggested are of course those of the English standard, which, as I have said, differ only in one case from the American standard. Below the ¼in. aliquot approximations of the finer Holtzapffel threads are provisionally inserted pending the settlement of fine threads by the British Association. These aliquot pitches may of course be used with any shaped thread, but considering the ease with which the Whitworth thread is cut, the medium angle of its profile, its general utility, and its wide currency, no other thread is likely to come into vogue, and the multiplying of standards is to be deprecated. Six of the most useful of these threads I have also indicated as mandrel-guides for those who still use the traversing mandrel.

The aliquot guides commence with 10 threads to the inch, a rate which will govern the mandrel-nose, slide-rest screw, and back poppet cylinder, and which will be most useful for coarse general purposes. They end with 36 threads to the inch, which gives the universal screw for microscope objectives, and is most useful for fine general purposes. All these aliquot threads, and many others, can be cut by the slide-rest, with six change-wheels, and thus the traversing mandrel and mandrel-guides may be got rid of.

Against the ornamental pitches there is no need for further argument. Their appearance in the table is enough, and we shall wait in vain for any-one to advocate them. Our valued friend and adviser in such matters, "J. K. P.," writing recently in the ENGLISH MECHANIC (p. 108) says, "as a practical man I should never dream of putting anything but a Whitworth thread on a new mandrel." The author of "The Lathe and its Uses" (p. 3), says, "It will be found of great convenience to have the screw on the nose of the mandrel (and, indeed, *all* screws about the lathe) of standard Whitworth pitch." Mr. Holtzapffel himself does not demur to the sentence which his. father passed upon these screws in 1846. Recently in the English Mechanic, so accomplished and experienced a lathe-maker as Mr. Evans, who has used these screws all his life. got into such great obscurity as to give Mr. Holtzapffel ground for imagining that he does not even yet understand these screws; and when I compare Mr. Evans's last letter (19873) with the table now published, I conclude that Mr. Holtzapffel must have been right, and that my table will be of use even to Mr. Evans. The screws of ornamental slide-rests were made 13·09 to the inch, but that was "too-too-utter," and they have been superseded by 10 to the inch. The back poppet cylinders are still, however, screwed 13·09 to the inch, and, therefore, when boring a chuck you have to stop and bore your own brains in order to figure out how much is an inch divided by 13·09, and how much that quantity, multiplied by, say, six or seven turns, amounts to. Kennan's poppets contain a square 10-thread screw, and the number of turns gives you in tenths of an inch the depth you have bored. The 15-16th and 13-16th mandrel-noses are both still screwed 9·45 to the inch. All the ornamental mandrels ought to be screwed 10 to the inch; and as the larger ones are generally drilled out, this screw-thread will be in more equal mathematical ratio, as well as of vast practical convenience. Now, when all these simplifications can be accomplished without sacrificing strength, proportion, or utility, why should an amateur of the year 1882 be worried by having to recollect that his mandrel is screwed 9·45 to the inch, his slide-rest 10 to the inch, and his poppet-cylinder 13·09 to the inch? There is no answer to these queries except that they indicate vices which, at present, permeate the whole of our ornamental lathe apparatus, and which tire out and disgust, and put to useless expense at every turn, those who take up the charming and instructive pursuit of geometric turning. A geometric lathe should be to the boys in every house of refinement and culture, what the sewing-machine has become to the girls. But that can only be when the apparatus is simplified by scientific development, and made capable of being multiplied without the cost of laborious individual reproduction and fitting. I trust that Mr. Holtzapffel will help us to bring this about.

---

* The radius of this arc would be one-eighth (·125) of the pitch. The exact radius, as given by Mr. Steinlen, is ·1011 of the pitch—*i.e.*, little more than one-tenth of the pitch, and this would round the thread off rather more sharply.

James Edmunds, M.D, &c.

Grafton-street, Bond-street.

WATCH MAINSPRINGING.

[19974.]—In my last letter (19893) on the above subject, a slight correction is needed as regards Fig. 2. The hooking should not be as depicted there. It should be a *hole* not a *hook.* The text, however, sufficiently explains it. In pursuing the subject of mainspringing a little further for the benefit of those who followed me in my former letter, I wish it to be understood that I do not intend to write an elaborate treatise upon the art, but just to set as clearly as I can before the reader the various ins and outs of the work and the tools required, or such as are generally used. Having that object in view, I made my letter as brief as was consistent with the subject.

A few words of advice and instruction upon the work of punching and hooking springs is necessary as a continuance of that. I introduce here figures of the various tools used in fitting springs. To the initiated they will be perfectly familiar, but to amateurs they will be a guide as to what tools to purchase for the purpose. Fig. 1 is actual size of a small turning tool which is worked in the centres of a pair of "turns." A I is the wheel, A the pivoted shank, B a flat round table solidly set on shank, C is a small coned collar, the coned end setting in a "sink" in B, D is a squared nut screwing on pivoted and threaded continuation of A, and butting against C. The shank is turned off to a pivot at E. In twining out a barrel-bottom or barrel-lid, no better simple tool can be found than this. The collar C holds the barrel or lid flat against the table B, and the squared nut D makes all firm and tight for turning or hollowing. A light horsehair bow is used with this tool; the turning out being done with a graver, flat edged, not pointedly, as that makes a series of rough rings. The inside surface of a barrel cannot be too smooth.

Fig. 2 represents a very simple form of punch, making a small round or other shaped hole, accordingly as the punch-point and bottom-hole are made. It is screwed in the vice, and the softened end of the spring placed exactly central over the hole. The punch is then held firmly down on the spring and struck with a hammer. The hole, if too small, is easily opened with a broach. Any burr should be removed with a file or a small steel chamfer, as shown in Fig. 7, which has three or four cutting faces upon it, and is fixed in a wooden handle. In Fig. 3 we have what is called a riveting-stake, but this tool is exceedingly useful for piercing springs that are too narrow for the other punches to pierce correctly. Fig. 5 shows a form of steel punch which may be used in conjunction with this stake. The end of the spring is placed over a hole, and the point driven centrally through.

Fig. 4 represents the ordinary jack punch. As will be seen, there are three punches in this tool A; these are set in the upper jaw, and held firmly there by screws, whose ends set in deep notches cut in the punches. The first punch is generally round, the others square and oblong, or both oblong, and of two sizes. A hardened steel plate C is screwed to the lower jaw—which is a double one—and in it are cut three holes corresponding in shape to the punches, and just a shade only larger. A check-screw B limits the fall of the punches through the plate C. The spring is placed under the punch, at right-angles with the tool. The handles are then closed until the spring is pierced. This tool is shown about quarter size.

FIG. 1.

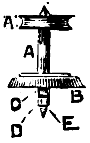


FIG. 2.

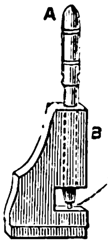

FIG. 3.

FIG. 4.

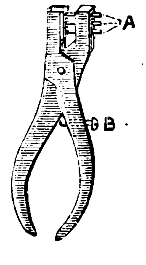

FIG. 7.

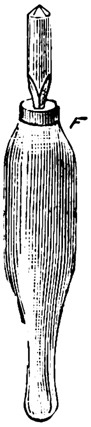

FIG. 5.

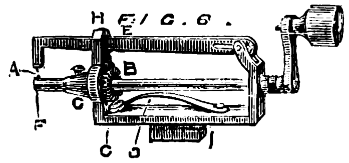
FIG. 6.



In Fig. 6 is seen the usual form of spring-winder drawn half-size. Any kind of watch-spring may be wound into barrels with this tool. It has a double action, which is controlled by the rocking-click C and the shifting spring D working into the toothed-wheel B, the arbor of which passes from the crank-handle through the uprights of the frame to the collar G, which has a poppet F screwed into it, and which carries a small protruding pin or hook A. Round this poppet the spring is hooked, and wound up, and when wound, may be securely held by the movable lever E, which is free to move upwards, or slide backwards or forwards; but, when pressed down, is held firmly by friction between the chaps H. The part I is screwed in the vice.

Reverting to the subject of springing; some old-fashioned workmen ignore all these methods of punching, and drill all the holes, opening out with a fine square file, if so required. The result is the same, but it takes very much longer to drill through a piece of comparatively hard steel than it does to punch it. The extreme end of a new spring should always be thinned off a little, and either rounded or pointed. It very frequently happens that the barrel-hook or hole is not set in the centre of the barrel-ring. The spring-hook or hole should, in those cases, be accommodated thereto; otherwise, unless the spring is low in the barrel, it will not sit properly down in its place. This should not be overlooked, as if the lid rises it will possibly jam against the barrel cock, and retard or stop the watch.

The barrel-holes should never be allowed to go large. When they are so, they should either be carefully punched up or rebushed. The latter job requires skill, and can be done only with a mandrel or a Swiss turning tool. These remarks apply to every kind of watch-barrel. Frequently, the barrel-lid does not hold firmly in the groove. When this is so, the edge of the lid should be slightly spread with a smooth-faced hammer on a smooth steel face of the vice. When sufficiently spread, it may be turned true with the centre, and bevelled off in the little tool, Fig. 1. The groove of the barrel may also be re-cut in the same tool. It should always be observed to keep the barrel perfectly free on the arbor, and clear of the cock and bottom plate; any rubbing retards the power exerted by the spring it contains. Occasionally, one finds that the barrel wobbles on the arbor. This may often be corrected by shifting the lid round. The barrel should not be let run unevenly. It is a commendable plan to always try the freedom and truth of the barrel when the spring has been taken out for any purpose. Geneve barrels in particular are prone to stick a little on the arbor. Watches often stop from this cause alone. The roller on Geneve arbors is readily removed by unpinning or unscrewing. The shoulder or hole should be reoiled before putting together.

In concluding this subject of mainspringing, I hope my instructions will prove of service to a few, if not many. With the Editor's permission I will, at a future convenient time, give a little instruction upon fitting new teeth to watch and clock wheels. The subject has been slightly touched upon by our esteemed "Fellow-Workman," who, I regret to see, has lately not been free from mud-throwing.

It is not often that men unite in themselves the artist as well as the mechanic; so I am sure any little want of correct drawing of the various parts of watchwork illustrated should not be too closely criticised. I had no difficulty at all in following and understanding all that "F. W." has illustrated, and I think he is to be warmly commended and encouraged for what he has done for the readers of the Mechanic, and for what he evidently intends to do. Certainly, while he has such a warm supporter as "Guyot," he should not quail or refrain from doing his desires in his own way.

Alfojoe.

WATCH-REPAIRING.

[19975.]—"Guyot," in letter No. 19917, tells us that the only and proper way to repair a wide hole is to rebush and repitch, but does not tell us how to do that. Now, I am not going to criticise, but, for the benefit of others, I will give my way of repitching and bushing holes. We will suppose we want to put in new third and fourth holes in verge watch, we will bush the third first. Broach the holes out top and bottom, chamfer both sides, and rivet in a brass stopping. Pitch centre and third wheel together in depth-tool; place one leg of depth-tool in centre-hole, and hold the tool upright and score off on to third wheel-bar. Now, take out centre-wheel from depth-tool, and put in contrate or fourth wheel, and pitch them together; now place one leg of depth-tool in old hole of contrate-wheel and score off, the lines where they cross will be the place for third wheel pivot. Mark it carefully. Now place pillar-plate in mandrel, upright with back-centre—*i.e.*, set the mark to run true and drill through; place top-plate in, and pin down upright top-hole, and drill off in the same way; remove from mandrel and stop up contrate pivot-holes, and pitch third and fourth wheels together again in depth-tool; score off on plate; drill off same way as before described. I think, in this way, you will get the wheels upright and not lose the positions. Of course there may be better ways than this, but I always adopt this plan for new watches as well as for old ones. Of course it cannot be done for the small charge of 2s. 6d.; the punch is generally used at that price.

I agree with F. C. Putley respecting hair-springs; they should not be drawn or interfered with to weaken them; better to fit a new one—it would be more workmanlike.

I would also ask "A Fellow-Workman" to give us a few more hints respecting the way to test the angle of verge pallets, and to know when they require opening or closing, also width of pallets. I think he has skipped it over. I may say that I am only an amateur **Working Blacksmith.**

BACK-STAYS.

[19976.]—There are a great many patterns of back-stays, both fixed and travelling, used in turning slender work which would otherwise spring from the tool, and of course some of them are much better than others. I give four illustrations of those made and used by myself, each for its own particular work. Fig. 1 is the one I use with the self-acting mechanism of my lathe when turning iron which is sufficiently long and slender to spring under the cut. It consists of a cast-iron upright, A, having a flat sole, which bolts on the saddle with two screws, which pass through the slots shown and into two holes tapped in top of saddle; the bottom of this sole is planed true, and has an arch cast in it to bridge over the surfacing screw. The side of the upright has a rectangular receptacle planed out to fit the shank of the frame B, which is of wrought iron, and is secured to the upright by a bolt, the head of which is seen, and the nut is at the far side. This bolt, passing through a slot in B, allows a certain amount of adjustment. The front (C) of the frame is a loose piece fastened by two screws, and can readily be taken on or off to change the dies. The inside of C, as well as the opposite side of frame, are V-chamfered, and between them slide two dies similar to a stock and dies for cutting screws, but of course not tapped. These are clamped together on the rod,

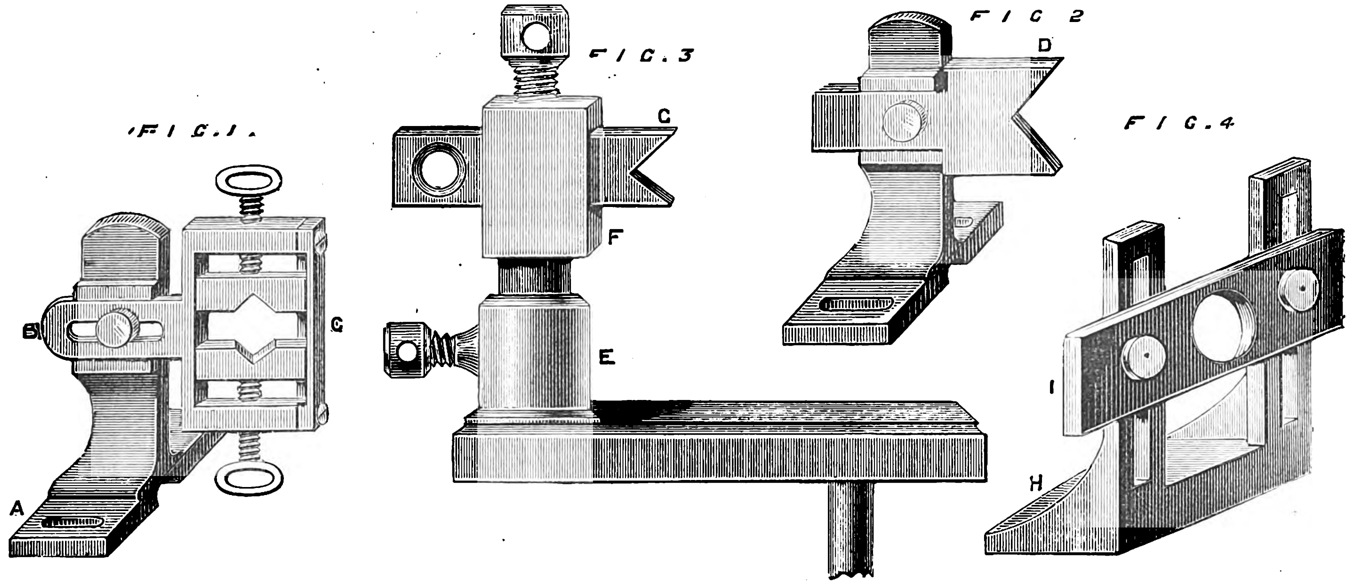


FIG. 1. FIG. 3 FIG. 2 FIG. 4

to be turned by two thumb-screws; the dies must be a good fit between the guide bars. In using this stay, the tool is set to cut in front of the dies; and while travelling, by a turn of the thumb-screws, the dies are at once adjusted to the diameter of work, and move along with the tool the entire length of cut. For roughing cuts, I find hard-wood dies are best. as the tool leaves a fine screw-thread which imbeds itself in the wood, but which metal dies would break down and allow the rod to spring a little; but when screw-cutting, hard steel dies, a pair of which I have, work very well. With this stay I once turned a rifle ramrod for a friend, 3ft. long, ⅜in. diam. Fig. 2 is what I use in cutting spirals in wood or ivory, with a revolving cutter driven from overhead. The upright is the same as Fig. 1; but in place of the frame and dies I simply put a piece of hard wood like D; this is sufficient support when using a revolving cutter as tool, but would not do in turning iron. Fig. 3 is the one I use when hand-turning in wood; for instance, for balusters or towel-rails. E is an ordinary tee-rest socket, which is bolted to lathe-bed under the middle of work. F can be adjusted vertically, and G slides through it horizontally, and the work is supported in the notch at the end. At the other end of G is a coned hole, and you may have a number of these holes of different sizes if G is made long enough. These are used for supporting the ends of rods while being bored. G is clamped in desired position by the capstan screw at top. Fig. 4 is used for supporting one end of work while the other end is secured in a chuck on mandrel. For instance, in cutting a screw inside the end of the box of a carriage-wheel, or as a temporary bearing to run the mandrel of a friend's lathe in while fitting a chuck to it. H is an iron casting which is bolted across the lathe-bed with the side H next the mandrel, it can be set true by a carpenter's square laid across the bed. I is a rectangular piece of well-seasoned mahogany nicely planed up, and fastened to the uprights with two bolts which pass through vertical slots, and so can be adjusted for height. In I a central hole is turned, either coned or plain, to fit whatever job is in hand. This, of course, can be made of metal, but I find mahogany answers admirably. These four stays I have found to do their work remarkably well, though there may be other patterns as good or better.

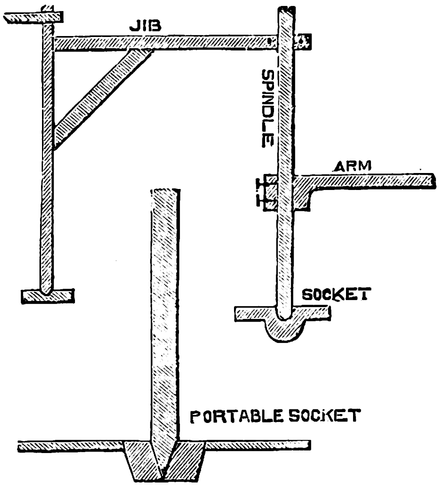
F. W. G.

IRON MOULDING.

[19977.]—I shall try, with the indulgence of my fellow-workmen, to place something before them which will sometimes prove useful. I shall speak on the different branches of loam, green-sand, and dry-sand moulding; show the different modes, and what I consider the proper one. Loam-moulding is considered the higher grade, and comes into use where there are large and heavy castings required, such as the cylinders, condensers, &c., of land and marine engines, turbines, &c.

Where they are wanted sound and free from dirt a full pattern is never required, as in sand moulding. To be a thorough loam moulder, a knowledge of geometry, and able to read a drawing, are very essential. In dry and green sand moulding the operation is much the same. In each case you require a pattern of the casting that is to be made. The difference consists in coating the dry sand mould with blackwash, and having the damp extracted in a stove or oven. Green sand moulding is handy and cheap, and does well enough for the general run of castings. In well-conducted shops there is hardly a limit to the difficult and heavy castings that can be made in green sand. I will take into consideration first the branch of loam in all its workings. The most essential tools required in a loam-shop to commence with are a spindle about 2in. in diameter and 8ft. long, some more and less. It requires to be turned true, and about 9in. at one end to be tapered or cone-shaped. Some require only to be rounded at one end.

A socket or cross (as it is generally called) is required for spindle to work in. To make a cross, a large centre or boss is rammed in what is called open sand with three or four arms (see figure).



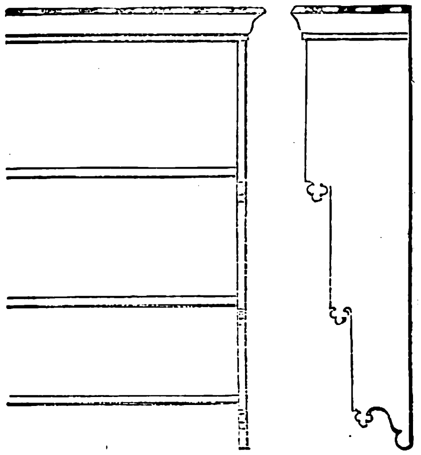
The tapered end of spindle is coated with oil and blacking or tar, placed upright in centre of mould, and then metal poured in. After the casting has cooled the spindle will come freely out, when, after being oiled and replaced in socket, will work better than had the socket been drilled out in a lathe, as is sometimes done. In some shops, where convenient, stays or jibs are placed against the side-walls with pedestal attached to steady and keep plumb the spindle. In such a spindle the socket will do 1in. deep, and will make the truest job. The deep socket is portable, and can be wrought with anywhere, and almost at any job, provided care be taken when setting the loam-board. To complete the tackle, an arm is required, to move up or down the spindle, with screws attached (as shown in figure), to fasten where necessary. When starting to a job, a good strong plate is required to build it on, all of which will be afterwards explained. Then come the loam-boards, or skeleton patterns, according to the different kind of jobs. The subject for my next letter will be screw-propellers, showing the different ideas and ways of moulding them.

Foundry.

(*To be continued.*)

HOW TO MAKE A CHEAP AND ORNAMENTAL BOOK-CASE.

[19978.]—As no one has answered the last letter of "Beta's" (19854), I venture to reply by sending an original design for bookcase, the sides of which can easily be cut by fret-saw or bow-saw, and smoothed up by file. The shelves are chamfered, and come within a ¼in. from the front, are grooved into the sides. The cornice is indented as shown.

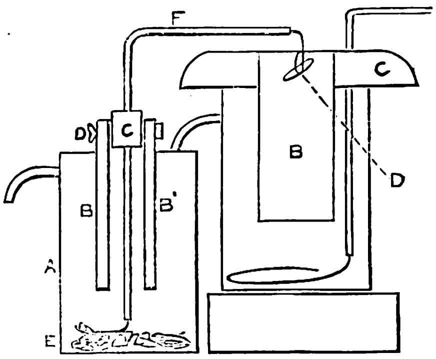


It may be made of pine, and stained with oak stain, or pitch-pine got up clean and polished, with parts of it ebonised if preferred.

Vega.

HIGGINS' CASCADE BICHROMATE BATTERY.

[19979.]—Many users of batteries must have regretted the waste which ensues from the necessity of discarding zinc plates before completely worn away, and bichromate solution when only partially spent. Mr. Higgins has constructed a battery wherein these waste materials are utilised, and wherein the mercury used for the amalgamation of the plates is recovered. A is a stoneware jar of about a quart capacity, and provided with a spout near the top; B and B′ are carbon plates, supported by the wood block C, and secured thereto, and placed in electrical communica-



tion with one another, by means of the binding-screw D; E is a mass of fragments of old zinc plates mixed with mercury; F is a guttapercha coated copper wire, bared and bent into a ring at the bottom end. It serves to make contact between the negative element of one cell and the positive of the next. The cells are placed in a row, one above another, as shown in the sketch, and above the highest is placed a reservoir of bichromate solution, below the lowest an empty reservoir. When in action, bichromate solution flows in a constant stream from the reservoir into the first cell, from that into the second, and so to the empty reservoir, whence the name of cascade battery. A single cell is stated to have, when used with new solution, an electromotive force of 1·9 to 2·0 volts, with a resistance of 1-10th ohm. The current is said to be very constant, even when the battery is worked for hours together. The bichromate solution may be passed until the colour changes. The necessity of adding fresh zinc is indicated by the formation of a red insoluble salt of mercury. It is stated that this battery costs 2¼d. per cell per day, and that 32,000 ft.-lb. of work cost 1s. 6d. The battery was exhibited in action before the Society of Telegraph Engineers the other day, and the account of its capabilities, when published in the Society's *Journal*, will be read with interest by those concerned in the question of economy in batteries. **Alfred W. Soward.**

ORNAMENTAL SLIDE-RESTS.

[19980.]—With regard to 19952, no doubt an eccentric lathe and drill can be adapted to "F. W. G.'s" slide-rest, but my objection referred to its not being well fitted to receive the ordinary cutters, &c., in use. For my own part I prefer a slide-rest which does not require such a special tool. So also with regard to the screw ferrule, which makes one independent as to the level of the cutting part of any tool. Like "F. W. G.," I make most of my own tools, but so various are they, made occasionally for the nonce, that it would be an intolerable nuisance to have to make them all accurately to one level.

As to the backlash, if "F.W. G.'s" plan stands the test of long wear and does not cause stiffness in working the leading screw, it is at least as good as mine, but I have the advantage of the easier working of the square threaded screw. I can screw up my divided nut without taking any of the slide-rest to pieces.

When, however, "F. W. G." proceeds to explain the modus operandi, then I prefer my theory to his explanation. However the screw is made, if backlash ensues in the course of wear, I fail to see how his clamping adjustment can act on the principle of a wedge. It may tighten the screw against the nut after some fashion, but I should think that backlash must soon ensue again.

The suggestion I gave as to drilling and tapping the nut before sawing it in two was a practical one. The first nut I experimented upon was not tapped before it was divided, and to this I attributed the imperfect working of the four screws. In the next nut I bored each of the four holes with two drills, and tapping the smaller interior holes, procured perfect action of the screws after the nut was sawn subsequently. With regard to this method of curing backlash, it is a very simple and obvious one, and I do not take any credit to myself for devising it when the requirement arose; but so far from "evidently quoting from Mr. Evans' article," I mentioned the plan to that gentleman a year ago, though I daresay it was no novelty to him.

As to "F. W. G.'s" question, I really can see no difficulty in the case. Supposing I had drilled and tapped the four screw-holes throughout, which, I suppose, is the dilemma, I should simply have had to cut away the thread half through with a larger drill. I did not care to occupy your space with such minutiæ, thinking that if a man had the skill to repair a slide-rest after my fashion, he would have the wit to work out such details.

M. A.

LATHES AND LATHE-MAKING.

[19981.]—In answer to "Tinker" (letter 19951), as to giving the dimensions of the different chucks and tools, they must be proportioned to each separate lathe. For instance, mine, though only a 5½in. centre, has the mandrel-collar against which the chucks bed 2in. diameter, and the nose screw 1¼in. There is also a boss, 3in. diameter, cast on front of headstock around mandrel, so that the ring of the oval chuck has to be rather large to go outside all, and the dimensions of it would probably be no use to anyone else.

In making any apparatus I always first make a working drawing full size, then wooden patterns of all parts requiring to be cast or forged, leaving them ⅛in. too large to allow for trueing up. From these patterns the castings and forgings are made, and anyone who follows my example can, by careful measurements, easily proportion their patterns to suit their own lathe. With respect to "Tinker's" plan of cutting a worm-wheel, I do not think an ordinary Whitworth pattern tap makes a good hub. In the first place the hub, and, of course, the tangent screw, requires to have the threads cut deeper and sharper than ordinary screw-threads—that is, if you want them to last well; and they should be cut with a single point tool of a smaller angle than 55°. Next, the straight flutes in a tap are not so well suited as spiral ones to give a good lead, as, during the passage of the flute there is no part of the tap touching the wheel unless the semicircular groove is pretty large, and if the flute is of any considerable width, the teeth of wheel might suffer damage through its revolution being slightly checked. I think it is of great importance that the teeth should be equally spaced if you want to have a close fit between wheel and tangent screw, instead of distributing any error over the whole number, as the milling wheel does. With regard to the dimensions of my combined eccentric cutter and drill, the front part B, Fig. 1, is 2¾in. diameter, the part of head which revolves is 1¼in. long, and the hole through it for spindle ⅝in. diameter, and the stem ⅝in. square. **F. W. G.**

DIVISION-PLATE FOR LATHE. — TO "J. K. P." AND OTHERS.

[19982.]—All lathe amateurs who read this journal must be delighted to see "J. K. P." back again. I know I am. I remember the old days from about Vol. X. to, I think, XIV. or XV. We used to get some real lathe articles and letters then. Just to keep his hand in, and to help an admirer a little, will "J. K. P." kindly consider the following?—I have a very nice little back-geared lathe to which I wish to fit division-plate. I shall have to fix plate to left-hand side of smallest speed-cone, left-hand end of mandrel. The largest plate I can get in will be 5¼in. in diameter; but I think the plate can be made thick enough to take two or three rows of holes on its rim; and to prevent crowding many rows of holes all on one side, I have an idea of placing half the rows on one side, and the remaining half on other side of division-plate. The arrangement of head stock will allow of this. Will "J. K. P.," and other lathe correspondents, think this over and kindly advise me how many rows of holes, and how many holes in each will be best, assuming the plate to be 5¼in. diameter, and three rows of holes to go on rim.

Division-Plate.

ELECTRIC LIGHT DANGERS.

[19983.]—There is some misunderstanding current upon this subject, which, I observe, is being made the basis of some little puffing and quackery. Among the reports as to the new lighting experiment of Edison's apparatus at Holborn, it is stated that, notwithstanding the magnitude of the machine and its great power, there is no danger from it. To prove this, the exhibitor is said to have taken the whole current through his body. Now, this statement is mere quackery, meant to humbug the observers. I should not have troubled to notice it if it had been stated only in the daily press, whose nonsense about these matters is too constant to be worth attention; but when the statement finds its way into "Scientific News," p. 149, it is time to explain the fallacy. If the whole current given by that dynamo were to pass through any human body, it would simply destroy life. It is quite safe for any man to lay hold of the conductors, for this reason, *that the current will not pass into the body.* That big dynamo would send no more current into the body than one of the medical batteries of 60 Leclanché cells.

That is where the humbug comes in very neatly, and leads reporters who are not up to the trick to state that the exhibitor, by way of showing the safety, passed the whole current through his body, when he simply laid hold of the two wires. Now, had he tried to do so by putting himself in the circuit between the machine and the lamps, the trick would have been at once exposed, as the lights would be instantly extinguished. The conditions would have been 120 / 8,000 = ·015 ampère instead of 1,000. If the exhibitor merely added himself in multiple arc to the lamps, even a smaller current would go through his body, and my ·015 is much too great, as it takes no account of the diminished E.M.F. of the machine.

The fact is that danger to life exists only with machines of high electromotive force, which are not used in any case with incandescent lights. The serious danger is in connection with the Jablochkoff candles, where alternating currents are employed, and the violent shocks incidental to these are brought into play in addition to the mere passage of current. **Sigma.**

NOTES ON DYNAMO-MACHINES.

[19984.]—1. Two closed coils, in which currents are flowing in the same direction, attract each other. Two coils in which currents flow in opposite directions, repel each other.

2. If a current is flowing in one coil and another be brought near it, a current will be induced in the latter, and will flow in a direction tending to oppose the motion, i.e., in a direction opposed to the direction of the current in the first coil. If the second coil be withdrawn, the current will flow in the same direction in the second coil as in the first.

3. The marked pole of a magnet behaves like a coil, in which the current flows in a direction opposed to the direction of the hands of a watch. An unmarked pole behaves like a current flowing in the direction of the hands of a watch.

4. Hence, if lines of force from a N. pole be added during the motion of the coil, the current will flow (looking on the side of the coil next the magnet) in a direction opposite to the hands of a watch, and if lines of force from a N. pole be subtracted during the motion, a current will flow in the direction of the hands of a watch. Let us call lines of force from a N. pole N. lines of force, and lines from a S. pole S. lines of force.

5. The induced current always flows in a direction such as tends to oppose the motion. If iron is placed in the coil the current tends to oppose the induced magnetism—that is to say, if by bringing the end of an iron bar, on which a coil is wound rapidly towards a marked pole, we make the end next the magnet a S. pole, the current flows in a direction which tends to make that end a N. pole.

6. Placing iron in the coil does not increase the number of lines of force, but renders the field more intense in the vicinity of the iron by bringing lines of force inside the coil, which otherwise would have passed outside it.

7. Adding N. lines of force on one side of a coil, and subtracting N. lines of force on the other side of the same coil, generates currents in the coil in similar directions. Adding N. lines on one side, and S. lines on the other side generates currents in the same direction. Adding N. lines on one side of the coil gives the same result as subtracting S. lines on the same side.

8. The E.M.F., in any coil in which a current is induced, is proportional to the rate of adding or subtracting lines of force; and the E.M.F. is at a maximum when the lines of force are being added or subtracted with the greatest rapidity.

9. For the same weight of wire on the field magnets, the strength of field is nearly proportional to the square root of the resistance, if current is constant and iron cores large enough to prevent saturation.

10. The E.M.F. of the machine, if the field remains the same, is proportional to the number of coils in the armature connected in series. Coupling the coils up in parallel circuit does not increase the E.M.F., but diminishes the internal resistance.

11. As a general rule, the efficiency of dynamo-machines is highest when the external resistance is double the internal resistance. The following gives the internal resistance of various machines:—

	Armature. Ohms.	F. Magnets. Ohms.	Total Ohms.
Bürgin (3-arc lights)	1·6	1·2	2·8
"A" Gramme......	·35	·64	·99
Siemens (Medium) .	—	—	·75
Brush (16-lighter)..	5·0	6 0	11·0

12. In the Siemens and Weston machines, the armature is a hollow wrought-iron cylinder on which the wire is wound from end to end along the outside of the cylinder only. The hollow cylinder is clasped by the poles of the electro-magnets. In the Gramme and Maxim machines, the armature is a ring; in the former constructed of soft-iron wire, in the latter of a series of fluted discs laid together. The surface of the ring inside and outside is covered with copper wire, all the coils being coupled up in series. The greatest dimension of the cross section of the rings lies parallel to the axle. The Bürgin machine armature consists of eight hexagonal rings formed of soft-iron wire, and wound somewhat like the Gramme armature. The armature of the Brush machine consists of a cast-iron ring, with eight coils coupled up in pairs, and so arranged that the pairs are thrown out of circuit in succession. Three pairs of coils are always in the circuit, two being connected through the commutator in multiple arc. The Schuckert machine has a ring armature somewhat like the Gramme, but formed of a series of wrought-iron discs insulated from one another. The greatest dimension of the cross section of the ring lies perpendicularly to the axle; the coils or sections are all connected in series.

13. The shunt dynamo gives a far steadier current under varying resistances than the ordinary dynamo. This at once constitutes its advantage and defect, for the current, although very steady, cannot be increased to any great extent.

14. To produce a field which is less likely to vary with every slight change in the current, cast iron has been employed for the cores of the field-magnets. Although, weight for weight, the current obtained with cast-iron cores is not so great as with wrought-iron, the current is much steadier under a varying resistance. **E.**

DYNAMO MACHINES.

[19985.]—I am sorry to say I cannot give "H." (letter 19929) all the particulars he requires, as I have not yet constructed my machine. I only put it forth as an idea, and certainly did not expect to get into such a hornet's nest. My position reminds me of that of the "Light Brigade"—"Cannon to right of them, cannon to left of them, cannon in front of them," &c.

I should have liked to have replied at length to "E.," "Humble Bee," "Sigma," and "LL.B.A.," but have not time to do so. "E." (19895) says nothing worth notice. "Humble Bee's" letter contains some useful information, together with the very absurd statement that a current can be induced in a conductor moving in one direction, in a magnetic field of uniform intensity. It is something to know this, for we need not run our armatures at all now this wonderful principle is brought to light. If only the above conditions are fulfilled, the magnetic state of the armature will never change, and if it will give current without any such change of magnetism, we may let the armature stand at rest, and get just as strong a current as when it revolves.

"Sigma" very rightly says just the reverse, that "the secret of getting current out of magnetism is to make the greatest changes possible." I must confess after having read "Sigma's" letter that I partly forgot this principle while designing my machine, and only aimed at making a variation in the intensity of the field during the entire revolution, in which at least I succeeded. Both "Sigma" and "Humble Bee" question whether I know if the opposing poles of the Brush field-magnets are similar. Where they got the idea that I did not, I cannot think. If on one side of the ring we place a N. pole and on the other a S. pole, it is very evident that the currents induced in the wire on opposite sides of the ring will be in opposite directions, and will neutralise each other.

I fully appreciate the kindly spirit in which "LL.B.A." criticises my unlucky machine, which suppose is a failure as it stands; but I am still going on with the subject, and hope to produce something which will not meet so hard a fate. I see several correspondents inquiring for a good, cheap, simple electro-motor. I have designed and constructed one which is likely to suit them, and will describe it shortly.

In conclusion, there is one good result which follows my describing my ideal dynamo. If the machine itself is of no use, the letters which its defects have provoked are. **Conrad.**

THORNBERRY'S (?) TELEPHONE RECEIVER.

[19986.]—The telephone-receiver, a description of which is quoted by you (p. 145) from the *Scientific American*, and which is stated by that paper to be the invention of Mr. H. S. Thornberry, is not altogether novel, as will appear from the following extract from a letter by Prof. G. Johnstone Stoney in *Nature* of Nov. 28, 1878:—

"A steel spiral . . . . was placed inside a coil of copper wire in circuit with a battery and the line. The spiral . . . . was fixed at one end, and kept tightly stretched by a string connecting its other end to a drum-head. In this arrangement no current passes through the spiral, but it is the core of an electro-magnet, and becomes magnetised in a degree which changes with the alterations in the intensity of the line-current. This causes the spires to attract one another with varying intensity, and the tremulous motion so produced is propagated by the string to the parchment. By this arrangement singing, whistling, &c., were heard when a Reiss transmitter was used. Probably a soft iron coil would have been better than the steel spring I used, and the apparatus is susceptible of other obvious improvements which would add to its sensitiveness."

Alfred W. Soward.

THE NEW TELEPHONE RECEIVER.

[19987.]—On page 145, No. 7, Vol. XXXV., you gave us a description of a *new* telephone receiver—another American invention.

I beg to inform you that the spiral core I invented and used in November, 1880; it was surrounded by a coil in precisely the same manner as the engraving shows it. Another modification of it: I used three coils, one connected to a few cells to magnetise the spiral, and the other two to receive the induced, or the current from the microphone direct. I also connected the two coils to the cells, and the centre coil to line. Again, I dispensed with the coils altogether, and passed the current through the spiral core, which I tried in copper, iron, steel, platinum: once more, I used a strained wire in place of spiral, with fair results. None of the experiments were so good as with a Bell telephone, whether through my unwilling attendant or not I cannot say. Not being satisfied, I placed them aside, where they still remain. I have not sent this as a boast or claim, but to show how it is possible for two men to invent the same thing, separated by thousands of miles.

George Tolman.

SEEING BY ELECTRICITY.

[19988.]—"W. L." (letter 19941, p. 151) is not quite right in supposing that no method has been suggested for forming an image in light and shade at the receiving station of the telectroscope. Professors Ayrton and Perry have devised a means of doing so. They say (*Nature*, April 22, 1880):—"Our receiver at the distant station was, in our original plan, a collection of magnetic needles, the position of each of which . . . . was controlled by the electric current passing through the particular telegraph wire with which it was connected. Each magnet, by its movement, closed or opened an aperture through which light passed to illuminate the back of a small square of frosted glass. There were, of course, as many of these illuminated squares as of selenium squares, and it is quite evident that since the illumination of each square depends on the strength of the current in its circuit, and this current depends on the illumination of the selenium at the other end of the wire, the image of a distant object would in this way be transmitted as a mosaic of electricity." The plan was a suggestion merely.

Alfred W. Soward.

ETHOXO-HYDROGEN LIMELIGHT.

[19989.]—In answer to Mr. Broughton's letter, No. 19900 in your issue of April 7th, in which he leads our readers to suppose that I have copied his apparatus, and that I am suffering from an explosion caused by limelight apparatus; now, as regards the latter, I was busy at work in my upper workshop, when an explosion occurred behind me, tearing up the floors, &c., and injuring myself, but not in the least damaging the work upon which I was engaged—viz., finishing off an ether generator ready to send away the following morning. In answer to the first part, I frankly acknowledge Mr. Broughton to have been the first to introduce the use of ether vapour instead of hydrogen gas from a bag under pressure; but, at the same time, allow me to assure him that I was not aware of the fact until last January, when a friend of mine lent me the *British Journal of Photography* of February 25th, 1881, containing a full description of his automatic limelight apparatus; but, had I seen the account of it before, I should not have been tempted to copy so complicated an affair as that. Since I made my first mixed jet (now about 12 years ago), it has been my study to improve the oxy-hydrogen apparatus: (1) by doing away with all superfluous accessories, and, if possible, to make it perfectly safe to anyone using it with ordinary care. I soon found the mixing chamber of the jet, packed with 30 thicknesses of fine gauze wire placed one-sixteenth of an inch apart, was useless for safety, as the flame would pass back through the whole without being extinguished. (2) That by placing both gas-bags in one pair of pressure boards, and using from 1½cwt. to 3cwt. pressure, according to the size disc required, and with the plain mixed jet—*i.e.*, the O and H tube joining as close as possible to the point of igniting without packing—there is not the least danger; in fact, the flame itself can only burn at its greatest brilliancy when the gases are properly mixed, and the taps themselves are the parts to regulate. Again, I have more often than not used bags of different sizes—viz., hydrogen bag 36in. by 30in. by 24in., and oxygen 36in. by 24in. by 24in., and have never once had the least mishap. I tried spirit vapour in lieu of pure hydrogen by passing a stream of oxygen under pressure through a generator containing cotton wool, lamp cotton, &c., &c., saturated with spirits; also the wash-bottle principle, as described by Mr. Broughton; but these I discarded as worthless, as I found the oxygen did not take up sufficient vapour to render it impossible for the flame to light back, for on turning off the hydrogen tap, or even in dissolving the gas remaining in, the tubes would explode with a nasty snap, and sometimes blow off the indiarubber tubes, but nothing more serious. It was not until last December that I was able to overcome these difficulties, and to offer a most safe, simple, and inexpensive generator to the public. I have used it with Chadwick's Oxygen Generator, both with the blow-through and mixed jet, using my usual 6-way dissolving tap, regulating the hydrogen flame with the by-pass to the lantern not in use, always with the greatest of success and superior results, to that obtained by the ordinary hydrogen. For public exhibitions I should prefer using a gasbag, especially if the disc required was from 20ft. to 30ft. in diameter; for that purpose a bag of oxygen 36in. by 30in. by 24in., and with 3cwt. pressure, would contain ample oxygen for a biunial or triple lantern for an exhibition of two hours. Mr. Broughton speaks of safety-valves; allow me to inform him that a townsman of his, Mr. Chadwick, has made a valve which he says he has tried under severe tests without lighting back, which I firmly believe; although by using my simple generator and jet, I defy any person to cause my generator to explode through any way it may be used for the oxyhydrogen light, and not using any more care than any ordinary gas-burner would require, and unless wilfully done. Any of your readers requiring information regarding the ether-hydrogen light, I shall be most pleased to give it to them.

Fredk. Fisher.

RAILWAY BRAKES.

[19990.]—I can confirm, from personal experience, the statement made by "C. E. S." this week, in letter 19962, with reference to small ejectors using a very large quantity of steam, and seriously detracting from the steaming powers of locomotives. From my experience, I estimate that the ejectors use about 2lb. of coal per mile. Now, Sir, I should be very much obliged if any of your correspondents could tell me the amount of steam required to actuate a pump to perform the same work, because I believe that a pump would be better and cheaper. I was much interested to notice that there exists a Westinghouse automatic *vacuum* brake. Will some reader furnish me with the details of this brake? It is satisfactory to find that the railway companies are fitting a large proportion of rolling stock with brakes which at least *appear* to be efficient. But I shall be glad to know the opinion of your readers with regard to the vacuum brake now used on the Midland. Is the statement correct that it cannot be applied to engines and tenders, and that the power leaks away in two minutes? If so, does it fulfil the Board of Trade conditions?

A Railway Servant.

Erratum.—Observations of Known Double Stars.—In letter 19937 there is a mistake I wish to correct in my observations. For ρ Cancri put ζ Cancri.—W. H. Gage, Eastbourne, April 29.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[45892.]—**Calorific Intensity (U.Q.)**—Errata.—Page 133, col. 2, line 25, for "(3·14 × 1·29)," read "3·14 + 1·29"; line 48, for "1,000 / 15·96," read "12,000 / 15·96; in formula at bottom of col., "*c*," read "*c*."—Alfred W. Soward.

[45923.]—**Brazing Bicycle Forks.**—To make a good job of this you want to be very careful, and if you know nothing about brazing, there is no doubt that you will make a mess of it the first trial; but practice makes perfect. Now, if you have a forge, take and clean and fit the joints, and drill a small hole in fork near the end of shank, towards the inside. This will allow the brass to run round the end of shank and make a solid joint, instead of a good many joints that we get with our machines; just the butted crevice filled with brass instead of a good solid joint, which ought to be where the strength is wanted. Now, considering that the fork will expand from the shank when placed in the forge, and get loose, you had better put a small pin through both, so as to keep steady while brazed. You will have to damp with water and put some powder borax in joint, place the joint together, and put pin through. Now place in a clear fire, but don't blow until you think the shank is as hot as the fork, as the fork will soon burn, being so thin. When hot, place some small pieces of sheet brass or spelter on the butted crevice, and the small hole that I have mentioned above. Now start blowing steadily, and keep adding a little borax, and keep the forge shovel over the joint, so as to beat the flames on to spelter. This will make a good strong joint if done right.—Jumbo.

[46069.]—**Automatic Arrangement.**—I know no reason why the arrangement described by "S. W. M." should not work well; the divisions would, of course, all be of one width; depth, of course, would be immaterial. I should prefer a continuous motion to the drum, and in fact the drum could have a pointer and a dial outside its circumference, so that the drum would, at the same time, indicate the time for the three hours during which it would work.—W. J. Lancaster.

[46221.]—**Clock and Watch Trains.**—There is a most excellent manual or handbook for clock and watchmakers, by Mr. F. J. Britten, the well-known secretary of the British Horological Institute, Northampton-square. There are 172 pages, octavo, and amply and indeed well illustrated by drawings of tools, and 'scapements and keyless work for watches, as well as plenty about clocks. There are tables of watch, clock, and marine chronometer trains, and others for various purposes belonging to such work. The book comes down to the latest date, having been published only in January last. It contains the cream of the richest horological milk in Clerkenwell, and that is saying something. No student of the art, whether amateur or otherwise, ought to be without it. It is to be had at the Institute, and is a fitting companion to Nellthrop.—C. S. M.

[46227.]—**Ground Pipeclay.**—In answer to "A Machine Tenter," I may inform him that ground pipeclay has for the past seven months been used by some of the largest calico printers in place of flour, gum, or other expensive substances, for the thickening of colour. It is a splendid article for this purpose, and is ground by a patented process, and sent out in bags as fine as flour. I do not know of any manufacturer except one at Bacup, who supplies all we use, the name of the firm being Preston and Co. As to the quantities used, it varies with the kind of colours or paste required, but if "A Machine Tenter" will state the particular shade and kind of colours, I will give him further information on his inserting a fresh query. The article is not as white as china-clay, but has far superior thickening qualities, and for all kinds of block printing on textile fabrics is an indispensable article and one that is slowly but surely making its way in the printing trade.—Practical Colourmaker.

[46296.]—**Harmonium or Organ.**—In case any of your readers should be misled by the statement of Mr. G. Fryer on p. 157, permit me to say that "any person at all acquainted with the interior construction of the American organ," provided he wanted tubes as shown by "Joiner," on p. 66, would plant them with just the same aspect as that gentleman has done. If the mouths of the tubes had faced the back, the reeds might perhaps have been removed a little more easily—say two or three minutes' quicker for the whole row; but "Joiner" has placed them with their mouths towards the inside for a purpose which evidently has not entered into the imagination of his critic. The reason that no one—save Mr. Fryer—has pointed out this "objection," is simply because it exists only in his imagination; there is no difficulty whatever in removing reeds placed as shown by "Joiner" on p. 66.—Organon.

[46355.] — **Photo. Enlargement.** — To Mr. Lancaster.—You can enlarge splendidly with an ordinary magic-lantern, and your achromatic lens; in place of the front belonging to your friend's magic-lantern, have the quarter plate lens fitted to the lantern; then cover all other parts of the lantern, so that no light can get on to screen beside that which goes through the lens. Now put the negative into the lantern, and on a card, same size as you want to enlarge, carefully focus the image; then put on cap, having sensitive paper on card, or drawn tight on a frame; then expose, afterwards developing as per the instructions sent out with the paper.—W. J. Lancaster.

[46371.]—**Barlow Lens.**—The plano-convex is crown, and the double concave is flint. I described this a fortnight back. The plane surface towards object-glass is the better way to use it.—W. J. Lancaster.

[46377.]— **Electro-motor for Tricycle.**— Nothing of the kind has yet been made to my knowledge. I have been for some time experimenting in this direction, but not with secondary cells. I have a simple form of an ordinary battery that gives ample current. It is the reduction of weight one has to work so much for; but even this will become possible.—W. J. Lancaster.

[46379.] — **Gramme Dynamo - Machines** — You evidently require someone to look after the machines. Too hard pressure of the brushes has nothing to do with it. They should press hard enough to make good contact, and the surfaces should be kept clean. The fire is caused by sparks jumping across from the divisions of the commutator as they come near the brush—*i.e.*, the current won't wait until it reaches the proper place to be taken off. Probably that is due to some faulty joints in the leads, or to driving so fast that more current is produced than is required.—T. P.

[46381.]—**Three-Legged Gravity Escapements.**—To E. H. Nelson.—You may, or may not, be perfectly correct in your statements concerning the above. As regards paragraph 14, I am not prepared to argue the point with you. For the benefit of the querist who addressed himself to me, I sent what was, as I said, an almost literal transcript from Benson's book. The particular paragraph, also all to which numbers are prefixed, are Benson's own. There are, I think, few more reliable authorities upon clockwork than Benson; so I think such a statement would not have been published to the world without proof being at hand. I may say that the book is about seven years old, so, possibly, Benson's ideas have since been improved upon. Should these letters meet his eye, one and all will, I am sure, be benefited by a few words from him in explanation.—Alfojoe.

[46388.]—**Plaster-Blocks.**—Alum will help to make plaster hard, but it also delays the setting. Lime-water prevents it cracking. I think if "Ladle" tries a little sulphuric acid in the water he mixes the plaster with, he may find the best remedy.—Nun. Dor.

[46392.]—**Froth.**—Froth is simply in this case a number of soap-bubbles, produced by air being driven in when agitating the solution, which, being of a slightly viscous nature, forms a more or less durable envelope. Hard water hinders the formation of the froth, simply because it hinders the solution of the soap.—T. P.

[46393.]— **Soap.** — I would suggest that this query could be answered by a few experiments. —T. P.

[46399.]—**Small Quantity Battery.**—As you want one to stand "turning upside-down," I am afraid you will find some difficulty; but, perhaps the lime chromate would be best.—S. E.

[46399.]—**Small Quantity Battery.**—To Mr. Lancaster.—I do not know of a cell that would do what you want, and to have its elements left in the liquid all the while. The bichromate is one of the most easily-worked cells you can have, and it would be an easy matter to so make the cell that the zinc should draw out, and a small valve close over it and keep cell watertight; the rod carrying zinc can also be hinged to fold down on the top of all.—W. J. Lancaster.

[46404.]—**Medical Battery.**—I cannot find any answer to your query in recent numbers, and if not too late I shall be pleased to give you all the directions you require. Insert another query, saying whether you wish to make a medical battery only or a coil and cells.—W. J. Lancaster.

[46413.]—**Bamboo Whistle.**—I would suggest that you copy the flute for position and size of holes, and also for the bore; but bamboo is not a suitable wood.—Nun. Dor.

[46414.]—**Electric Engine.**—Electric engines for driving tricycles may be "coming"; but at present they would involve a considerable weight in themselves, and a heavy load in the shape of battery, the cost of which for zinc and acid would add materially to the "disadvantage" side of the question. For information on carbonic acid engines see Brunel's "Life" (Longmans), and look through the records of the papers read at the Royal Institution by Faraday, in 1823. Sir Isambard started the experiments which were carried on by Mr. Brunel with all the assistance to be gained from constant intercourse with Faraday, and the result was that the carbonic-acid engine was relegated to the limbo of failures as of not sufficient account.—Nun. Dor.

[46414.]—**Electric Engine.**—To Mr. Lancaster.—I am sorry I have been unable to write an answer before, but it has been impossible (much to my regret) for me to keep up my correspondence. The causes are too many to mention, but one was due to falling off my tricycle and sustaining a severe sprain of my right thumb, which has prevented my holding a pen for any lengthened period of time. I found that with the pen holder strapped to my forefinger I could write slowly for an hour; then having a rest, I could go on again, but of course I only wrote what was absolutely necessary, and even now, while I am writing, it is very painful to hold the pen for any length of time, but I cannot longer forego the pleasure of doing what little I can to assist the readers of the Mechanic. As to the motor, I have been unable to continue my experiments, but I hope soon to be able to do so, and I will at once communicate anything worth knowing.—W. J. Lancaster.

[46424.]—**Circular Saw.**—I am much obliged to "Pattern Maker" for his advice in reference to this query, viz., "to send the saw to a saw-fettler's and get him to hammer it." No doubt that would be a good plan; and, of course, a good plan is what I wanted. But as I do not know of any saw-fettler in my neighbourhood, and as, more particularly, the object in asking questions in this journal is to elicit information by which querists may *themselves* do what is wanted, I again ask some practical correspondent to look at my original query (46424, page 44, March 17, 1882), and kindly tell me how to make my saw flat and in good working order without taking it to a saw-fettler or anyone else.—Circular Saw.

[46435.] — **Magnetic Bell Hammers.** — I cannot quite understand the form of bell hammer you have which you call a "wheel-revolving magnetic bell-hammer." Let me know something more about its construction, and I will do my best to advise you correctly.—W. J. Lancaster.

[46452.]—**To "Finem Respice."**—I am obliged to "Finem Respice" for his reference to my quarter view lens, sold at 5s. I need hardly say in the pages of the Mechanic that the lens "Finem Respice" refers to does work as well as lenses costing ten times the money—there are so many of "our" readers who have them, and who have sent to me charming prints and equally charming letters about these lenses. It is always a pleasure to me to put scientific apparatus in the hands of every amateur at the lowest possible cost; there is much more gratification to me in doing this than there would be in charging exorbitant prices.—W. J. Lancaster.

[46457.]—**Battery.**—Half a dozen Fuller's cells ought to do the work you require. You, of course, know their build: if not, I shall be very pleased to give you full instructions for fitting them up, &c.—W. J. Lancaster.

[46472.] — **Magneto-Electric Machine.** — A machine to do the work you want it to do would be past your hand. You can buy a machine that will do it well, but as to making one, that is out of the question. You could not depend upon a small machine to equal a couple of Daniells; better go on quietly with your present cells than bring upon your head a heap of troubles.—W. J. Lancaster.

[46481.]—**Boiler-Pump.**—I am sorry to say that I cannot give "Slocum Podger" any given rule for finding how full the pump is; the only guide, to my knowledge, being the speed and condition of pump. If the pump be running very fast, then the full stroke will not be delivered, as the barrel does not get time to fill. When the water is driven out again, or if any of the valves are not air-tight, the vacuum will be partially destroyed, and consequently the pump will not deliver the full stroke. Being only a "younker," I would like very much to hear from any of the "old hands" if there is any correct way of finding this out.—Was-heil.

[46489.]—**Bicycle Making.**—To "Sunlight." —In reply to your inquiry, my lathe is a 5in. centre, single geared, having only hand-rest. I shall feel grateful for the promised instructions as to making drilling-spindle, and if you could also set me right as to the following, you will confer a further boon. Has front wheel spindle and back wheel cone to be case-hardened before brazing the hubs thereto or after? If the former, will not the heat caused by brazing tend to soften them? and if the latter, will not the heating of spindle and cone for the purpose of hardening melt the brazing?—An Amateur.

[46491.]—**Telescope.**—To Mr Lancaster.— The eye-lens of eyepiece in your telescope is too near to your eye when using the telescope. If you could alter the cap over eye-lens so that the lens might be a good ¾in. away from your eye, then the telescope would work well; generally the cap is a distance above front of eye-lens; then the glare is not apparent.—W. J. Lancaster.

[46492.]—**Horizontal Winding Engines.**— As I have not yet seen this query replied to, perhaps I may be allowed to state my views on the subject. To begin with: for engines of the size given, I would recommend drop valves (called by different names in different parts of the country, such as stamper valves, equilibrium drop valves, &c). With these valves there is less friction than any other; they can be placed closer to the cylinder, and so save long steam-passages. You will require four valves (two at each end of cylinder), one steam, and one exhaust. They are best worked by a lay shaft driven from crank shaft by mitre gearing, and the valve levers worked either by tappets or eccentrics. The reversing is similar to a slide-valve, but easier as a rule. The first cost of an engine with drop-valve is greater than the cost of one with plain slide-valves, but the difference is amply returned by the lessened cost of working.—Labor Omnia Vincit.

[46497.] — **Fortified British Cities.** — The subject mooted by "Antiquary" is an interesting one to all readers, as the existence of such fortified places is instructive as to the condition of this land in early times. No doubt members of the Archæological Society, who have access to all documents relating to this subject, are well up in the matter, and if one of them would condescend to give a little information to the readers of "ours," it would be conferring a boon on many who have not the opportunities they have. I understand Oswestry was anciently a fortified town, had strong walls, and four gates. The gates existed up to 1783: remains of the walls are still to be seen in various places.—Curious.

[46503.]—**Jamming of Tapered Journals.**— Many thanks to "J. J. A.," Liverpool, for his communication; but if he will refer again to p. 31 he will see that it is hardly an answer to my question. What I want to know is what slant to give the sides of a cone (I merely gave the sketch as an example for convenience of reference), in order that it may be theoretically on the point of jamming when fitted into a similar female cone. I am aware that the taper shown is far too "quick" for an actual lathe, but it was necessary in order to get the sketch into the space allotted to it, and at the same time to give my meaning clearly. If "J. J. A., Liverpool," will answer my query in the precise terms of the original, using the same letters, he will be doing me a great favour. Perhaps

"Tubal Kain" or "Sunlight" will give the required information?—GLATTON.

[46517.]—**Preserving Wood Troughs**.—Procure a few sheets of laminated lead and a small quantity of copper tacks; line the troughs with the same, and the desired end will be obtained.—A. MANOCK.

[46518.]—**Cotton Wadding**.—I should imagine the necessary machinery to make a single sheet of wadding would cost several hundred pounds. The cotton, after it has been "ginned" to free it from husk, &c., is passed through the "carding" engine, which delivers it in a thin, wide sheet, or film; and I believe "wadding" is a number of these sheets laid one on the other, and finally gummed on one side. I hoped someone better qualified would answer this. Would anyone remind me of the precise uses of the "slubbing frame" and roving engine?—MURANO.

[46526.]—**Removing Spots from Telescope-Glass**.—Do not attempt to remove the spots yourself, or you will most probably destroy the lens altogether. You might send it to any good optician, who would do it for you without at all damaging the lens. A Darlot lens is generally a good one, and should never be tampered with.—W. J. LANCASTER.

[46531.] — **Yacht - Deck**. — I fully endorse "J. J. A.'s" correction of my reply. I had overlooked the size of 20 tons, and was thinking of one that I was once part happy owner of, and about 12 ton size.—WORKING TOM.

[46537.]—**Miniature Spectroscope**.—To MR LANCASTER.—You had better purchase the five prisms already cemented, then build them in a tube with an adjustable slit at one end and an eyepiece at the other end—by which the slit can be accurately focussed. The prisms are difficult to make, and I would not advise you to attempt them. Canada balsam would not at all answer the purpose.—W. J. LANCASTER.

[46552.]—**Loosening Green Baize**.—The best method for "G." to adopt will be to get a pail of hot water and a sponge. Afterwards damp the green baize for about five minutes, and it will become quite loosened. Then, taking a chisel, scrape off the baize as required, and our querist will find that a very neat and satisfactory finish will be the result.—A. MANOCK.

[46556.]—**Skin-Disease**.—If "A Sufferer" will try the following, I think he will find a benefit. Half lard without salt in it, and half Stockholm tar melted together, and a little rubbed in at night and washed off in the morning.—J. COLLINS.

[46575.]—**Photo-Lenses**.—To MR. LANCASTER.—To begin with, see that the lenses are placed in their cells correctly. Thus, the front lens should have its convex surface outwards, then the back combination should be put into cell as follows: the crossed convex lens should be put into cell with the weakest convex down, the deeper surface being upwards; then a ring of tube ¼in. deep should be put on to lens, and the concave surface of the concavo-convex put down upon the ring, and the counter-cell screwed in its place; and lastly, screw the two cells into the tube, so that the two inside lenses should be 3in. apart. The lens will work then at its best.—W. J. LANCASTER.

[46583.]—**Small-Quantity Battery**.—If a bichromate cell would suit your purpose, make one with a water-tight lid; have the carbon and zinc plates long enough to reach half-way down the cell; then add sufficient solution to be within ¼in. of the plates, and by turning the battery upside down, the action would commence. The lid should be hollow, so that you could pour some melted paraffin to cover the connecting brackets, &c. You cannot have a dry battery at present. Would a small dynamo suit you?—GEORGE TOLMAN.

[46587.]—**Dynamo-Machine**.—Let us know a little of the construction of it, and I will soon set you right.—GEORGE TOLMAN.

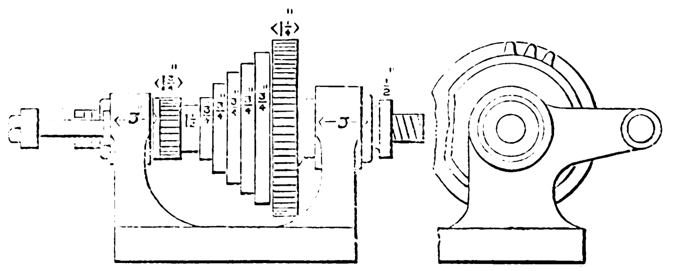
[46594.] — **Heating Water**. — To "LABOR OMNIA VINCIT."—Many thanks for your answer on p. 137. I will explain a little better about the tank if possible. We have 5in. pipes from our boiler carried many hundred feet for heating purposes. About one hundred feet from the boiler my water-tank is fixed and supplied with water independant of the boiler. The water is required boiling all day long, and to feed with cold when any is drawn. We have a cold-water cistern to feed the tank, and all goes on well enough until the water boils back into the cold supply pipe, then it overflows the cistern and tank gets nearly empty. I have heated the water as you see with the steam rushing into it, and as soon as it boils the waste of steam goes on through my air or vent-pipe. The tank is below or under the 5in. pipe the steam is taken from.—JEFF.

[46599.] — **Photographic Portrait-Lens**. — Read my answer 46575, and if your lenses are put together correctly as there described, let me know something more about its construction and size, and I will do what I can to help you.—W. J. LANCASTER.

[46603.]—**Induction-Coil Failure**.—I think the fault is in the cell. If you will have a bichromate battery, then wind your primary to suit it. Two layers of 20 would have been better; as it is, two layers of 16 offers about 0·1 ohm. resistance; this would soon take all the pluck out of the cell. You had better, now the coil is wound, use a 6in. Bunsen or more cells. The varnished paper will do for insulation. Test the secondary again, and place the galvanometer several feet from the coil. Let me know result.—GEORGE TOLMAN.

[46605.] — **Dynamo-Machines Sparking**. — This is sometimes due to a little oil being on commutator, or brush a little behind time.—GEORGE TOLMAN.

[46606.]—**Headstock**.—To "SUNLIGHT."—The time at my disposal is so very limited that the sketch I send you is a very rough one, but it will perhaps give you some idea in conjunction with the description. First let me say that the main casting looks somewhat heavy, but I am strongly opposed to flimsy castings in any tool, and I therefore sketch such proportions as I should use myself. You will note that the mandrel is made with double cones, the back one sliding on a feather and set up with lock-nuts. For a 5in. headstock I should use a thread on the nose 1in. diam. and 8 threads to the inch; let the screw be 1¾in. long, total length of mandrel, 19in, bearings to be 3in. long each. The gears must be according to what patterns you can get, except you buy them ready cast of the correct size and pitch. The gears you had better let me know as to whether you can get patterns or not. There should be the two large wheels, about 7in. diam., 1¼ wide and about ⅜in. or ½in. pitch; the back gear shaft is carried on arms cast in one with the headstock, as shown. The other details will, I fancy, best be got at by your asking me questions, but I would strongly advise you to make a scale drawing before you attempt a start.—SUNLIGHT.



[46607.]—**Fuller's Battery**.—It is not suitable for your purpose, unless your apparatus is made for it.—GEORGE TOLMAN.

[46607.]—**Fuller's Battery**.—I have had large numbers of these at work, and at one time had them in circuit for months at a time. They are a fairly constant form; but the great thing is that they are practically powerless. I had a variety of forms, to arrive at (if possible) the best form; the result being I classified them into two forms—one for the maximum of constancy, and the other for maximum power, the time in action being a secondary point. If the utmost power be wished for a limited time only, say a week or two, then I found a cast-zinc plate in a flat porous cell the best form; if for constancy, then a star-shaped zinc in a No. 5 round porous cell—the carbon element being the same in both cases: viz., a plate of carbon 7in. by 3½in. It is really a double fluid bichromate form. You would require a containing-pot, either flat or round, as the case may be, a porous cell the same, a plate of carbon the size I name, and the plate or "star" of zinc. A sketch of the zinc star will be found in Vol. XXXII. or XXXIII. I think. I write this away from home, or would refer you to the exact page. The carbon needs, however, careful preparation. First melt some paraffin wax, make the carbon plate hot also, and dip it endways into the melted wax for the first 2½in., and thoroughly soak the wax in with heat. When cold, with a Bunsen flame and the blowpipe, drive the wax back from the extreme end for say 1in. towards the centre, so that a band or zone of wax is left in the pores of the carbon, say 1½in. wide. To the top 1in. of the carbon the binding-screw is fixed. I always prefer to electrotype this part with copper. It is a very little trouble, and you then solder the binding-screw on, and get a connection far superior to anything else that can be got. The zinc plate or star must also have its binding-screw fixed to it, preferably either cast in or else soldered on. Now, we place the carbon plate in the containing pot, whether flat or circular, then the porous pot in that, and the zinc element inside the porous jar. The zinc should be just dipped in fairly strong acid and water to clean the surface. To charge the battery, into the porous pot place 1oz. of mercury, and fill up to within an inch of the top with pure water. In the outer pot pour water saturated with bichromate of potash, and then add crystals of same, 2oz.; sulphuric acid, 6oz, and the battery is ready. It will not work for a few hours, as the acid needs to penetrate the porous cell. If the porous pot is too soft the battery gives a good strong current, but does not last. If too hard, is very constant, but does not give the power. The mean is what you want. Exhaustion of the bichromate solution is evinced by its turning purple, whilst the current being found slow, can be remedied by taking out some of the water from the porous pot and replacing with pure water, as it becomes saturated with the salts of zinc. You can use it for almost any electrical purpose, not forgetting that it will not give the current of the Bunsen, and that, therefore, many more cells are requisite to do the same work. I have repeatedly used it for driving induction coils, as it was constant and fumeless.—SUNLIGHT.

[46608.]—**Strength of Battery Current**.—This is alternating (the coil) current. I have not seen anything for testing it.—GEORGE TOLMAN.

[46615.]—**French Express Locomotives**.—A reply to this query appears among the letters.—ED. GOBERT.

[46616.]—**Leclanche Battery**.—Perhaps some of the zincs were amalgamated: that is no detriment; the cells will work.—GEORGE TOLMAN.

[46616.]—**Leclanche Battery**.—Many thanks to "Kappa" and A. W. Soward, for noticing my query. By copper pole, I mean free carbon of battery. My cells are connected thus: zinc of No. 1 with wire from bell-carbon with zinc of No. 2, carbon of No. 2 with zinc of No. 3, carbon of No. 3 with wire to push. The zinc in No. 3 turns quite black, the others remain bright. I obtained the water from a small stream, the sal-ammoniac was sent with cells. I have examined wire to push, and believe insulation to be perfect.—ODDFELLOW.

[46617.]—**Sewer - Gas**.—Stop all the proper openings to the drain, and burn some sulphur in the drain in the lowest position accessible, in an iron vessel into which some burning coal has first been put.—C. S.

[46621.]—**Dynamo Machine**.—I do not like the ring of iron wire unless it is cotton covered, and the ends perfectly insulated. Are the coils all in one direction? Can you test for any leakage between wire and ring? The coils must be insulated from ring. Annealed cast iron is best for ring.—GEORGE TOLMAN.

[46627.]—**Watch Escapement**.—You can examine roller and lever contact in the following way:—Move balance round till tooth drops off pallet on to other pallet, locking face. When that takes place, hold balance still, take hold of lever-tail and try if there be shake: there should be just a little corner shake of lever on pin, so that pin can pass out free, when wheel tooth drops; if it does not, corner of lever wants shortening until there is corner shake of lever. Also when guard-pin is pressed against roller the pin should pass free into lever-notch; if not guard-pin must be brought nearer to roller and banking-pins opened. There are lots of causes of watches setting, i.e., motive force not sufficient, balance-spring not pinned in right, pallets out of angle. It is difficult to tell without seeing your watch.—WORKING BLACKSMITH.

[46634.]—**Fixing Electric Wires**.—1. They are not strained, merely stapled. 2. Candle and blowpipe, rosin, solder, experience. 3. Some bells will ring through half-mile, others fifty yards, according to purpose they are made for.—GEORGE TOLMAN.

[46634.]—**Fixing Electric Wires**.—To "SUNLIGHT."—Thanks for answer; but my query referred to how to strain and fix wires on posts and insulators, or rather to outdoor walls and insulators. Will you, therefore, kindly further answer? Longest distance between insulators about 50 yards. Please also say the nearest distance the copper wires may be to a damp wall so as not to leak.—Meme.

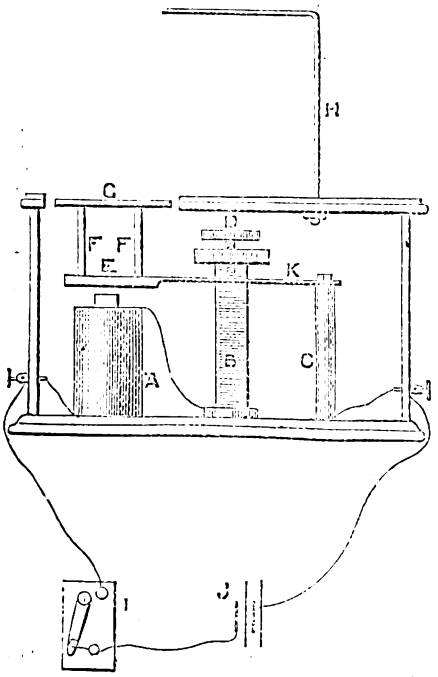
[46635.]—**Fixing Electric Wires.**—(1) Wires for domestic telegraphs or bells do not require any straining up; they should simply be laid along, either under flooring or close to ceilings. As they are insulated and covered in different colours, they may match the general colour of wall-papers, and any straining would certainly injure the insulation. Ordinary bell-staples should be used to keep wires in position, but must not be driven home tight. (2) All joints should be soldered; but in places where this is very inconvenient, the ends should be well cleaned and twisted together, and covered with indiarubber tissue, sold for that purpose. This readily melts, and should be well pressed round joint with wet fingers, so as to exclude the air. (3) The length of wire through which two Léclanche cells would work a bell depends on size of wire used, as the resistance is in proportion to the sectional area. If No. 14 B.W.G. copper wire were used, a mile or mile and a half would not be too long; but for work in a house, No. 18 insulated wire is large enough.—Philolektron.

[46636.]—**American Cloth.**—If "B.'s" table is covered with what is called bright-grain American cloth, and in a warm room, we are not surprised at his papers adhering to it. We would advise that the table be covered with dull grain American cloth, and then washed over two or three times with milk.—A. Manock.

[46637.]—**Mount-Cutting.**—May I supplement my letter upon page 160 by stating that a retired carver and gilder informs me that he resided next door to a mount-cutter for some years, and that his gear consisted of a beech cutting-board, one or two stones for sharpening the knife, and the knife itself was merely a shoemaker's old knife, which was covered with guttapercha, within ½in. of the point, so as to obtain a very short hold of it, with the requisite steadiness of cut, and that having pencilled out the desired oval or square, on the cardboard (by means of trammels and straight edge, &c.), he whipped the knife round with amazing dexterity and celerity to any desired bevel, using his thumb as a fulcrum. Then, taking a thin stip of gold paper, which had been previously prepared with size; drawing this across his mouth, he applied it to the said bevelled edge. J. J. A., Liverpool.

[46640.]—**Electric Dancing Figure.**—What kind of figure? If a light one, the bell-fittings you have would do it, with three cells.—George Tolman.

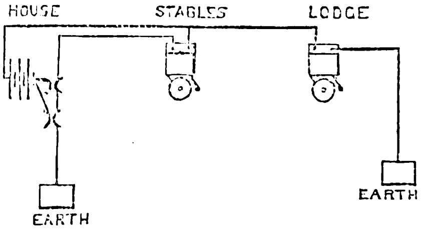
[46640.]—**Electric Dancing or Working Figure.**—The following description is of an electric dancing figure which I have myself constructed and found to work extremely well. I do not think a very long description is needed, as the querist will see from my drawing how to set about constructing it. A is an electro-magnet, horse-shoe shape, wound with about ¾lb. of No. 18 cotton-covered wire. The poles are about 3in. long and the same distance apart, and ½in. diam. B is a brass standard with a thumb-screw, D; C is a brass pillar for supporting the spring K, made of rather stiff steel (clockspring), carrying the round iron plate E, 2in. diam. and ⅜in. thick; FF are two brass rods about ¼in. diam. for supporting the brass plate G, upon which the figure stands; H is a wire for supporting the figure. It should be supported by the wire so that its feet only just touch the brass plate G; I is an ordinary switch, and J is the battery. I have never seen or heard of Mr. Bennett's battery, having only just commenced to take the "E. M.," but my machine would work for two hours at a stretch with a bichromate battery of two elements, 6in. by 2in., just giving the solution a stir up now and then. The whole machine is inclosed in a mahogany case, so that only the figure and binding screws are seen.—Grapho.



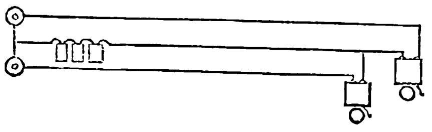
[46641.]—**Electric Bells to Connect.**—You may use one battery to ring any number of bells, provided it is strong enough. You had better run one additional wire from the house to the lodge, and another from the lodge to the stables, joining one of the wires already laid anywhere between the stable-bell and the house. You might use the earth for the return current; but I think the cost of two large copper plates would exceed that of the insulated wire for so short a distance.—Tortoise.

[46641.]—**Electric Bells.**—Your best way is to use one direct wire to either place; then use either an earth connection, or else carry the return wires to the nearest point, and then, by one main wire, to the battery. Or, to put it plainer—You need to carry one wire from the house to stable, and another wire to the lodge. As the lodge is but 200 yards from the stable, I should run the return-wire from the lodge on to the stable's return-wire. You then need only the new length of wire to reach from house to lodge by shortest route, and from thence to stable for the return.—Sunlight.

[46641.]—**Electric Bells to Connect.**—This is a very easy affair. You will have to make earth at house and at lodge-gates. The sketch I send will explain.—George Tolman.



[46641.]—**Electric Bells to Connect.**—You can make use of both your present wires, extending them from the poles of the existing bell to the new bell; but in such case both bells will ring simultaneously. If you wish to ring them separately, you can use your present battery-wire as far as it goes, connecting the new push to one end of it, and the new bell to the other end, so as to include the battery between the connections; but you must run a separate wire from the push to the bell, as shown in the diagram above.—R. T. Lewis.



[46644.]—**Painting.**—There is a kind of paint called flatting, which would probably answer "Cambridgeshire Boy's" purpose, as it has both a dead appearance and takes the varnish well, the same as he speaks of. It is mixed with turpentine instead of oil.—A. Manock.

[46649.]—**Mounting Micro. Lenses.**—There is no standard for the microscope threads used other than the universal thread and gauge for the objectives. These can be obtained at the Micro Society's office, I believe, at King's College. The threads used for the other parts are the usual and various threads used by mathematical instrument-makers, opticians, &c. Now, as to mounting the lenses: The eyepiece lenses are at once the simplest, and the objectives the most difficult lenses to mount possible. For the e.p. it is necessary to turn a shoulder with a rim or, as it is called, a bezzle standing up just high enough to turn over, say, a 1-50in. above the glass. The glass is held in lightly with one finger of the left hand, while the cell is on the lathe; then, by bringing a small steel burnisher to bear with slight pressure against the bezzle, it is pressed neatly over the lens while the lathe is slowly revolving. The left hand finger in use soon feels when the glass is fast. It is essential not to use too much pressure in burnishing, or the glass will break. Also, that the bezzle must be thin, say as thin as notepaper. As to the objectives, the mode I adopt will be explained in the construction of achromatic e.p., which I intend to bring forward as soon as the specula is treated of. I dare say "Micro." will not mind waiting, unless some of "ours" give their procedure. This will be be better. "Micro." may then choose if the modes differ.—Prismatique.

[46654.]—**Storage Battery.**—"Dix-huit" will find Sutton's Storage Battery as easy to make as any. The following is the inventor's description:—"The cell is composed of a sheet of lead cleaned with dilute sulphuric acid, and amalgamated thoroughly with mercury, and a sheet of thin copper a little shorter; the two sheets are perforated with a number of holes, and then rolled in a spiral, separated by rubber bands cut every five inches, the holes in plates and cuts in rubber bands being to allow free circulation of the solution (the short plate being uppermost before rolling). This combination is immersed in a solution of cupric sulphate [to which, in a later paper, Mr. Sutton recommends the addition of one-twelfth of sulphuric acid], and the amalgamated lead plate made the positive electrode of a suitable source of electricity. The chemical action being, the oxygen of the decomposed solution combines with the lead, forming a perfectly even coating of the insoluble peroxide, the hydrogen replacing the copper of the solution, the copper being deposited in the metallic state on the negative electrode. As the decomposition of the cupric sulphate proceeds, it gradually loses its azure blue colour, becoming more acid, and finally, when the whole of the copper is deposited, we have the solution colourless, and transformed into hydric sulphate and water, the positive electrode peroxidised, and copper deposited on negative electrode. During discharge, the peroxide is reduced and the copper element oxidised, the oxide combining with the acid and forming cupric sulphate, the solution returning to its original colour. This change of colour forms a beautiful means of telling when the cell is charged." The strip of lead may be about 4in. wide by 30in. long, and the copper the same width, but about 6in. shorter. One or two Bunsens may be used to charge the battery.—Alfred W. Soward.

[46655.]—**Astatic Galvanometer.**—The needles must be as near astatic (i.e., of equal power) as possible without completely overcoming the directive action of the earth upon the system, so that, when no current passes, the index will remain at zero.—J. M. Stocks.

[46655.]—**Astatic Galvanometer.**—Both statements are correct. The needles being equal in power a perfect astatic system would result, moving with infinitesimal action. But there must be some resistance to bring the indicator to zero, and it is convenient to leave one needle rather more powerful than the other.—Sigma.

[46655.]—**Astatic Needles.**—When the needles are equal in strength, and their magnetic axes are in the same vertical plane, the system will be perfectly astatic, and will set in the direction determined by the torsion of the suspending fibre. When the needles are equal in strength, but their magnetic axes are not in the same vertical plane, the system will set at right angles to the magnetic meridian. When the needles are of unequal strength, the system will set *in* the magnetic meridian. In constructing a galvanometer, it is generally sufficient to make the needles approximately equal; but where very great delicacy is required, they should be exactly equal. Owing to the practical impossibility of fixing the needles in the same vertical plane, they will always point either north and south, or east and west.—Alfred W. Soward.

[46655.]—**Astatic Galvanometer.**—Quite so. As far as practicable the needles should be of equal power, so that one would balance the other in relation to the tendency to point north and south. But it is an impossibility, almost, to get the magnetic power the same in both. Hence, one needle is a little more powerful than the other. Therefore the strongest magnet of the two controls the stationary direction. As far as the quotation goes it is correct: that is, that if the one needle is much stronger than the other, there is less oscillation, and after a deflection, a state of rest is again arrived at sooner. But as far as extreme accuracy goes, the more accurately the one magnet balances the other, the more precisely exact is the indication. The question may be thus put: an unmagnetised needle would be not deflectable, therefore, to make it so, we need to give it magnetic power. When this is done, we also find that the property so given it, holds it, as it were, against a force which should tend to deflect it. Therefore, the inherent power must first be overcome before any deflection is obtained. Hence, the astatic form, in which also we have imparted to a needle the magnetic pole-seeking property; by the addition of the second needle we counterbalance, to a very large degree, the previous inherent resistance that it interposes to being deflected by a test current. Therefore, for extreme delicacy, the needles should as far as possible, balance one another; whilst, at the sacrifice of some delicacy, we get a steadier deflection, and a state of rest is sooner arrived at. —SUNLIGHT.

[46657.]—**Turkish Bath.**—Remedy: Pipe C should enter at the bottom at one end, and pipe D should come from out of the top at the other end, also pipe D should be considerably larger than pipe C. Also there should be divisions on the inside of chamber A to prevent the cold air rushing through before thoroughly warmed.—WORKING TOM.

[46657.]—**Turkish Bath.**—If the relative positions of the heater to the bath-room be as shown in sketch, then there is but little wonder. The bath-chamber E must be at a higher level than the heater A B. Then the pipe C should be carried to the lowest joint and coolest part of A B; whilst D should be taken from the top of the heater. Then you also need a valve to allow the hot air to displace the cold air in E at starting, and you would not be troubled with the flow being the wrong way. —SUNLIGHT.

[46657.]—**Turkish Bath.**—The reason why the hot air will not pass into the room seems to be because the two pipes are on the same level. The cold-air pipe should be very much lower than the hot-air pipe. Perhaps the defect may be remedied by bending the end of the cold-air pipe down. If this is not sufficient the hot-air pipe must be removed to the top of the heating-chamber. The hot-supply pipe should on no account dip downwards, as the heated air ascends. If the two pipes are re-fitted so that there is a perfectly direct rise from the mouth of the cold-air pipe to the entrance into the room, there will not be any more trouble. —EAST MEDINA.

[46658.]—**Date-Mark.**—The oldest date-mark known is in the reign of Henry VI. The cycle began in 1438, and the mark is a Lombardic letter. It appeared as an *h* in 1445. The next letter was in 1481, Henry VII., and was a D. The next was in 1498, Henry VIII., when a small Lombardic *b* was used. A good many gaps occurred during that king's time, but not so much as previously, and six "cycles" of the Goldsmith's Company had gone by. It was not until the era of Elizabeth, 1558, that yearly date-marks commenced for continuity. This mark was the black letter, small *a*, inclosed like the Lombardians. The mark for 1796 mentioned by "Alpha" was the Roman capital A inclosed in line. See Chaffers's "Hall Marks."—C. S. M.

[46659.]—**Spongy Platinum.**—Did "G. F." use chloride of sodium instead of chloride of ammonium? Even the ammonium precipitate is slightly soluble, and only requires a slight washing to reduce the fumes given off when heated.—SIGMA.

[46659.]—**Spongy Platinum.**—If you evaporate the solution and ignite the residue, your Pt will be left in the spongy state. In future, prepare the chloride, precipitate, evaporate, ignite, and wash at the finish if necessary.—J. M. STOCKS.

[46659.]—**Spongy Platinum.**—A solution of ammonic chloride produces with platinic chloride a yellow precipitate of ammonic platinic chloride ($2\,NH_4ClPtCl_4$), which is soluble in much water. Hence, "G. F." has redissolved his precipitate on washing; but on evaporating the yellow solution to dryness over a water-bath ammonic platinic chloride will be again obtained, and on heating to redness, by which means ammonia and chlorine are expelled, leaving only spongy platinum.—L. HEAP.

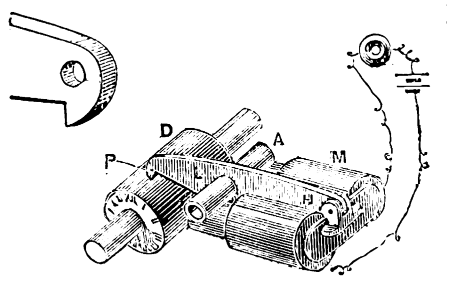
[46659.] — **Spongy Platinum.** — Evaporate your solution of double chloride to dryness, and then ignite the residue at a dull red heat. Be very careful not to raise the temperature higher than is necessary for the decomposition of the double salt, as the lower the temperature at which the decomposition is effected the more spongy is the metal obtained. Assuming that your platinic chloride and ammonic chloride were pure, there was no necessity to wash your precipitate. Certainly you should not have added sufficient wash-water to dissolve it.—ALFRED W. SOWARD.

[46660.]—**Sutton's Secondary Battery.**—Mr. Sutton, in his supplementary paper read before the Royal Society, says that the addition to the solution of culpric sulphate of one-twelfth of sulphuric acid "improves the cell at once." Mr. Stutchbury might try the effect of adding a quarter of a pint of sulphuric acid to his sulphate solution. —ALFRED W. SOWARD.

[46661.]—**Watch-Balance Springs.**—You can get pendulum-springs at almost any price from 2s. a gross to 2s. 6d. each. I use Lutz's springs, at 5s. 6d. per dozen, best quality, and I believe they are generally used. The secret make I have not used. For verge work, I generally make my own. I will give a description of tool if you like.—WORKING BLACKSMITH.

[46661.] —**Watch Balance-Springs.** —The most costly watch balance springs that I know of are from Switzerland, I believe they are called "Hillgren's springs," and the flat ones with overcoil are 2s. 6d. each to the trade. They won the gold medal of the Horological Section of the Society of Arts, Geneva, and are making a high reputation in this country. They are only used for first-class watches, unless by special request. Mr. W. G. Schoof, of the British Horological Institute, Northampton-square, can give every information about them, and is the only person in England though whom they can be obtained. Mr. Schoof has tried these springs extensively, and as he is an experimental horologist as well as a practical watchmaker, his opinion about their merits will be conclusive. I have long thought of testing one or two myself. —C. S. M.

[46662.]—**Electric Tell-Tale Clock.**—A drum carries a strip of paper which is wound upon it. The surface has grooves cut in it, either circular or (if to indicate for more than 12 hours without attention) spiral. In the latter case, one end of axis of drum is cut with a screw of the same pitch as the grooves on the drum, and works in a fixed nut, so that when rotated the drum travels along an axial line at such a rate that the grooves retain the same relative position to a fixed point, such as the indenting point, presently to be described. The drum has the hours engraved at one end, and is made to rotate once in 12 hours. A spring (not shown) holds the cylindrical armature off the face of electro-magnet (*m*) until a current passes, when the lever is drawn down, and the point (*p*) makes a puncture in the paper. The position of this puncture relatively to lines drawn from the figures on end of drum along the paper in direction of drum's length will indicate the time at which current passes. A simple contact spring, such as is used for ringing electric bells, is pushed by the watchman, when making his rounds, and a record is made on the paper. If this is not sufficient please write again.—GLATTON.



[46663.]—**A Street Nuisance.**—Any person collecting a crowd in a public thoroughfare, to the annoyance of the inhabitants or passers-by, is undoubtedly guilty of committing a nuisance, and he can be proceeded against criminally by indictment and civilly by an action for damages. But though this is the law, I am well aware that its application is a troublesome and expensive matter. There is also the remedy under the Police Acts for causing an obstruction in the highway; and the police ought to interfere, but it seems that they refuse. The only advice I can give "Ajax" is to get his neighbours to unite with him in bringing an action for damages against the leaders of that branch of the Salvation Army by which the meetings are organised, and thus raise the question, and I believe they would succeed.—FRED. WETHERFIELD, Solicitor, 2, Gresham-buildings, Guildhall.

[46664.]—**Resistance of Electric Lamps.**—"Nun. Dor" is informed that connecting up lamps in multiple arc does not reduce their resistance, it only reduces the resistance of the total circuit to one fourth of what it would be if joined up in series. The lamps must always remain the same, although the current has one fourth the distance to pass through.—GEORGE TOLMAN.

[46664.]—**Resistance of Electric Lamps.**—Taking the resistance of a Swan lamp as 50 ohms, the resistance of four ranged in series would be 200 ohms, as stated; but if the four are arranged in multiple arc, the resistance will be 12·5 ohms, not for each lamp, but for the four together. There are four pathways open to the current, each as large as the original pathway, and the total resistance of the four lamps is, therefore, just one-fourth of the resistance of the single lamp. If 50 lamps were arranged in multiple arc the total resistance would be one-fiftieth that of a single lamp, that is 1 ohm.—ALFRED W. SOWARD.

[46664.]—**Resistance of Electric Lamps.**—Does not "Nun. Dor." see that the resistance of 12·5 ohms is the resistance of the whole four lamps together—not of each? The resistance of each lamp never changes. When the lamps are joined in series, the current passes through all in succession, and the resistance is quadrupled. When arranged in multiple arc, the current divides and passes equally along all the resistances. The four are, in fact, equal to one of one-fourth the resistance of one lamp. The four carbon loops are equal to one loop of four times the sectional area of one. Hence it is plain that the resistance of 50 lamps in multiple arc would be 50 / 50 ohms = 1 ohm.—W. H. L. H.

[46664.]—**Resistance of Electric Lamps.**—The resistance of each lamp is not altered by any arrangement; but if we give the current four equal paths, of course fourfold current will pass if the source can supply it; and this is expressed as being due to diminished resistance, though it is truly due to increased conducting capacity. When circuits are arranged in multiple arc—that is, as concurrent conductors, the resistance to the current, that is the total resistance of the combined circuits, is diminished in the ratio of their number, while if placed in series it increases in that ratio. But this in no way affects the separate resistances.—SIGMA.

[46664.]—**Resistance of Electric Lamps.**—The resistance of a lamp cannot be changed by changing from series to multiple arc, as "Nun. Dor." presumes, but the total resistance in circuit can thus:—

Let R = Resistance of circuit.
„ r = „ 1 lamp.
„ n = Number of lamps.

Then, if several equal resistances (lamps) are in series, then $R = r \times n$, thus $50 \times 4 = 200$ ohms; or, if several unequal resistances are in series, then R = their sum; thus $100 + 50 = 150$. If several equal resistances are joined in multiple arc, then $R = r / n$, thus $50/4 = 12{\cdot}5$ ohms; or, if several unequal resistances are in multiple arc, then, as the conducting power of a conductor varies as $1 / r$, and the total conducting power is the sum of all the conducting powers, thus:—$1 / 100 + 1/50 = 3 / 100$ is the total conducting power, and the total resistance is $100 / 3 = 33{\cdot}33$. The total resistance of conductors in multiple arc must always be less than the resistance of the conductor of least resistance in circuit. Upon this rests the fact that Holborn is lit by a current which (it is said) cannot traverse the human body.—J. M. STOCKS.

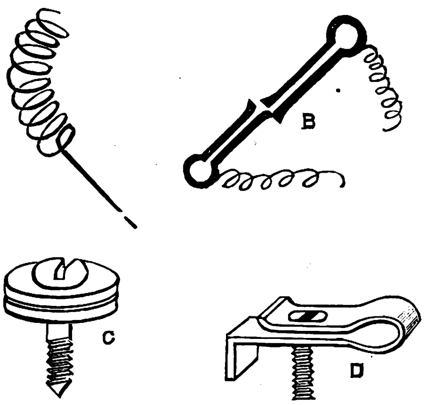
[46664.]—**Resistance of Electric Lamps.**—The resistance of each lamp is a constant. Perhaps an analogous illustration with water would help you. Suppose you have a syringe full of water, and that by applying a given weight to the top of the piston-rod you empty it through a single hole in the bottom in one minute. Now make another hole of the same size. The same weight which was used before will now empty the syringe in half a minute about; that is, the water meets with only half the resistance to its flow which it did before. If three holes are made, the resistance will become ⅓rd of that in the first instance, and so on. Now, each hole offered the same resistance per unit of water passing. Now, it is clear the greater the number of holes the less the total resistance, although each hole offers a fixed resistance to a fixed rate of flow. The syringe must be filled more often than before—i.e., will use a greater quantity of water per minute with a large number of holes; but the weight does not need to be increased to maintain the same rate of flow in each hole. Now, for the syringe substitute a dynamo-machine, let the holes be each replaced by an electric lamp, the weight will become electromotive force, and the quantity of water used per minute by the syringe will be represented by the current flowing from the dynamo-machine. As before, the resistance is diminished, and the capacity for current increased by increasing number of lamps, so that instead of altering construction of dynamo—i.e., putting more weight on piston of syringe, we need only drive it faster. Fifty lamps would together (not singly) offer a resistance = 1-50th of a single one—i.e., 1 ohm, and would require 50 times the amount of current.—GLATTON.

[46665.] — **Discolouration of Paint.** —The question of the discolouration of paint containing zinc-white as a basis, has been investigated by Dr. Phipson; who arrives at the conclusion that the discolouration is due to the presence of an hitherto unnoticed metal, which he calls actinium, whose sulphide has the property of darkening in the light and of regaining its colour in the dark. He states that such paints can be protected from the action of light by thin plates of glass, but this does not seem to agree with "Achromatic's" experience.—ALFRED W. SOWARD.

[46666.]—**Organ.**—American organs, which all work on the suction principle, have swells which are practically identical with the venetian swell of the harmonium. The difference is this: In the A.O. the reeds are exposed to the atmosphere, and each row (or, to be more accurate, each side of the tubeboard) has a swell shutter—that is, there might be two rows, one over the other, when one swell shutter does for both. In the harmonium the reeds are inclosed in the well, and it is the pallets that are boxed up in a chamber fitted with venetian shutters. The effect can be produced by varying the air supply; but all decent American organs are fitted with swells. The fact is, the reeds speak with so little wind that it is difficult to keep at pianissimo by mere regulation of the blowing, for you are liable to get no speech at all from want of wind, so gently must it be done.—Organon.

[46672.]—**Binding Screws.**—"Crux" evidently goes to Bond-street to make his purchases. They are sold elsewhere at from 1s. 6d. per dozen; that is cheap enough.—George Tolman.

[46672.]—**Binding Screws.**—I send sketch of a few substitutes. A is a bit of wire twisted into a spiral and bent as shown. It is held straight while end of wire to be connected is inserted, and on being released tries to resume its former shape. B represents two bits of stiff wire. They are bent as shown, and connected by being slid together—one of the best connections I know for temporary work. C, two brass plates with a wood screw, screwing into woodwork of instrument to which it is attached. The lower plate is soldered to one wire, the other wire being pinched between the two plates. D scarcely needs any explanation. The screw may be dispensed with.—Glatton.



[46672.]—**Substitute for Binding Screws.**—To join two wires without the aid of a binding-screw, proceed thus:—Clean the ends; amalgamate them by aid of a mixture of tallow and mercury spread on chamois leather: bend an inch of the end of one wire back on itself, forming a V-shaped bend; twist the end of the other wire into a small spiral that will fit spring-tight upon the V; dip both into mercury, and press the V into the spiral. In joining up batteries, solder wires to the plates wherever possible, and join these as above, being careful to make all battery wires terminate in V's, and not in spirals, as the former are more easy to clean and re-amalgamate than the latter. Two V-wires may be joined together by a single spiral. Thus, platinum and zinc of a Grove's battery may be held together by an American paper-clip (price one halfpenny.) If the spring is not strong enough to give good contact, press a small wooden wedge between the open jaws, and so force the jaws holding the plates more closely together.—Alfred W. Soward.

[46674.]—**Telephone.**—"Crux" can make an induction coil for 2s. Surely that is not expensive. The use of the coil cuts off a lot of the jarring noise, so the current must be evidently weaker.—George Tolman.

[46674.]—**Telephone.**—The induced current will go through a greater resistance than the simple battery current. The cost of making induction coil need not necessarily be large.—Glatton.

[46675.]—**G.N. Engine, No. 48.**—No. 48 is one of the 8-footers. Cylinders 18 by 28. I will not give more particulars, as your correspondent will find all the dimensions, as well as other particulars, in back volumes (XXVI.-XXVIII.). The engine was built at Doncaster, in 1875, and was in the Abbotts Ripton accident. No. 48 was not at Darlington, the engine sent by the G.N. Co. was No. 47 of a similar class. With regard to query 46612, "N.L. Engines," addressed to me, I wish to state that I have no particulars of either of the newest types of these engines.—Meteor.

[46677.]—**Musical-Box.**—The defect is probably caused by the comb not being screwed down tight. In such a case, the remedy, of course, is simple. The comb being anyways loose, will produce a similar noise as described in the query.—G. Fryer.

[46680.]—**Horizontal Escapement.**—To put in beat, notice three dots on plate near rim of balance, and one on the edge on balance rim. Put bristle from brush in escape-wheel, to keep it from moving, and pin pendulum-spring in so that the dot in balance stands in a line with centre dot on plate.—Working Blacksmith.

[46682.]—**Hydrometers.**—The values of the degree of Baumé's scale for heavy liquids are as follows:—

B.	Sp. Gr.	B.	Sp. Gr.	B.	Sp. Gr.
0 =	1·000	25 =	1·210	50 =	1·532
5 =	1·036	30 =	1·263	55 –	1·618
10 =	1·075	35 =	1·321	60 =	1·714
15 =	1·116	40 =	1·385	65 =	1·823
20 =	1·161	45 =	1·454	70 =	1·946

To convert Baumé's degrees into Twaddell's, find the specific gravity by the above table, subtract 1 from that figure, and divide the remainder by ·005. Thus, a liquid is of the specific gravity of 10 according to Baumé; what is it according to Twaddell? 10° B = 1·075 (where water = 1·000), 1·075 – 1·000 = ·75. ·075 / ·005 = 15 = specific gravity according to Twaddell.—Alfred W. Soward.

[46684.]—**Photo. Background.**—There is no difficulty in obtaining a dead surface with either distemper or oil-colour, the latter being mixed with an excess of turps; but the defect complained of is probably owing to some irregularity of surface reflecting light into the camera. Try the effect of leaning the background forward a little.—W. Robinson, Jun.

[46685.]—**Piston.**—Either the engine has been standing some time, and the piston is rusted fast, or you have run a long time without cleaning it. You must now take out the broken eye-bolt and get another made. Let the cylinder be warm to begin with, and run plenty of petroleum round the piston cover, pouring some in through the bolt holes of cover as well. Let it have time to soak through, and try again, gently tapping the cover with a hand-hammer. If it will not come off this way, then the quickest way will be to take piston out of cylinder whole, and get the cover off by heating it with pieces of hot iron, keeping the block cool at same time by waste dipped in cold water frequently renewed. This last job requires care and judgment, and if you have never had such a job it would be well to get someone to assist you. But any advice I can give I will with pleasure.—Labor Omnia Vincit.

[46686.]—**Organ Reeds.**—It is not to be wondered at that the querist is at his wits' end after interfering with his organ in the way he has. It is impossible for any correspondent to advise with any degree of success in such a case as this, as it is, beyond doubt, one requiring personal inspection by an organ-builder. No person can form any idea of the cause of the defects mentioned in the query, without examining the organ in question. The best advice that can be given through the columns of the "E. M." is that the querist should consult an organ-builder, who will, no doubt, give his advice gratis, if he thinks he is likely to have the job to put it right again, which I must assure the querist will undoubtedly be an exceedingly troublesome one. The querist asks for a few hints on what he terms "the mysterious subject of reed-voicing." As he is evidently ignorant of the difficulty in the art of voicing reeds, he had better scout the idea of attempting it, as it is an art requiring considerable practice and skill. My advice to "Wits' End" is (with regard to voicing reeds), that he had better not attempt it. I can furnish him with a few hints on the subject, but without practice and skill they would be of no practical use to him.—G. Fryer.

[46688.]—**Intensity and Quantity of Current.**—The words "intensity" and "quantity," as applied to a current of electricity, really have the same meaning. Given a certain number of voltaic cells, it will entirely depend upon the resistance of the circuit whether the most intense current (i.e., the current of greatest quantity) would be obtained by joining them up in series, or in multiple arc, or partly in one way, partly in the other. The current is strongest when the cells are so arranged that their combined resistance is equal to that of the remainder of the circuit.—Alfred W. Soward.

[46688.]—**Quantity and Intensity.**—These terms are often confusing. To give you a rough idea, take a Bunsen cell, and try what length of platinum wire it will heat to redness. Connect a couple of such cells in multiple arc; you will find that you cannot heat a much greater length of the wire, simply because it is now as one large cell; but connect the cells in series, and it will heat twice the length, because you have the electromotive force of two powerful cells. Four Leclanché cells in series will not charge an electro-magnet wound with 2½lb. of 16 wire (at least it will only support a few ounces); in multiple arc it will sustain many pounds—now we have the quantity of four weak cells arranged as one large cell.—George Tolman.

[46688.]—**Intensity and Quantity.**—When "intensity" is used now it means the quantity of electricity which flows through a section of the circuit in unit time. The term "strength" is used oftener, and means the same. If the electromotive force of one cell equal E equal 2, and the resistance of one cell equal R equal 3, and the resistance of the external circuit equal r equal 3, and the strength of current equal C, then $C = E/R + r$, and if you join six cells, as you say, for quantity, then $C = E/1\text{-}6\,R + r = {\cdot}571$; or, if you join six cells, as you say, for intensity, then $C = 6\,E/6\,R + r = {\cdot}571$; so that, if there is any difference, they are both alike, and which gives which "B. H." may settle if he can, as he does not say what was meant by "intensity" and "quantity" in his electrical days.—J. M. Stocks.

[46689.]—**Focal Length of Photo. Lenses.**—Yes, the figure referred to on p. 124 should be F / 16 and not F / 14. The principal or solar focus of a lens is the point at which all objects beyond a certain distance are sharply defined. As this distance is lessened the focal point gradually recedes; but except in copying or enlarging, it will seldom happen that this has any material influence upon the length of the exposure.—W. Robinson, Jun.

[46690.]—**Waterproof Cloth.**—Procure sufficient unbleached calico, or still better Drogheda linen, cut to shape and sew into form, give it a coat of size, and, when dry, one or two coats of boiled linseed-oil.—J. J. A., Liverpool.

[46690.]—**Waterproof Cloth.**—A sailor once informed me the only thing he could get waterproof was silk, boiled in linseed oil in which the whites of eggs had been mixed. I could not say the proportion.—Working Tom.

[46691.]—**Retouching Photos.**—"F. C." will find some useful information on re-touching in Vol. XXXI., p. 366, Vol. XXXIII., p. 496. Spots and streaks on negatives may frequently be filled in with pencil; but if not sufficiently opaque, a little black varnish should be used, the resulting white spots and marks on prints being afterwards touched out with colour. Of course this sort of patch-work should not be pushed too far. Better take a fresh negative, if practicable.—W. Robinson, Jun.

[46692.]—**Scotch Bagpipes.**—The usual hideous and monotonous sounds of the bagpipes, with which we are often favoured in our streets, will not present much difficulty in learning; but if "Cosmo" desires to learn to do anything decent with the bagpipes, he will find that it requires some little study and practice. You can obtain suitable music for the bagpipes from G. Butler, Haymarket, London. I have no doubt but that he can supply you with an instruction book also, if you write to him.—G. Fryer.

[46693.]—**Staves.**—I do not see how there can be any difficulty in reducing Baltic staves to Petersburg standards. If "H." will give an example with which he finds a difficulty, I shall be pleased to help him if I can.—G. W. B., 27, Wilbury-road, Hove.

[46696.]—**Bichromate Battery and Intensity-Coil.**—Make a fresh solution. What do you mean by an intensity-coil equal to 60 cells of this battery? J. M. Stocks.

[46696.]—**Bichromate Battery and Intensity Coil.**—These cells are not fit for electric lighting, as it means short-circuiting of the cells, which these will not bear. I have not been able to gain on the cells by the use of a coil; have tried a quantity coil, with 30lb. wire, but with no better results.—George Tolman.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

QUERIES.

[46697.]—**Railway Grease.**—Will some of "ours" inform me of the composition of the railway grease at present in use for lubricating trucks and carriages? Does soap ever find its way into the mixture?—Inquisitive.

[46698.]—**Fatty Anhydrides.**—Will Mr. Allen or some other kind reader inform me of the difference between fatty acids and fatty anhydrides in soap analyses? As some chemists estimate the amount of fat as fatty acids, and others as fatty anhydrides. Which is correct? And is there any rule by which one can be converted into the other?—Ignoramus.

[46699.]—**Shellac Cement.**—In back vols. recipes have been given for repairing broken glass by heating the glass, then sprinkling powdered shellac over the heated surfaces—join, and you will have, in a few moments, a joint so firm that it will bear a greater strain than any other part of the glass. Now I have attempted this mode of repairing glass articles over and over again, but invariably have failed. Will some kind reader assist either by pointing out my error in working, or by giving some recipe in which success is nearer certain?—Unfortunate.

[46700.]—**Intensity Coil.**—To Mr. Lancaster.—I have just completed an intensity coil of the following dimensions, viz.: core 3½in. long by ⅝in. dia. of No. 16 iron wire; primary, two layers No. 16 cotton-covered, with two ounces No. 36 silk-covered for secondary. When connected to a bichromate cell, gives a very small spark at the "breaker," which however, does not appear to vibrate. When the condenser (40 sheets tinfoil) is attached, the hammer sticks to the core. Will you kindly say where the fault is?—Bronte.

[46701.]—**Moment of Inertia.**—Would someone help me to an answer to the following?—1. The moment of inertia of a uniform rod with respect to an axis at right angles to its length passing through one end is $\frac{1}{3}$ (mass) × (length)^2. Show that when the rod coincides with one edge of a cube its moment of inertia, with respect to another edge which neither meets, nor is parallel to that edge, is $4/3$ mass × length^2. (2) Find moment of inertia—first, with respect to one edge; second, with respect to a diagonal.—Inertia.

[46702.]—**Drills.**—What is the difference between drills for iron and brass, and how should I set and harden them?—Tinker.

[46703.]—**Mounting Oleographs.**—In mounting oleographs on holland, does the latter, when on stretcher, require any preparation before putting on the oleograph? After mounting, and previous to varnishing, should the picture be sized? and if so, what can I use instead of parchment size?—An Amateur M.

[46704.]—**Blake Transmitter.**—Would Mr. Lancaster or other competent reader kindly tell me in what manner the carbon is fixed to the iron diaphragm so as to insure electrical connection in the Blake transmitter? A small sketch, with advice as to best means of making one of above, would be greatly esteemed by—Practical Amateur.

[46705.]—**Cart-Axle Grease.**—How is it that no axle grease is made in this country to correspond or rival American Frazer's? The common grease found in oil and colour stores is adulterated with powder of some sort, and is altogether bad stuff. I am anxious to prepare, on a commercial scale, a good, pure, cheap grease. I have made very good grease from rosin oil and milk of lime. This will not crust on the axle, and is very smooth; but it is too troublesome and too expensive in consequence of the water not combining, and having to be worked out. Will someone suggest a remedy or propose a different method of preparing a good cheap grease?—Mathew.

[46706.]—**Bleaching Palm-Oil.**—I have tried several times to bleach palm-oil by Watts' bichromate of potash process, but never with satisfactory results. Once, indeed, the bleaching was accomplished, but the oil had acquired a soapy consistence, which no amount of sulph. or hydrochl. acid would alter. I tried these acids separately, and together with bichromate of potash; but the soapy compound of a greenish colour always resulted. I used the exact proportions recommended, and carefully watched the temperature. I think the recipe is incorrect in one particular, as at 130° Fahr. (the temperature given for the chemical change to take place) I could see no change; but about 180° F., froth appeared, and changed colours just as expected at 130°. Will someone kindly say if this recipe can be used practically, and if so, give me the necessary specific directions?—Mathew.

[46707.]—**Scrofula.**—To Dr. Edmunds.—If you have not already treated on the above subject in these columns, I should be very grateful for a few remarks from your able pen that would guide me as to treatment and diet to keep the disease down (I am doubtful as to its cure). I am now about 22 years of age. Its first appearance was when a child in the form of a nub in the glands of the neck. Since that time it has broken and gradually spread year by year until it now extends from ear to chin. About February in each year for the last six years there is an excess of humour, which causes much pain until it is discharged, otherwise, I suffer no pain whatever. The natural skin appears to be eaten away, leaving a smooth red skin, which would bleed profusely if punctured in the slightest way. All round the edges a dry scurf-like substance forms, which is easily removed by a little vaseline being applied to it. I am a life abstainer and a non-smoker. I have tried a diet of vegetables for 10 and 12 months,—but am not doing so at present. It did not appear to affect me one way or the other. I naturally prefer living without meat. I get plenty of exercise and bathing in the season, and enjoy very good health as a rule.—"What Can't be Cured Must be Endured."

[46708.]—**Rain-Water Tanks.**—Will some of your correspondents kindly inform me what will be the best and cheapest material for a tank 11ft. × 6ft. × 3ft. deep, so that the water will keep sweet and good? Will it be necessary for bottom of tank, if of iron, to rest on a plain floor, or will three supports, one at each end and one in the middle, be sufficient? Would frost be likely to injure a tank of this size exposed to all weathers? Any hints will be thankfully received.—W. L. P. P.

[46709.]—**Mildew on Composition Statues.**—I have two very handsome composition statues very much stained by mildew. They will not take paint until the mildew is removed. What is best to be done?—Blackwater.

[46710.]—**Depositing Trough.**—Can an experienced electroplater inform me what "varnish" I should use to make a wooden trough impervious to the solution? I am depositing silver.—Electric Light.

[46711.]—**Terra-Cotta.**—Having seen some plaster busts and medallions that were coloured in imitation of terra-cotta, and having a few that I wish to do myself, would some correspondent kindly tell me what colours to mix, and how to produce that dead or flat appearance?—An Amateur M.

[46712.]—**Yacht.**—I am desirous of making a small yacht to carry one person comfortably, or two squeezed up. As the draught must not exceed 24in., and the boat cannot remain in the water, but be taken out and home when done sailing, it is necessary she should be as small and light as is safe. Where I want to sail is a very large shallow pond. If any of our kind readers could tell me the length, beam, and weight of ballast on the keel, and give as many hints as to building and rigging as they might consider useful, they would greatly oblige—Minim.

[46713.]—**Bleaching Clothes.**—I should be much obliged if you or one of your correspondents would let me know the proper way to use chloride of lime for bleaching linen and cotton things which have a bad colour through bad management and indifferent accommodation for washing on board ship during a long sea-voyage?—A Captain's Wife.

[46714.]—**Power of Engine.**—Would some reader kindly state the actual power of steam engine? Stroke, 4⅝in. × 3in., steam-pressure, 50lb. to the sq. in. Also, rule for finding same? and oblige—A. B. D.

[46715.]—**Photographic.**—1. How are opal plates got ready for painting on? Please explain the whole manipulation, how sensitised, &c. 2. I have made a camera after my own idea, which works remarkably well except in the bellows body. Would anyone please say how I might make a cloth body cheaply, what sort of cloth, and how to fold, &c.? Any hints on above will greatly oblige—Semper Fidelis.

[46716.]—**Sound in Pipe.**—Thanks to "Sunlight" for answering my query. I am afraid I did not give it quite clearly enough. But what I want is to prevent the water-pipe conveying the sound from tank to bed-rooms and let steam-pipe remain as it is. The steam-pipe is carried over top of tank, then down, and perforated pipe across bottom. This pipe has been the same as now for many years, but noise never heard in bed-rooms until water-pipe was laid to bath-rooms.—Anxious.

[46717.]—**Gas-Engine.**—To "Sunlight." — Will "Sunlight" kindly help me out of a difficulty?—I have made a model gas-engine, somewhat similar to the "Otto," which I cannot get to work. The reason, I think, is in the lighting arrangement, which I have made according to an illustration in the Mechanic of October, 1880, which does not give the means by which the gas reaches the slide-light; which, and the means taken to prevent the light blowing out too soon, are what I require to know. This is referred to in Crossley's specification, where it says that the lighting port is opened out towards the cylinder port to prevent the sudden pressure forcing the light back up the supply-pipe. I have cut a channel in the slide in the way I understand this to mean; but it will not do. So kindly explain the actual meaning of this passage in the specification. Also, when is the gas to the slide-light cut off? It seems to me that the mixture in the cylinder should begin to pass into the cavity in the slide as soon as compression begins, and therefore the gas should be cut off just before that. Is this correct? The slide cuts off the air supply to the cylinder about ⅛in. before the gas. Is this correct, or does it interfere with the lighting? A sketch of slide and cover would much oblige. May I ask "Sunlight" what gearing he used in his gas launch, as I have seen a steam winch with the engine constantly going, the barrel being connected to it by grooved friction-wheels, which appeared to be connected and disconnected with very little shock. Would not such means do well for a launch?—A. M. G.

[46718.]—**Varnish for Venetian Blinds.**—What is the best clear varnish for pine venetian-blind laths, mode of application, and price?—M. C. H.

[46719.]—**Reading-Lamp.**—The overflow of colza oil from a Queen's reading lamp is now and then so excessive as to fill the waste reservoir in two hours. This does not occur every night. The oil, wick, &c., are at all times precisely the same. Can anyone explain and give a cure?—M. C. H.

[46720.]—**Pitch of Cogs.**—Please to tell me the way to measure and strike out the pitch of cogs, gear, &c.—Jaff.

[46721.]—**Rights of Way.**—(1) Have Highway Boards power to come to an agreement between themselves and a landowner, or (2) tenant to stop a footpath? If not, what means are required to stop a footpath? (3) Also, what constitutes a right of way?—Q.

[46722.]—**Clockmaker's Lathe.**—Will some clockmaker or mechanic kindly give drawings and particulars of a clockmaker's lathe? as I am desirous of making one for myself.—Amateur.

[46723.]—**Marbling Chimneypiece.**—My chimneypiece is painted dark brown. Would some reader oblige by saying how I could imitate marbling or graniting? I may say I have a fair knowledge of common painting.—House Proud.

[46724.]—**Concrete Walls.**—What proportions of cement or ground lime mixed with broken stones (Portland) for walls of basement-floor about 8ft. high and 1ft. 6in. thick, the stones from an old building. Would they require washing? Which makes the best and cheapest work, cement or ground lime?—W. L. P. P.

[46725.]—**Plumbers in Paris.**—Would some reader of the "E. M" kindly oblige me by stating what prospects there are for English plumbers seeking employment in Paris or any part of France?—Shavehook.

[46726.]—**Paints, &c., for Steel Spanners.**—Will any of our readers kindly inform me the best way of getting up spanners in steel after cast and filed up? I mean what mixtures of paints to apply? And also, how to get that dark black oily surface which is usually on small steelwork? Also, the best mode and how to get a japanned surface on? At the same time, none of these mixtures to stick to the hands or come off when the article is being used.—Steel.

[46727.]—**Firing Loose Gunpowder by Electricity.**—Will any brother-reader tell me how to fire loose gunpowder by electricity? What strength and kind of battery (small as possible)? Will an induction coil be necessary. If so, what price?—Experiment.

[46728.]—**Ferrules.**—How do makers of ferrules for fishing-rods make the brass ferrules a steel or bronze colour?—Koptica.

[46729.]—**Vegetable Ivory.**—Will any of our readers kindly give us some recipes for preparing above? —Practical Colour Maker.

[46730.]—**Cheap Oils.**—I lately saw an advertisement in a newspaper stating that a good lubricating oil could be made at twopence per gallon. Would any of our readers who have such a receipt kindly give it for the benefit of ourselves?—P. C. M.

[46731.]—**Moulder's Blacking.**—I wish to make some of this. How is it made?—P. C. M.

[46732.—**Microscopic Fungi.**—Would some of your numerous readers say the best medium in which to mount microscopic fungi for the microscope.—L. L.

[46733.]—**Screw Propellers.**—Will any reader of "ours" kindly answer the following?—What is the diameter and pitch of the best known propellers?—Enquirer.

[46734.]—**Midland Engines.**—Can any reader give me the dates and principal dimensions of the following engines?—510, 481, 431, 429, 406, 395, 291, 274, 271, and 270.—C. H.

[46735.]—**"Eames" Locomotive.**—Would some correspondent give a sketch of the above engine, lately tried on the L. & Y.R.? The dimensions have already been given in the "E. M." It would be of great interest to know what trials are going to take place with it. —Tyre.

[46736.]—**Deliquescence of Salts.**—I observed—I believe correctly—that potassium nitrate in an anhydrous state refuses to absorb water from an ordinary saturated atmosphere. But when a fair quantity of water is first added to the salt, it goes on absorbing more water regularly from the air. Is this known? If so, are there other salts that act likewise? What explanation can be given of the experiment?—Kerux.

[46737.]—**Wild's Anemometer.**—Could Mr. Lancaster, or any other meteorologist, kindly give full description of the above with diagrams, if possible, and say how effective it is for measuring the strength of the wind? What ought to be the size of the swinging iron plate—what weight? What design could be adopted for keeping the plate always towards the wind? Could a curved piece of an iron strip graduated be placed in the direction of the plate's movement with an indicator to slide freely that way, but not back till again set by hand, so as to mark the force of wind? And if so, how, or what rule should be observed in graduating this? Full particulars will greatly oblige an amateur.—S. R. C.

[46738.]—**Universal Brake Couplings.**—Will any correspondent kindly furnish details of the Midland universal vacuum brake coupling selected at Euston, and also of the Westinghouse universal coupling, which, it appears, is likely to supersede it? Also, of any details being published relating to the construction of the vacuum brake being tried on the L. & N.W.R.? It is reported that the East Coast, West Coast, and Midland joint stock carriages are all to be fitted complete with two brake systems—air and vacuum—in order to avoid the present difficulty of interchanging vehicles. I notice that some carriages are already so fitted with duplicate gear. I shall be glad to receive any further information on the subject. Can any reader give me the date when a railway brake was first used or tried which worked through the compression of the spring-buffers? What line was it tried upon, and what was the reason of the idea being abandoned?—A Railway Servant.

[46739.]—**Nitro-Glucose.**—Can anyone give instructions for making nitro-glucose?—G. Thomas.

[46740.]—**Tests for 3in. Telescope.**—Will anyone give a few double stars, &c., with which I might test the powers of a 3in. astronomical telescope? Let them be such as I can find without the use of a star-map.—Wykehamist.

[46741.]—**Landscape Photography and Dry Plates.**—I have a pocket camera with a number of dark slides. I wish to take some views of landscapes, and will be thankful for information on this subject. The gelatine plates which I can buy are very quick. This would be of no advantage to me, as it matters not if I take the landscape in two seconds or in half a minute, and these very sensitive plates require manipulation in inconveniently dark non-actinic light. There may be a method of gelatine which is not more rapid than ordinary wet collodion and of good keeping properties both before and after exposure. If not gelatine, what is best for my purpose? Gelatine is wonderful for instantaneous work, but for landscape, where we can afford plenty of time, we want something more easily handled, at least, in the dark closet.—Holiday Work.

[46742.]—**Daniell Batteries.**—Why does the copper find its way into the porous cell? It becomes deposited on the zinc itself. I believe I always keep the sulphuric acid solution quite up to the level of the sulphate one. I am told that Daniell cells are very constant with the porous cell charged with plain water. Would not that increase the difficulty of the copper penetrating, owing to the greater specific gravity of the sulphate solution?—J. E. A.

[46743.]—**Microscope and Magic-Lantern.**—I have a good lantern for 10ft. disc; also a £5 microscope, and I want to know (they were purchased independently) whether I can adapt the microscope for use with lantern without damaging its proper uses. If so, how, and what parts thereof, and in which way to be attached?—Meme.

[46744.]—**Marble.**—Of what colours are Bethersden and Purbeck marbles, and is marble found anywhere but at Bethersden in the six "home" counties? Are there any books on marble?—describing the different varieties and giving a list of quarries in the United Kingdom.—Murano.

[46745.]—**Stopping for Decayed Teeth.**—I have been recommended to use cotton-wool, saturated with collodion and carbolic acid, "finishing off" with mastic. Is this good? Filling a hollow tooth with metal seems to me likely to make it ache—and that would be worse than hollowness. Would some of "ours" kindly give their experience of this interesting subject? I could not get the cotton-wool and collodion to harden or stick in the least; and everything I eat was flavoured with carbolic acid for three days.—Murano.

[46746.]—**Balmer's and Phillip's Gas-Stoves.**—A month or two ago someone advised me to alter one of Belmer's stoves to Phillip's plan. Would they kindly say what the latter is? Is a Mead's patent gasmeter likely to be in order that has been in use 18 years? It makes a peculiar squeaking.—Murano.

[46747.]—**Rapid Drying-Box.**—To "Gelatino Bromide."—Referring to your letter (19958), I, for one, should be glad to have, through the columns of "ours," a description of a good drying-box for an amateur.—R. T. B.

[46748.]—**Sharpening Carpenter's Saws.**—Will "Jack of All Trades" (see reply 46559) kindly go into this more fully, and say whether only one side of a single tooth should be filed at a time, whether all the teeth, whether set from or to you, should be filed with the saw in one position, and what the meaning of "buckle" is? I hope that he will forgive the ignorance of—Tiro Tironum.

[46749.]—**Hay.**—New hay, after being stacked a short time becomes heated by the chemical action of the various constituents of the grasses. In the case of hay not seasoned properly, the heat developed is often sufficient to char the hay and cause it to burst into flame. Can any of your correspondents give me any particulars as to the degree of temperature which is natural, and beyond which point the temperature acts injuriously on the hay? Also, what would be the probable degree of heat which would cause the hay to char or blacken, as seen in the case of many stacks after being cut?—Farmer.

[46750.]—**Tricycles.**—It would be very acceptable information to myself and to many other if some obliging correspondent versed in tricycle matters would kindly give the dimensions of some of the best-known machines. The important question is, what width opening the various kinds will pass through? The majority of those I have seen will not go through an ordinary doorway, and the trouble and expense of stabling make many would-be bicyclists afraid of investing in a machine. What I wish for is a table showing width of opening each will pass through, height, length, and approximate weight?—R. Smith.

[46751.]—**Windmill.**—To "T. N. C."—I should be glad if you would give us some more information about the windmill you mention on p. 525, No. 880. What is the use of the second set of sails? A sketch would greatly oblige. I should be obliged to anyone who would give a design for a turntable for windmill top that would be good and easy to make.—Samothes.

[46752.]—**Windmill.**—To Mr. Vallance.—I should be greatly obliged if you would give us a sketch and description of your horizontal windmill. I think it would be interesting to many beside—Samothes.

[46753.]—**A Water-Closet Nuisance.**—I have a water-closet in my house having the usual cistern supplied by a ball-tap from the main. The flush is excellent, and every time the closet is used the cistern is emptied, or nearly so, at the option of the user. But in the act of refilling by the action of the ball-tap, and just before the ball closes the tap, a very disagreeable loud hissing noise is made, ending in a loud whistle, sounding all over the house, and lasting for nearly a minute. I had the tap changed, but it was much worse, and had the old one put on again. Perhaps some of your readers or Mr. Davies (who has supplied those excellent articles on plumbing) will be able to suggest a means of remedy? I may say that the tap used is called a silent tap. I have two other ball-taps in the house not silent taps, which are perfectly silent. My plumber cannot effect a cure.—Silence.

[46754.]—**Repairing Watch.**—To "Alfojoe."—I cleaned my lever watch according to your instructions, and have it now going in perfect order with the exception of the stopwork, as I have broken the fusee chain several times, and have now to look at the barrel every time when winding, so as not to wind too far, or the chain would fly off. If you would kindly inform me how to remedy this I would be greatly obliged; and please accept my best thanks for your valuable instructions on how to clean a lever watch, which appeared some time ago. Also, how could I fasten the 'scape-wheel of a verge watch?—Country.

[46755.]—**Enlargements and Developing Tins.**—I have seen in some book that an enlargement can be made on bromo-gelatine paper by a French lens. I have a 2in. plate portrait lens. Would someone say how I can do it without a lantern?—giving full details, or recommend a cheap book with it in. I have made some tin developing dishes. What can I coat them with so that the pyro-alum or hypo will not affect them? Shall I paint and varnish, or coat with Brunswick black, or with shellac varnish—or what?—H. C. F.

[45756.]—**Bookbinding.**—I want a glue with which to attach sheets of paper in a block bound only at one end to the binding paper, such that any sheet can be removed at pleasure without loosening others. I have seen small note-books so bound. Can anyone tell me what ingredients to use?—X.

[46757.]—**Emery Wheels.**—To "Sunlight."—I have a small grindstone mounted in my lathe, but find that it is a slow and laborious way of doing the work I principally put to it, which is making tools for turning metal out of old files. I have heard that emery-wheels are much quicker in their action, but that they are required to be run at a high speed. Will you kindly give the following information respecting them: What sized pulleys and wheels shall I use on the overhead and spindle of emery-wheel to obtain the necessary speed?—the driving-wheel of lathe being 28in. dia.? Also, what thickness and dia. should the emery-wheel be, and is it to be used dry?—F. E.

[46758.]—**Bicycle Varnish.**—Can any reader kindly oblige with a formula or the kind of varnish for coating bicycle spokes to keep them bright?—one that will stand damp and exposure to air, &c.—Bicyclist.

[46759.]—**G.W. Goods Engines.**—Can any reader give description and dimensions (with a small sketch) of the leading types of G. Western goods engines? Are they double or single framed, and by whom are they built? Have the company any broad-gauge goods engines running?—Meteor.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or requies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6 Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, April 26, and unacknowledged elsewhere:—

Barnett Son and Forster.—W. C. Hughes.—K. M. Cunningham.—D. A.—Rev. S. R. Craig.—G. R. Miles.—N. G. Numsen.—R. Reyburn.—T.—Rivetter.—J. C. King.—A Fellow of the Royal Astronomical Society.—B. M.—R. A. V.—H. C. F.—Milford.—F. W. G.—One Leg.—R. D. D. M.—N. W. S.—J. S. B.—Invincible.—Aspirant.—Chemist No. 50.—Summit of England.—J. H. Huxley.—H. T. Barnett.—Sharples.—F. C. Putley.—W. H. S. W.—Dix.—Foundry.—Ascalon.—Teddy.—Douglas.—W. G. E—C. B. A.—Fellow Workman.—H. R.—Maj.-Gen. Cunningham.—A. Surridge.—J. Hezmalhalch.—Queensland.—Scotus.—Penuria.—Long Tom.—H. C. Sutton.—E. B. F.—D. Brown.—A. B. C. Pargo.—Cinquanta.—Brake Block.—Civis.—Pholas.—Cat's Tail.—Jumbo.—A. E. Harris.—R. D. T.—Carstairs.—T. J. C.—T. M. Hewetson.—G. Pinnington.—W. Worley.—A Canadian Subscriber.—Swan.—Screw Propeller.—David.—H. A. Wassell.

David Carson. (Several blowpipes of the kind in back volumes. See p. 146, No. 838, for instance. For colouring gold, refer to pp. 45, 93, 116, 165, 297, Vol. XXIX. The solder is made of gold, silver, and copper; but without knowing what it is wanted for, no one can give proportionate parts. As a rule, the solder should be the hardest it is possible to use.)—Three Legs. (Will not the article, "How to Make a Camera-Stand," on p. 445, No. 877, suit?)—One Interested. (You are bound to pay the House Duty, but are entitled to deduct it from the next rent paid to your landlord.)—A. H. K. (There is probably nothing very serious the matter with your wife, beyond the ailments for which she has been treated, but no advice worth giving could be had without personal examination. Why not consult a physician, or take her to Dr. Edmunds, at the London Temperance Hospital?)—Bradfordian. (See the announcements respecting steamers in Bradshaw's "Railway Guide.")—Roko. (If described in our columns, it would certainly invalidate a subsequent patent.)—Moahak, Paterson, N. J. (They are 7s. each in England, but we do not know what the U.S. duty is. Order them through Willmer and Rogers, or any respectable American bookseller)—G. W. (Simply add any bitters you fancy to the spirit.)—W. E. K. (We think not, but an inquiry at the Admiralty would settle the question. We do not know where photos of the ships in question can be obtained, but good illustrations of most of them are given in Vol. I. of Sir T. Brassey's "British Navy," which we reviewed on p. 557, last Vol. The book is published by Longmans.)—G. W. Dunn. (You will find a table on p. 336, No. 872, giving particulars of various sizes; but you will have to use enough battery-power.)—J. Main. (It would simply not be so powerful, as the larger sized wire would make fewer coils. Read what has been written recently, or study the principles as given in Sprague's book.)—Delta. (We have described M. Faure's battery many times, and plain directions for making have been given by correspondents. See p. 258, No. 869, and the indices of the last two volumes.)—W. Newbould. (Buy the double salt ready prepared. What has "nickel silver" to do with it?)—F. W. D. (Canada balsam is the short answer, if we understand you; but the varnish is applied after the painting is done. See p. 25, No. 782, for an article on lantern transparencies, and the index of Vol. XXXI. for references to an exhaustive discussion on the subject.)—G. Pinnington. (You will find accounts of the experiments of M. Lodyguine in serial publications, and in the *Transactions* of the St. Petersburg Academy of Sciences, by which society he was awarded an important prize in 1874 for an incandescent lamp, subsequently improved by Messrs Konn and Bouliguine. Lodyguine inclosed carbon in a glass vessel from which the oxygen was expelled. Several notes on his lamp in back volumes.)—A. H. K. (The core is magnetised by the passage of the current. When the circuit is broken the current ceases to flow, and the core ceases to be magnetised, or is said to be de-magnetised.)—Semper Fidelis. (If wanted for a short time only, the bichromate battery is the cheapest and best; but if required for hours the Bunsen is best. See recent back numbers.)—Cousin Dobbin. (On p. 336, No. 872, you will find a table giving dimensions of electro-magnets of various sizes. On p. 414, No. 876, you will find that the lead plate is connected to the positive electrode of the generator, and becomes coated with insoluble peroxide.)—H. (The connections are practically the same in any system. See p. 87, for instance, and other recent numbers.)—Wiseaf. (We do not know the process named; but see the indices under head of Lantern Transparencies, Photo. Transparencies, and Colouring Photographs)—A. L. Houston. (There is nothing better than aniline dyes. The sprigs take the dye best after being dried.)—F. B. (Hot fomentations to draw out inflammation. Certainly not a "magnetic" knee-cap, though one of scarlet wool might be useful. 2. A saturated solution: until the paraffin has soaked thoroughly into it.)—E. M. (If you know number, year, and price, send stamps to Mr. H. R. Lack, Sale Office for Specifications, Cursitor-street, E.C., with extra stamps for postage. If over one shilling, send postal order.)—Labor Omnia Vincit. (We do not remember any book or even a paper on the subject. Probably it is looked upon as a trade secret. Perhaps in some of the German technical journals there may be a paper in which the question is treated.)—Pro Bono Publico. (Several recipes in back volumes, but possibly the best is good glue, to which a little tannin is added. 2. See pp. 192, 236, last volume, for microscopical and chemical tests for silk.)—Dundonian. (See p. 538, Vol. XXI., and p. 153, Vol. XXII. 2. The simplest fountain is made by connecting the jet with a water tank some feet above it. 3. What part of a dwelling-house do you want to keep animals in? As to plants, geraniums, fuchsias, coleus, &c. 4. No, zinc does not injure them.)—An Amateur Photographer. (See p. 424, last volume, and the indices of recent volumes.) B. M. (In the ordinary pattern, the reeds are reached by removing the fretted slip just below the keys for the front set, and the back of the case for the other set. With the knee lever pressed over and the stop drawn, you should be able to see the reeds. See a diagram on p. 117, No. 655, or p. 605, No. 518.)—Mirror. (You proceeded quite correctly, but did not use enough mercury, and did not slide the plate on, so as to exclude air. In Ure's Dictionary (art. Mirrors) you will find the process given with much detail, also in back volumes. See, for instance, p. 354, No. 716. The process is a difficult one until practice has made the operator skilful, and we think amateurs will always find better results by depositing a film of pure silver by one of the wet processes, for which see almost any back volume. The previous answer contains all the principal parts of the mercury process, but makers use so much quicksilver that their tables have a trough to catch it as it is driven off by the advancing edge of the plate. If you try again, be sure that you get *tin*-foil, not composition. The mercury should appear to eat it up.)—W. Johnstone. (See previous answer, and the reference given. It is not an easy matter to resilver a looking-glass, and if time is of any value, is a costly experiment.)—Robt. Muirhead. (We do not know of any book specially devoted to the electric light which we can recommend; but if you will make up your mind to study the principles you can have no better book than Sprague's "Electricity," published by Spons. Look through our recent back volumes for many papers on the subject. You can procure lamps of the Swan Electric Lighting Co., Mosley-street, Newcastle-on-Tyne.)—M. W. D. (Copying-ink can be made by adding moist sugar to any good writing-ink in the proportion of about 1oz. to a pint.)—Tormented One. (Many plans suggested in back volumes; but if you run coal-tar into their holes once a week for, say, a month, you will effectually disgust them.)—Steam. (No; the remedy is either ventilation or inclosing air-tight.)—E. R. M. (We do not think there are any assisted passages to Australia now; but you can ascertain by applying to the agents-general of the respective colonies, whose addresses you will find in the Directory. You might possibly, by applying to some of the shipping companies, get a chance of working your passage out.)—Ego. (No, we know it would not—there is no thinking about it)—T. P. N. (Use methylated spirit and loose cotton wick; the benzoline fires because the heat vaporises it. On the bottom, because it has the weight of water plus the same pressure as the top.)—Ino. (You used too much. Rub the ink into the lines, and then clean the surface of the plate with a leather or cloth rubbed on a piece of whiting or chalk. As you proceed you will find that once the lines are filled with ink they readily take a supply from the roller while the rest of the plate is scarcely soiled. You can print from your monogram in the same way, but to do it properly you should have a counterpart to force the paper into the lines.)—A. B. (A crane, but it can be done with a differential pulley.)—Tinker. (Your second question was answered by "Alfojoe," on p. 113. See also his papers in the preceding volume. The professional painters usually lick the surface with the tongue; but perhaps you will prefer to wash the photo with solution of ox-gall.)—Phono. (If you want to make one, see p. 157, No. 683. There is no book on the subject, but you will find several articles in back volumes.)—W. J. B. (A description of Sutton's battery is given in the Replies (46654) in this number.)—Fred. Wooton. (Ask for caustic potash or, preferably, caustic soda, or refer to recent letters on the subject, and you will learn how to prepare it.)—Cheap Battery. (The porous pot ought to be a little above the outer jar. 2. Half full will do. 3. Not necessarily. 4. Yes, saturated solution with one-twelfth sulphuric acid.)—

AND
WORLD OF SCIENCE AND ART.

FRIDAY, MAY 5, 1882.

TELEPHONIC COMMUNICATION.

ALTHOUGH six years have elapsed since the invention of the telephone in its practically useful form, it has not, so far as this country is concerned, at least, taken the position which it ought to occupy. There are several reasons for this apparent neglect of a really useful invention, the most important of which is probably the action of the Post Office, though the difficulty of determining the rights of the holders of the patents has had something to do with the delay. No doubt, too, there is some natural hesitation on the part of would-be users, who, judging by their experience of other inventions, are, perhaps, justified in looking for improvements which will supersede the instruments at present employed. The telephone as devised by Bell, though still holding the first place as the receiving instrument, is rarely employed for transmitting purposes—the instruments in which carbon contacts are used being preferred for the reason that they allow of stronger undulatory currents being sent than are possible where a magnet alone is available. Of these instruments there are several seeking the public favour, some having many carbon contacts, as the Ader, the Crossley, and Wollaston, while others have only one, as the pantelephone. The fact that among such well-known forms as the Edison, Blake, and Hunnings so great a difference in the number of contact points is found, leads Col. Webber, the president of the Society of Telegraph Engineers and Electricians, who read a paper on the subject last week before the Society of Arts, to the conclusion that we are still a long way from comprehending the true meaning of the work performed by the pressure of the carbon. So many minds have however in the last two or three years been devoted to the study of the telephone, that we may safely assume no radical change of any importance will be made in its construction, and those who can find a use for it may instal it with the certainty that it will answer its purposes even if something better is found next year. The history of the telephone affords an instance of the difficulty of introducing even a meritorious invention; for although six years have passed since it was patented, it cannot yet be said to be so widely used as it deserves to be. It is true that in this country the application of the telephone has been delayed owing to the existence of rival companies, partly, but mainly in consequence of the action of the Post Office, which, according to the law courts, is entitled to the monopoly it has claimed. The merits of the new method of transmitting messages are, however, now fully appreciated, and there is no lack of subscribers whenever it is proposed to establish an "Exchange." In Germany, in France, in Belgium, in Italy, and in other countries on the Continent the exchange system of telephoning is in full work. In Berlin, for instance, it has reached that degree of perfection which is indicated by the fact that any person can have five minutes' conversation with any of the subscribers to the exchange by the expenditure of 50 pfennigs (about 5½d.) in the purchase of a list of subscribers, and in this country exchanges are already in existence, which cost the members about one penny per message. In the United States telephonic communication has reached its highest development, for in New York alone there are 5,000 subscribers divided into about fifteen exchanges, besides 1,500 private telephone lines. It is no secret that the arrangements of these exchanges, admirable as they are, considering the absence of experience, are not altogether satisfactory, for besides the objectionable network of wires with their supporting masts, there is also considerable carelessness or want of thought on the part of the subscribers, which has led, in some cases, to the adoption of a rigid time-limit during which a given wire can be at any member's disposal. The necessity for this rule arises from the fact that subscribers frequently neglect to "ring off" when they have finished their conversation, and the attendant at the central office is thus induced to keep others waiting unless he adopts a plan which, probably, he does not care to practise, and which might not be agreeable to the members concerned. That is known as "listening off"—viz., listening to the speaker, and waiting until the hanging up of his telephone is heard. According to Colonel Webber, in practice it is found that 20 per cent. of the subscribers forget to "ring off" when the exchange is first established, but improvement follows with a little practice; still the neglect is so serious that means of doing it automatically have been devised, notably by Mr. Johnson, one of Mr. Edison's assistants, who utilises the action of hanging up the telephone to slowly depress a lever, which causes a current to be sent to the subscriber's instrument for several seconds. A further improvement devised by the same inventor consists in making a distinction between the call of the subscriber for his correspondent and for the exchange. That is done by sending the battery current continuously or intermittently, the change being effected by the movement of a little handle. The bells at the out-stations are "chatterers," and act under the influence of a continuous current, but not when subjected to an intermittent current. The annunciator at the Exchange, on the contrary, acts under the influence of an intermittent current, and slightly vibrates only when a continuous one is passing. Possibly, however, until some undreamt-of automatic appliance is invented, the time-limit will be enforced on busy exchanges, for it is not difficult to conceive that a subscriber having been put into communication with his correspondent might lay the telephone down to look for some paper or other reference to refresh his memory, and his search might occupy a much longer time than would be altogether convenient to his brother members. It is not easy to suggest an automatic arrangement which will meet all cases, and we suspect that on busy lines it will be necessary to enforce the time-limit with a certain allowance at the discretion of the attendant, or switch-clerk, as he is called. If no calls await attention, there will be no advantage in cutting out the subscriber who has the line; but if others are ringing to be connected up the time-limit must be enforced. The question of overhead wires is not so easily settled as Col. Webber seems to imagine, and whoever he may mean by "the mouthpiece of what should be the highest authority in the land on such matters," we cannot agree that he has full justification in stating that overhead telegraph lines need never be an eyesore or a nuisance. The question is not so much whether they are eyesores or nuisances, as whether they are dangerous and subject to frequent accident. We pass aside the hint that the "clamour" is more or less encouraged by the cable and guttapercha interests, in view of the obvious facts that wires stretched across from the tops of houses are not easily placed in position, are not readily repaired, and are subjected to the effects of acid and other vapours, besides the often destructive action of the wind. It may be, as Col. Webber says, that in by far the largest number of cases, the line wires "have been put up unmechanically, and are in consequence dangerous and unsightly," but if erected by those who are now supposed to understand the business, they would be all that could be desired. That is scarcely the question—the public can judge only by experience, and at least in Germany and Paris the authorities do not seem to have much faith in the technical skill of the overhead erectors. Mr. Graves, the Engineer-in-Chief of the Postal Telegraphs, in the course of the discussion, pointed out that the Post Office had many overhead wires, and must continue them in certain districts, the business of which would not pay for an underground system; but wherever wires were massed in large numbers there was first the difficulty of finding room for them on the tops of houses, and, secondly, the weight became a source of danger. Further, oxidation is a serious evil, for unless the wires are carefully and continuously inspected, corrosion goes on unsuspected, and there is that source of danger added to those of frosts and high winds. Mr. Graves is clearly of opinion that wherever the collection of wires becomes heavy, they should be put underground. The wires in the neighbourhood of a telephone exchange will, of necessity, be numerous, and, consequently, heavy, and though the cost of insulation may be very great, it is almost imperative that they should be placed beneath the roadway; and looking at the constantly recurring expense of repairs, which are not easily made when the wires are carried on poles fixed upon the tops of houses, it is conceivable that, in the long run, it would be more economical to put all wires—in towns at least—beneath the footpaths.

As to the cost to subscribers, the rates charged at present are confessedly high; but while there are so many applicants, and the difficulty of obtaining permission to erect fresh wires increases, there is small likelihood of the rate being lowered. Even as it is, with the charge fixed at £20 a year, many customers pay only one penny per message, and some only one farthing. That, however, arises from the fact that they make as much use as they can of the facilities afforded, and if every subscriber did the same, it is clear a great many more wires would be needed to carry on the business. It would seem, therefore, that before long it will become necessary to have a graduated scale of charges—subscribers paying to a certain extent in accordance with the use they make of the lines. In the United States the tariff ranges from £6 to £9 10s. on small social exchanges; but on the commercial and business lines it ranges from £10 to £21. In Paris, as in Germany, the uniform tariff is about £20. As at present arranged, an exchange system can be worked most economically when it is on the large scale, requiring the use of several switch-boards, so that subscribers can be classified, and those most frequently corresponding amongst themselves placed in one group; but in the case of large switch-boards there is much liability to confusion and delay. The smaller exchanges, though more expensive in first cost proportionally, are more easily worked, and could undoubtedly be carried on for very much less than is now demanded, if the subscribers were left to themselves to provide the lines and the instruments free from any royalties. Whether these telephone exchanges are to be created and controlled by a number of companies, or whether the Post-office is to take the work in hand and carry it on as a monopoly, is a question that is coming up for settlement shortly. One thing at least

VOL. XXXV.—No. 893.

is certain, that the telephone exchange is a growing innovation which will ultimately absorb much of the business that is now done by telegraph, especially local messages, for there are several reasons why those who desire to send them would prefer to speak direct to their correspondents instead of writing the words on a form, and would also prefer to receive the answer in a voice that can be recognised instead of on one of the familiar forms. It will be difficult to make general arrangements of the nature of the existing telephone exchanges, but it is satisfactory to learn that the Post-office is prepared to extend existing facilities whenever the public demands warrant the requisite expenditure.

CART AND WHEEL-MAKING.—XV.

(*Continued from page 609, Vol. XXXIV.*)

By J. Charles King.

In the course of cart-making, much of the painting may be done as soon as the body is finished. In the trade, the body is often finished painting while the carriage and wheels are being got on with; this expedites work, and as the body has so much contact with the cushions and the hands, in the riders getting in and out, it is the best course to have the body finished first. It will be useful to describe at once the process of carriage-painting as followed in the best English shops. I, therefore, proceed to give full working details of painting as applied to carriages, with a few hints of what you must avoid doing. You may have perfect confidence in your successful completion of the job in a short time if the directions are followed; the main requisites being cleanliness, method, and flexible dexterity of wrist and fingers.

Before commencing to paint, be sure you have a shop secure from currents of fine dust, and be careful to get your body and carriage free from dust, especially in the corners, and the wood free from glue, grease marks, or smoke, from any part of the wood having been scorched by the hot ironwork. Should any be on, scrape and wash off with turpentine.

The colours, as the liquid pigments are termed, are the priming colour for first, second, and third coats of paint. The preparing colours first, second, and third coats. The fancy colour, and the relief of "striping," or "picking-out," by some different colour, to be finished by varnish on the fancy colour, and japan on the ironwork, and black paint where wanted. "Filling-up" an intermediate coat of paint between the third priming-coat of paint, and the first preparing coat of paint is not termed colour, and is a special mixture. How to mix these colours in proper proportions of ingredients will be fully explained, and it will be seen it is the simplest part of the process of painting. To lay on the paint, and "flat-down" between the drying of each coat, requires the care of forethought, and sensitive dexterity of touch.

To give confidence to anyone disposed to try his hand at painting, I may mention that I had to appoint a painter to do the work on a large estate near London. In chosing a suitable man out of several who wanted the job, I rejected several who had done painting before, and selected a farm-labourer who had never done such work; within a week's time he could mix properly any colour he wanted, and had finished a first-rate oak-graining job, with a flowing coat of varnish. His success was due to cleanliness, forethought, method, and a critical sense of touch in handling a brush.

As briefly as possible I proceed to tell how to mix the various paints, "lay-on" and flat-off for varnishing. Priming colour is made of white-lead (as sold ground in oil) 2lb.; linseed oil, $\frac{1}{4}$ pint, thoroughly well mixed, then add turpentine, $\frac{1}{2}$ pint. This makes cream-colour, to darken to lead colour of any shade, add lamp-black, and stir up till of the consistency of milk; to insure quick drying, add to this mixture 2oz. of "dryers"—this is sold ready for use.

I am obliged to remark now that as much of your cart as can be taken easily apart, must be done so, before beginning to paint.

The body should be upside down on tressels, the springs resting on the top of a stool or tub, or hung up on one end, the scroll-irons apart. The dashiron, wings, and body-rail all off, the back-door off at the hinges; in fact, only the steps need be fixed to bar and shafts. Begin this upside down and turnover as you go on. Begin always at the under sides or inner angles of your parts, working the first coat of priming with a rather stumpy worn brush, so as to force the colour thoroughly into the grain of the wood and crevices of the ironwork; let this coat of paint be put on in fair quantity, but thoroughly laid-off so that outer projections have as much as inner angles; leave it 24 hours to dry; then give another coat with a longer haired brush, using both hands; thus, work the brush with the right or left hand, and with the other have a small tool to wipe off any extra quantity of colour likely to run into a bead or angle; where it would remain wet paint while the adjacent surface was dry; in another 24 hours it will be dry.

The third coat of priming is put on with care to cover every part with a level coat. On this depends good work.

I must remind a learner that paint, being compounded of materials of such different densities, the mineral portions sink to the bottom of the paint-pot—so that the colour must be stirred frequently with a small bat-shaped stick; avoid wiping your brush on the edge of the pot, to regulate the amount of colour in your brush—the edge of the piece of wood, or a bit of wire stretched over the pot will serve better. With practice, you will not need to use either, but dip out, with brush or tool, only just as much as you want to use each time. Cover up your paint-pot with a sheet of card or leather when not using it, to preserve your colour from dust; let the paint-brush handles project through the cover.

If your paint stands by, it becomes thick—the turpentine has evaporated, and requires renewing. If dust gets on your work, be sure to dust off before you begin to paint again.

The axle may be fixed to the springs after the first coat of priming; you are then sure all the bearings have paint under them.

Now comes the puttying-up of holes, joints, and uneven places, with putty and "hard-stopper." I must again pause to explain that putty may be many weeks getting hard if not properly made, and that hard-stopper may get hard almost before you can use it all up on the job, in a few minutes. I describe how to make both, and how to keep hard-stopper soft for use while the job lasts.

Putty of any colour is made in a very simple manner by mixing thoroughly linseed-oil and whiting together, beating it up and kneading it. Usually a piece of sugar of lead the size of a small walnut is used with a 2lb. cake of whiting; this forces the drying and hardening of the putty. It may be darkened to any shade by the addition of lampblack, mixed up with the putty in making. Thus, this crevice and hole-filling material is distinctly different from hard-stopper used for the body, and has to be differently treated in use, being pressed and worked well in — level and smooth — with adjacent surfaces; while hard-stopper, which is used in a softer state, must be dexterously pressed into the hole to be stopped with the stopping-knife, and left to stand up above the surface in all cases, as it shrinks in the course of drying, and if not prominent would leave a hollow place at every stopped hole or joint. But well made putty, which alone is used for the wheels and under-carriage, does not shrink. Hard-stopper is kept in a gallipot, which, when not in use, must be turned upside down in a saucer. This causes the residuum of oil to filter to the under-surface of the hard-stopper, and keeps it from hardening and spoiling, which would be the case if the stopper got at all hard before using it. A careful workman knows success depends upon keeping his materials as well as tools in a state fit for immediate use. The following is the way to make hard-stopper and to use it:—Mix up on a stone slab or hard smooth board, dry white-lead $\frac{1}{2}$lb., and tub lead (as lead ground in oil is called), well worked up with gold-size into an adhesive putty; this is done with a stiff-bladed putty-knife, till the "stopper" is of the consistency of soft cheese. As most carriages are painted dark colours, the stopper should be darkened with a little lamp-black; not ivory-black. It is pressed into every pin-hole, screw-hole, or flaw that is visible on the surface of the body with a knife. Don't attempt to level it. The body may now be "filled-up," as it is termed; that is, painted with colour, having a large amount of silica in it, which has the effect of hermetically sealing up all the previous coats of paint and grain of the wood with a surface resembling stone, which has to be made level and smooth by facing-off with hard pumice-stone and water. This process is termed "rubbing-down."

Filling-up is made thus: 2lb. of coarse brown ochre, and $\frac{1}{2}$lb. of spruce ochre ground in turpentine, to which is added $\frac{1}{4}$lb. of ground white-lead; this softens the brittleness of the ochre, and gives a denser surface to the filling-up when rubbed down; the filling-up must be of the consistency of cream; to this is added $\frac{1}{2}$ pint of carriage-varnish to give toughness, adhesion, and elasticity to the filling-up, preventing it from chipping off when knocked, and making it less absorbent of water under the action of rubbing-down; this coat dries quickly—ten minutes after it is laid on. If it does not soil the hand when passed over it, it is dry, and may be followed up by a second and third coat rapidly; but the first coat is better for a night's drying. Filling-up must be laid on quickly with the firmness of an experienced hand, not timidly or daubed on; the use of a stiff brush will equalise the coat, and a small brush or tool will level corners of panels and on mouldings, which must never be daubed up, nor left bare at sharp angles. Thus a body may have three coats of filling-up in six hours, if urgent. If the filling-up gets thick it must not be thinned by adding turpentine, or bad results will follow in cracks and other annoyances in after-painting.

The thinning of filling-up must always be with the same material. When making the filling-up, carriage-varnish dregs may be used if strained warm through a sieve. The thorough cleansing out of a varnish-can may be effected by putting a little turpentine in the can to be cleaned and drained, and letting it stand near the hot stove-pipe for a few hours. In a small shop this is a matter of economy, not so likely to be omitted as in a large shop. The filling-up coat having stood 24 hours in summer, or 48 hours in winter, will be ready for rubbing down. This is effected with pumice-stone and water. The pumice-stone has a grain like wood, the end grain is the proper rubbing surface—it cuts down the filling-up quicker, and does not crumble away at risk of scoring the surface with little pieces under the pressure of rubbing. Plenty of clean water should be used, and the pumice-stone allowed to float in the water to cleanse, not laid on steps or the floor, by chance to pick up grit by contact.

It is as well to remark on the plan of some painters who employ incompetent men to rub down, for them to give the filling-up coat an overcoat of lamp-black and turpentine as a guide to the rubber-down of how much he is to rub off, that is, all this black coat, and then calling the job finished; this is just the way bad workmen are made, and kept so; moreover, the turpentine acts prejudicially on the filling up. The hand of the painter, as well as his eye, should be used to judge the levelness of rubbing down. It does not matter how much or how little of the filling-up is rubbed through. So critical does the sense of touch of the painter's hand become, that he tests the accuracy of surface, and level, by the hand being passed carefully over the panels he has done to try them. In rubbing-down, a facing-stone is used for cleaning and levelling the pumice-stone upon.

Washing-off should follow immediately, as the process of rubbing down goes on, and plenty of clean water and a clean wash-leather with sponge should be used, or a piece of linen or calico rag will do even better than wash-leather, as it does not clog like the leather does, and is more easily rinsed out and wrung dry for use.

From the preceding remarks, it will be seen that from the commencement of a piece of work with the priming coat, to the finish of the rubbing down, occupies from seven to fourteen days, according to the season of the year, the dryness of atmosphere, and the emergency of the work; it need hardly be said that the longer paint has to dry the better. The same processes modified, and material made up for quick-drying, may be carried out so as to complete a repairing job in twenty-four hours; as a new panel, or boot side. Before concluding these remarks upon filling-up, it cannot be too forcibly urged that while the paint is laid on copiously, and all projecting parts well covered, the inner angles of mouldings, quirks, and corners need hardly have any more than a light coat of the paint. It is a common practice of careless painters to daub over the bodies, filling up the angles and corners, using twice as much stuff over these parts as is needed. This is the starting of defective work which follows. What has been put in the angles and corners of mouldings has to be got out. In the attempt to do this the prominent parts are cut through to the wood, and yet the corners remain daubed up. Time is then wasted looking at it, talking about it, perhaps, and then making a botch of colouring over the bare places, waiting for it to dry, flatting off, or perhaps, as is mostly the case, it is considered a trifle. This, and the bare wood and thick plaster of filling-up, are painted with a preparing coat, just as if it was the proper thing for those parts of a body, the most exposed, to be barely painted, and other parts, not exposed, to receive a needless amount of paint. It may happen, however, that a joint will rise, or a screw-point bulge a part of the surface to be painted, and escape the notice of the body-maker in cleaning off, and if noticed by the painter in priming over, allowed to pass. It often happens in large shops that workmen of one branch resent interference from another about trifles, as these would be called. When it so happens, there is no alternative but to rub through to the wood. Do it boldly, as follows:—If there is not time to paint over again with "filling-up stuff," when the wood is dry (and it ought to be dried quickly so as to dry the wet out of the grain before it can soak deeply in), rub the wood with a piece of rag, having on it a mixture of three parts of linseed oil, two of turpentine and dryers, or sulphate of copper; for a quart, as much driers or sulphate as will be as large as a walnut. Indeed, this mixture in the hands of an intelligent painter is a valuable surface mixture or dressing to stop the too rapid absorption by the filling up of the preparing coat of paint which follows the rubbing-down process. This coat is not put on with a brush, but rubbed on in a small quantity at a time with a rag. It has the additional beneficial effect of killing the damp that may be left in the filling-up coat, after rubbing-down. Where a body has been rubbed through the filling-up, in parts, into the primary colour, this dressing, carefully rubbed in, equalises the action of the absorbing surfaces, and favours the laying on of the first preparing coat of colour, so as to prevent an unequal drying and sinking-in of following coats of paint, which will otherwise be manifest even through successive coats of paint and varnish by surface cracking, or mottled and cloudy dimness of lustre.

We will suppose the carriage and wheels to have been put through the usual course of three priming coats at the same time as the body with its extra coats of filling-up; and flaws, unequal joints, surfaces, and screw-heads have been duly stopped, filling-up rubbed down, third coat of priming glass-papered to get smooth and level, then comes the three courses of preparing colour. This paint is made of white-lead, linseed-oil, and lamp-black, just as the priming colour was, except the proportions of oil and turpentine are altered for preparing colour, the oil being diminished by one half and the turpentine being doubled in quantity. The painter's object now is to fill up thoroughly the absorbent pores of the filling-up surface stuff with preparing colour, just as he had done the grain of the wood with the priming colour before the filling-up was laid on. When much oil is used in the preparing colour, the filling-up surface will not absorb it at once, as it should do; it will be simply glazed over and slowly and unequally absorbed, according to the variable thickness of the coat of filling-up, or to the chance of being laid on well or badly by the painter that does this part of the work, which is one of the most critical coats of paint that is laid on. With the last coat of some delicate glaze colour, the eye will aid the painter in his operation; but for this first preparing coat the experience of judgment, to which vision lends little help, is essential for putting on plenty of paint, and also for *laying it off level*, so that there is not a superfluity, and in the rapid manipulation and watchful attention to the absorption of colour, as it is laid off, so that the saturation of the filling-up base is thoroughly effected.

The first coat of preparing colour will be dry in twenty-four hours, and may be faced-off with pumice-stone. This produces what is known as eggshell dulness of surface, and levelness of parts, or fine glass-paper may be used for the same purpose; though for well-done work a lump of crisp, curled horsehair will serve for the purpose. To the young hand it may help him to explain why it is requisite that this first coat of preparing colour must be faced-off. The different degrees of absorption of the under coat of filling-up produces an uneven surface, and any little "nibs" or projections of paint, unless levelled off, become doubled in size by the addition of the next coat of paint. To face off the next coat of paint, instead of the first, would be to rub through two coats of paint instead of one at some parts, and by that, laying bare in invisible specks the filling-up, which would not fail to show in some way its effects on the next coat, even to the varnish. It may not be amiss to remark upon the liquids that form the vehicle, for the flow of colour which is when used, in a few hours to become a dry, hard-surfaced paint. Linseed-oil gives to almost any pigment it may be mixed with, the tenacity of leather when dry. Turpentine, which also contains oil as well as spirit, does the same to a very slight degree; the greater fluidity of turpentine, and the ready absorption of its spirit by any porous matter it is laid on, insures its penetration into the filling-up, even right through it to the priming colour, in places where, if the priming coats have been made with red-lead, or contained any boiled-oil, or similar objectionable substances, an action analogous to fermentation takes place which, reacting on the overlying paint, causes flaking, blistering, cracking, pin-holes, sweating, dead or cloudy surfaces, &c., to show up through the varnish. This, of which we hear so much complaint in American painting, and note it in their imported carriages, is almost unknown either in Britain, or with the best work on the Continent. Of course other fluid vehicles for pigments may be, as they have been, used; but the two named are proved to be the best yet known, and the best dryers for preparing colour are sugar of lead, and sulphate of copper; this last certainly preferable.

After this long digression, intended to save workmen from the annoyance of failure and hap-hazard processes, we now proceed to explain that the second and third coats of preparing colour, if intended for final colours—as lake, vermilion, ultra-marine, verdigris-green, canary-yellow, or lighter shades of colour, should have the preparing colour made of correspondingly lighter shades, and also where glazed-colours are used; or, if it be thought desirable, some of the final colour may be mixed with the preparing coats. These coats may be "flatted"—*i.e.*, made dead, or of dull surface, by pumice-stone dust and water being rubbed over them; this dull surface insuring the more thorough cohesion of coat upon coat of paint. Having followed up the courses of painting as far as the finish of the third preparing coat, duly flatted down, on all the panels and mouldings, and on the carriage and iron work, glass-papered smooth and level, the carriage is ready for the coats of final or fancy colours.

I will leave, for the present, the description of the various pigments, of which these colours are composed, and describe their mixing and manipulation by the carriage-painter. The fancy colour for the first coat is made by grinding the dry pigment with linseed-oil till it becomes of the consistency of cream. This may be done in a paint-mill worked by hand or steam, or from an engine worked by gas, or by the ordinary "muller" and paint-stone. This latter operation requires not only a critical sense of touch to know when the paint is ground fine enough; but the sense of hearing, as well as vision, aids in the perfect manipulation of the paints. As the successive coats of paint already laid on have sealed the grain of the wood, and levelled the surfaces of the ironwork, a small quantity of fancy colour will cover a large extent of the surface of a carriage. Assuming that a quantity equal to a gill measure of the fancy colour in oil has been ground to the consistency of cream, it has to be thinned by adding turpentine, to make it equal in measure to three-quarters of a pint; this must be well stirred in a large paint-pot with a brush, which is repeatedly drawn over the edge of a stout-bladed pallet-knife held over the paint-pot to insure thorough mixing. This, though so thin and liquid a paint, has a veritable body for covering work thoroughly; but it must be strained through a fine wire or gauze-sieve, or a "Stapfer" filter. It is now thickened to its proper consistency for use by the addition of about a gill of the best body-varnish; the purpose of this varnish is not to give lustre, that being just the reverse of what is wanted, but to give thickness and fulness to the paint in working, and a hard texture of surface when dry that will bear "flatting." Many other fluid materials may be used instead of varnish, but none are known to serve the desired purpose so well. In mixing this varnish with thin paint, it is best to have the varnish already measured into a paint-pot, and to pour the paint into it, stirring it with the brush thoroughly. In painting, there are two technical phrases, "laying-on" and "laying-off" the colours—the latter phrase simply means spreading it, i.e., painting. This is just the trained manipulation which, by its effectiveness, constitutes the workman who commands a high wage, and a leading position in his craft.

In laying-on the first coat of the fancy colour, the judgment soon aids the workman. It now depends upon himself entirely if he is to turn out good or bad work; that is, when finished, with a perfectly level glassy surface of japan or varnish, or with a streaky, silky, or ropy unevenness to mar his work. These are not frequent faults in English coach-painting. But they are about the only ones that are conspicuous with some second-rate work. They are invariably ascribed to a defect in the japan or varnish, which is so erroneous a notion, that we affirm that the very worst japan or varnish could not be made to assume ropy or streaky lines without the mechanical action of the brush and laying-off the previous coats of paint had laid the lines for the flow of the varnish to follow into. In fact, the manufacture of English varnish and japan has been brought to such perfection that painters have long since ceased to find fault with it to excuse their own errors. Laying-off colour on carriage-panels is to carriage painting what "stippling" is to artistic colouring and finish of art painting. This process of laying-off colour marks the highest mechanical qualification of a painter; the accurate conjunction of the action of the eye and hand determines it simply by the DEGREE OF ANGLE from the surface at which the brush is held in working the final strokes. If the brush be held too upright, or at a slight angle from the surface, streaky or ropy lines on the surface are certain. The points of the bristles act mechanically, and rake the paint into lines or ridges; these become enlarged by each subsequent coat of paint, and show glaringly in the varnished or japanned coats.

The highest grade in the craft of coach-making is that of the "picker-out," as that workman is called who lays on the relief lines and ornamentation to the body, mouldings, wheels, and carriage parts. These are done in one or more colours, different to the fancy colour of the panels and under-carriage. The widths of the reliefs vary from 1in. to 1-32in. The wide lines are called "bands," and are mostly the width of the body mouldings, or of the carved beadings of the carriage parts, if from $\frac{1}{2}$in. to [illegible]in. wide. The next narrower lines are called "stripes," and are used mostly for centring lines, either on the "bands" or on the fancy colour. These vary in width from [illegible]in. to [illegible]in. wide.

WATCH-CLEANING AND REPAIRING.

By "A FELLOW-WORKMAN."

(Continued from page 166.)

PIVOTING.—The top pivot of the verge often gets broken, and I think you will find it easier to repivot than fit a new verge.

First make a hollow drill (Figs. 39 and 40). This is done by drilling a hole in the end of a piece of steel wire, a little larger than the body of the verge, and about 1-16in. deep, and turn it down, as shown in sketch, Fig. 39, so that it will cut away enough brass to make room for a plug, but not to loosen balance on its arbor; now make an arbor of a pivot drill and slip a piece of brass on it, as shown Fig. 37; you should file this arbor quite as small as the body of the verge, so as to be able to get a substantial plug. Now turn this plug so that it will enter about ⅔ into the hole made with the hollow drill (I forgot to mention that the piece of the verge body left in by the hollow drill can easily be removed by trying to bend it); now put plug back on to arbor and cut off as shown in Fig. 38, leaving a little piece of arbor protruding at bottom to act as a wedge to the plug when it is being driven home. Now put your verge on the "verge riveting stake"; put Fig. 38 in the hole and with spring punch, Fig. 42, drive the plug home; keep working the punch round while driving—you will feel when it is home, and then you must leave it alone, for if you drive after the plug has reached the bottom you will be upsetting it, and your job will be spoiled. Fig. 41 is a section of the plug after it has been driven; now put it in your calipers, and if balance runs true you can make your pivot, but if you find that in driving the plug it has got a little out of true, then you must make a true male centre, put it in the turns and turn pivot true before filing.

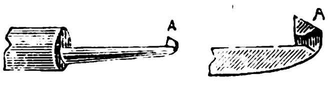

FIG. 46

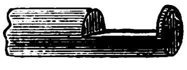

FIG. 47.

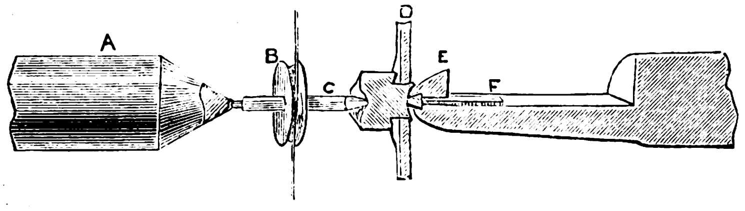

FIG. 42.

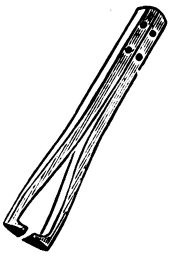

FIG. 49

Using the graver is got by practice. The following may help you: always cut above the centre, keep your rest as near your object as possible; *cut*, but don't *scrape*. Don't press on your graver: feel it cut, the same as you would a diamond; wet the graver with your tongue for brass, use oil for steel, turn very steadily, and hold your bow lightly; use a diamond-shaped graver, get up your graver with care. There is more practice required for sharping, or getting up, your graver, than there is to use it.

Fitting a new pivot to a pinion is very simple; it only requires patience, and may be learnt in an hour or two by anyone who has had any experience with watches, supposing the bottom (pillar plate) pivot is broken off. A 3rd wheel. You must drill a hole in the centre of pinion, fit in a steel plug, so as to get a new pivot. Now the following is a very simple plan, and will turn out a better job than many of the "pivoting turns," and it is not necessary to remove the wheel. Get two pieces of steel wire that will fit in your bench turns; make one end of one piece as shown Fig. 43, the other end as Fig. 44. Take the other piece of steel wire, make one end as Fig. 45, the other end as Fig. 46. Now place third wheel between the centres (43 and 45), as shown Fig. 47. A is Fig. 43, B is a rose or head, taken from a pivot drill (the hole is broached large to fit pinion). C is pinion, D wheel, E is A, in Fig. 45, F is a piece of broach, Fig. 48. It does not require any previous centring; simply place it as described (Fig. 47). Now put Fig. 48 in at the back of E, Fig. 47, and push it through until it touches the root of the pinion. Now, while you turn your pinion, you must press Fig. 48, which will find its own centre, and also make a hole for the plug, and the best tool in the world cannot do it more true. Now, having made your hole, make a plug out of a pivot-drill and drive it in; leave about enough for pivot. Now remove Fig. 45, and put Fig. 44 in its place; put face of Fig. 44 up against the root or shoulder of old pinion, so that the piece of plug left for pivot rests in a slot made for that purpose. Now take pivot file, and with the old shoulder as your guide, make pivot to size required, and polish as described in previous number. Now remove Fig. 44, and put in Fig. 46, and round off. It is not absolutely necessary to round off, but it looks better.

I do not think it is necessary to say any more about the verge watch. I will, if requested, go on with the horizontal escapement, unless some other correspondent would like to take it up, in which case I will stand over. I quite agree with "Tempus" that the best use should be made of the space, which is so generously given us by the Editor. That is one reason why I made my articles as short as possible. Hair-springs will come in best with the horizontal movement.

(*To be continued.*)

APPLICATION OF OZONISED OXYGEN FOR BLEACHING.

On p. 126 of the last volume we gave an account of the process, amongst others, of preparing oxygen, adopted by the firm of Brin Brothers, of Passy. The inventors have recently taken out a patent in this country for the production and application of ozonised oxygen for bleaching and other purposes, which may perhaps be taken as conclusive evidence of the commercial success of the baryta method of preparing oxygen. It is well known that ozone partakes of all the properties of oxygen, and that it possesses them in a more active and powerful degree; also that endeavours have been made a long time for the production of ozone. The present laboratory process consists in submitting oxygen to the action of the electric spark, or rather the efflux of a continuous current. The feeble production of ozone obtained by this method does not amount to more than a small per cent. of oxygen transformed into ozone. The reason of the non-success is that oxygen is a bad conductor of electricity at ordinary pressure, and resists its absorption; the electricity therefore escapes therefrom to a very large extent. It is not so with dilated oxygen. As the pressure diminishes, its conductivity increases: and if electric sparks are made to pass into a glass tube in communication with an oxygen reservoir it will be seen that the sparks become elongated and more powerful when the density of the oxygen is diminished; when this density falls to one-tenth, one-fifteenth, or one-twentieth of that of the atmosphere, the length of the sparks, which was originally respectively about three-eighths, three-fourths, and one and one-eighth inches, increases rapidly to 19, 28, and 38in. In this state the fluid is more quickly and completely electrified. In the manufacture of oxygen, according to the patent of the Messrs. Brin (1880, No. 1416), the oxygen is drawn from a retort containing barytes under a pressure of about one-twelfth to one-twentieth atmosphere. It is under these conditions that the inventors have observed the aforesaid phenomena of sensitiveness as regards electrification, and have been enabled thoroughly to investigate this state. According to the present invention cold oxygen is attenuated to a density about, at, or below a column of 4in. of mercury In this state the oxygen is passed through a circuit of electricity, which it closes, the current being in the form of sparks or continuous efflux. The oxygen may be made to enter a vacuous vessel, where it expands as required, and is exposed to the aforesaid electrical action. The oxygen is by preference, by an ordinary suction pump, or by a jet pump, or by any other suitable exhausting apparatus, made to pass through a cooling apparatus having, for instance, a coil for the oxygen and a continuous circulation of cold water around the same; it is then passed through the ozonising apparatus in an attenuated condition. The ozonising apparatus may be arranged as a vessel containing acidulated water, and having a series or system of tubular or other passages or chambers arranged with corresponding interior or intermediate tubular or other passages containing acidulated water. One pole of the battery or other source of electricity is connected to the water in the latter passages, and the opposite pole to the outer acidulated water, and the oxygen passing between them closes the circuit and becomes electrified, that is, ozonised, more or less as desired or required. The oxonised oxygen thus prepared—in the specification (No. 3728, 1881) the patentees show suitable plant—is of considerable use for many purposes in the arts, as it exercises a very powerful bleaching effect on organic and other soluble and insoluble substances in a very short time: for instance linen, cotton, jute, &c., saccharine liquids of all kinds, oils, &c. The process of preparing the oxygen was so fully described at the place cited that we need not recapitulate; it must suffice to say that, made on the large scale, its cost is said to be not more than 4s. per 1,000 cubic feet, to which of course must be added the expenses of the processes above described to arrive at the cost of the ozonised oxygen.

LUBRICATING BEARINGS.*

It is impossible for a bearing to run cool until the high places are reduced, so that there will be a uniform film of unguent between the two surfaces. It is a custom for purchasing agents, and in some cases for practical men, when ordering oil, to mention simply "lubricating oil," without specifying the kind of bearings for which it is to be used. The latter is a very essential point. Frequently, when the oil is received, it is found to give poor satisfaction, and some of the bearings are found to run hot. Under these circumstances, the oil is generally charged with the fault, when, in reality, the fault has been in giving the order. A good lubricant for small, close fitting, fast-running bearings must be of a very fine quality, and have a light body in order to distribute itself between the close-fitting surfaces. Such a lubricant is entirely unfit for large bearings, where more body is required to carry the heavy weight which is placed upon them. It is the practice in most shops to use the same kind of lubricating oil for all the machinery, which, when properly considered, is both unreasonable and extravagant, for the reason that a bearing, when imperfectly lubricated, is worn away much faster it than would otherwise be, and on fine machinery the lost motion in the bearings requires frequent attention.

Experiments are constantly being made with a view of producing a cheaper lubricant than the best oils now known, and which shall possess all their desirable qualities as lubricators. For heavy shafting the journals are generally lubricated either by means of oil boxes or cavities in the upper part of the cap of the journal, so that tallow, grease, oil or other lubricant may be placed therein. The old way was to fill the oil-box with tallow, leaving a small space for oil; and, in case the box should heat, the tallow would melt and run down over the journal.

I remember some years ago in a mill, there was a wall box supporting a five-inch shaft which would get hot and remain so in spite of all the efforts made to cool it. Oil, sulphur and tallow, water, were each used in great abundance, but still the journal refused to surrender. Finally, one night I raised the shaft and removed the composition box,, and had it carefully cleaned. The shaft having also been cleaned, a very light film of lamp black was applied to the shaft, after which the box was gently rubbed over it. This test revealed the fact that the bearing was all right so far as fitting was concerned, but the surfaces of both the shaft and box were rough, and the skin of the metal disturbed. The load upon the bearing being heavy, it was sure to heat. I obtained some pure flake graphite, and having melted a pot of pure tallow, I stirred in a liberal dose of the graphite. The box having been replaced, both bearing surfaces were covered with the mixture of graphite and tallow, and the shaft lowered to its place. In the morning when the machinery was started the box warmed up to about a blood heat and remained so for several hours, after which it cooled down and gave no more trouble. In a few days it was examined, when the surfaces were found polished like a looking glass. The graphite had become imbedded in the pores of the metal and formed a very fine wearing surface which ran with very little friction. I have since made use of this mixture for cooling heavy journals and have always found it successful. I have also used graphite mixed with oil for lubricating purposes, but have experienced difficulty from the graphite separating from the oil. I understand, however, that quite recent experiments have resulted in a chemical combination of oil with pure graphite, so perfectly that they fail to separate after standing quietly in a vessel for months.

---

* By L. F. Lyne, in *American Machinist*.

In using oil for lubricating a line shaft I prefer to use automatic oil cups, except in cases where self-oiling boxes are used. I believe the latter plan to be the most economical. The boxes should have wipers so as to exclude every particle of dust which mingles with the lubricant and scratches the surfaces of the journals. The great cause of the journal bearings upon railway cars being worn away is the fact that dust is freely admitted to the bearings, mixes with the oil and destroys the journal. I have known absolutely tight boxes to run until the wheels had to be renewed, simply by the addition of a little pure oil occasionally.

With automatic oil cups I have known journals to run with from 35 to 40 drops of oil per week, and have all the lubrication required. In many shops a "doper" is required to oil up the shafting every other day, and, as a rule, each time he oils up more than as much oil is wasted as would be required to run a month. The best oil judiciously used will in every case prove the cheapest and most economical in the end.

RECENT IMPROVEMENTS IN THE MECHANICAL ARTS.*

A NOVEL invention, which has for its object the automatic setting out of the packing rings of a piston-head within the cylinder, has been devised by the Master Mechanic of the Pennsylvania R.R. Co., and will be adopted by that company for use on their locomotives. The improvement consists of a solid piston-head suitably cored out for the reception of the packing rings and their actuating levers, as also for the two adjustable bolts which centre the piston and provide the bearings against which the weight of the piston exerts itself to set the packing out automatically. The two operating levers are each fulcrumed in a block resting on the packing rings at the bottom of the piston and extend, one on each side, into the upper circumference of the head, where they rest against other blocks having their bearings on the packing rings and constituting the resistance of the levers. The power is applied through the two threaded bolts referred to and which work adjustably in screw bearings in the solid head. These bolts are each arranged on an angle of 30°. Thus, it will be seen that the whole weight of the piston rests upon these two bolts, which, in turn, bear respectively against their levers, whose fulcrums are in the bottom of the piston and whose resistances or operating ends are in the upper part of the piston, whereby the weight of the same is utilised, through said levers, to bear directly against the upper circumference of the packing rings to expand the same in the upper part of the cylinder.

A recent improvement, tending to increased safety in railroad travel, consists of a frangible tube projecting from the cab of a locomotive and communicating with the brake-pipe of the Eames or Westinghouse system of air-brake apparatus. A switch, drawbridge, &c., have wires or ropes attached to them which lead to semaphore arms arranged at a distant point on each side of the switch or draw. These semaphore arms are so arranged that when a switch is misplaced the arms will lie across the path of the frangible tube on the locomotive, whereby said tube will be shattered and the brakes instantaneously applied. In the Eames improved system, a constant vacuum is maintained in the brake-pipes, the brakes being set up by the destruction of the vacuum, which has the effect of opening up the vacuum power of auxiliary reservoirs located under each car; thus, it will be observed that the breaking of this frangible tube will destroy the vacuum in the brake-pipe. In like manner, in the Westinghouse system, a continuous pressure of air is kept up in the main brake-pipe, the reduction of which opens up secondary reservoirs under each car, which operates the pistons of the brake apparatus.

A late invention provides means for extinguishing fires in the stoves of passenger cars should they, by any accident, upset. For this purpose an elongated water reservoir is suspended along the side of the car. Cords, attached to the stove and to valves which normally close outlets in the reservoir, serve to operate said valves when the stove is upset, and allow the water, through a perforated distributor, to flow into the fire.

A new staple of manufacture consists of the fibre of the stalks of cotton plants. The stalk is disintegrated and the fibre separated from the rest of the stalk, preserved and prepared according to the following method: First separating the fibre from the stalk by passing through rollers or by retting, then drying, then scutching or breaking, and then carding or hackling the same, thus producing a staple of the fibre alone. It is proposed to manufacture from this staple woven fabrics by spinning it and converting it into twine, cordage and yarns, wadding, packing, calking, and paper.

ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY—VIII.*

Third Lesson in Development.

IN considering the subject of exposure in a former lesson, we assumed that correct exposure is a fixed point, and that any deviation from it would give imperfect results. This is not the case, however, for there is a certain "latitude," which is due to two causes: first, a certain latitude of effect is permissible. Thus, if the plate be a little under-exposed, there will be somewhat less detail in the resulting picture than is visible to the eye, but this need not spoil the effect. Again, if the plate be somewhat over-exposed, the effect will be a slight fog or want of transparency in the shadows of the negative; but the only result of this will be that what is called a "slow printing negative" will be produced. The latitude in effect is not great, however. It may be said that if two seconds be the best exposure, anything between one and a-half and four seconds will give good results. We have, however, a second method of gaining latitude, and this is by means of the treatment with the developing solutions. Thus, simply by leaving the plate for a longer or shorter time in the developer, we can compensate to a certain extent for under or over-exposure. It is, however, by varying the proportions of the ingredients of the alkaline developer that we gain the greatest latitude. We must enumerate the chemicals used in this developer, and try to make clear what are the properties of each.

The essentials are as follows: First, pyrogallic acid, or more properly, pyrogallol; second, liquor of ammonia, or occasionally some other alkali; third, a soluble bromide, usually bromide of ammonium or of potassium. The pyro. is the true developer, and acts very energetically when rendered alkaline. The stronger the developer is in pyro., the denser will be the negative; but the effect of increasing the pyro. is to "restrain" devolopment—that is, to make it take a longer time, and to prevent a certain amount of detail from appearing. The ammonia is used to render the developer alkaline, and the greater the quantity in the solution the more energetic the action. The effect of increasing the ammonia is to shorten greatly the time of development, to increase to a slight extent the amount of detail, and to increase the density. A point is reached, however, where the action is so energetic as to reduce or blacken even those parts of the plate which have not been acted on by light, and fog is the result. Some plates will stand much more ammonia than others. The use of the bromide is to retard development—to make it slower, so that it may be more under control. Without it the development is very rapid, and unless the quantity of ammonia be very small, it is difficult to avoid fog. The result of increasing the bromide is to make the developer much slower, to keep back a little of the detail, and to increase ultimate density greatly.

A little consideration of what we have said will show that by varying the proportions of the constituents we have enumerated we have the power of greatly modifying the resulting negative, and have a power of compensating to a great extent for error in exposure. This is especially the case for over-exposure. It is true that in the case of under-exposure we can correct to a certain extent by using an increased quantity of ammonia; but the fog point is soon reached, and thus it is only to a small extent that we can correct in this direction. In the case of over-exposure, however, it is different. Either pyro. or bromide may be increased indefinitely. The latter is the best to increase, as it is the cheaper. By largely increasing the quantity of bromide the development is rendered slow as regards the appearance of detail, but less so as regards the increase of density. It is thus possible to stop the process in the case of an over-exposed plate before the shadows veil over, and yet to have a sufficiently dense negative.

We have said that it is right, in using any particular make of plates, to use the developer given in the "instructions;" but it is by no means necessary to mix the "stock solutions" exactly as directed.

We recommend that the solutions be mixed in the following manner:— Dissolve quarter of an ounce of citric acid in eight ounces of water. Add this to one ounce of pyro. Make the whole up to ten ounces, and label "Pyro solution."

Take once ounce of bromide of ammonia and make up with water to ten ounces. Label, "Ten per cent. bromide solution." Take one ounce ammonia, strength ·80, or two ounces of the ammonia diluted with an equal amount of water as recommended before, and make up with water to ten ounces. Label "Ammonia 10 per cent. solution."

There is no developer which is suitable for all subjects. Those given in instructions can only be taken as typical. If the photographer expects to excel, he must vary his developer to suit his subject. Thus, when the contrasts are very strong—say in the case of an interior with white columns and deep shadows—he must reduce the amount of pyro, or he will have a negative giving a "chalky" print. If the contrasts are naturally weak, as is sometimes the case in open landscape, he must increase the quantity of all the ingredients, but specially of the pyro and bromide. If he knows that he has under-exposed, he must increase the ammonia. If he knows that he has over-exposed, he must increase the bromide.

The following we have found to be a good developer for general purposes:—

Pyro....................	from 1 to 2 grains
Ammonia........................	3 minims
Bromide	1½ grain

To each ounce of developer.

This is a more restrained developer than is usually recommended. We find, however, that the increase of the bromide beyond that commonly used does not necessitate an appreciable increase in exposure, whilst it gives a better quality of negative, and permits of a considerable latitude in exposure simply by allowing the plate to be a longer or shorter time in the developer.

We shall now tell how the best result can be got from a plate when there is uncertainty as to whether or not it has had the correct exposure.

A developer made as follows should be flowed over the plate:—

Pyro......	1 to 2 grains according to subject
Ammonia	2 minims
Bromide	1½ minims

To each ounce of developer.

This is a very slow developer, and even if the plate be much over-exposed the image will not appear for some time. A little experiment will enable the photographer to know whether the plate has been over-exposed, correctly exposed, or under-exposed by the length of time which elapses between the time of pouring on the developer and the appearanceof the image. If the exposure appear to be correct, let one minim of ammonia be added to bring the strength up to that recommended. If it appear to be over-exposed, let development proceed, or even add more bromide. If the image be very long of appearing, showing that there has been under-exposure, ammonia may be added to any amount short of that which will produce fog. Good plates should stand ten minims of ammonia with one and a-half grains of bromide. The greater the quantity of bromide, the larger the amount of ammonia that may be used; but the quantity of ammonia permissible is not proportionate to the bromide used. Doubling the quantity of bromide will not permit double the quantity of ammonia to be added. With the ferrous oxalate developer, under-exposure and over-exposure may be corrected to a certain extent, but not so greatly as with the alkaline developer. The developer may be acclerated by the addition of any quantity up to ten minims of a 1 per cent. solution of hyposulphite of soda to each ounce of developer, or retarded by the increase of bromide. It is commonly said that there is difficulty with gelatine plates in getting a sufficiently dense image. Such a difficulty results from inorance of the principles of development. The secret of getting "plucky" negatives lies in using in alkaline developer strong in all the constituents, but specially so in bromide, and, if necessary, giving a slightly longer exposure than might otherwise be thought necessary. The real difficulty lies in judging when the density is sufficient.

* Condensed from the *Photographic News*.

UTILISATION OF TIDAL ENERGY.

AT a meeting of the Society of Engineers, held on Monday evening last, a paper was read on "The Utilisation of Tidal Energy," by Mr. Arthur Oates. The author commenced by stating that the recent advance in the application of electricity to the storage and transmission of mechanical power has caused attention to be directed to economising our coal, by the employment of some of the inexhaustible sources of power, amongst which the tide takes the first rank in this country. After giving a table showing the power and value of the energy derivable from the rise and fall of tides, and explaining how they can be calculated, the means which could be employed in utilising the energy were stated to be almost innumerable. Of these, the tidal dam is by far the most important, therefore the rest of the paper was devoted to the consideration of it, illustrated by drawings showing the nature of the proposed dam. It would have to be constructed across an inlet, or in any position where it would inclose a portion of the sea, and would be provided with machinery to utilise the fall of the water into, and out of, the inclosure, near the times of high and low water respectively. The difficulties connected with this way of utilising, and the means of overcoming them, were then dealt with, and the various purposes for which the energy could be used, touched upon. After describing the principal modifications of the tidal dam, and the probable effect it would have on the currents and sea-bed in its neighbourhood, some of its structural details were considered, and the mode of constructing the class of dam illustrated, described. The author concluded by stating the physical and economic conditions necessary to render tide-utilising works an engineering and a financial success, and expressed a belief that in the future the design and construction of such works will form an important branch of civil engineering, and a remunerative field of investment to the capitalist.

SCIENTIFIC SOCIETIES.

ROYAL MICROSCOPICAL SOCIETY.

The President's Address.*

AFTER reading a number of obituary notices relating to Fellows of the Society, the President referred to the report of the Council, as to the general prosperity of the Society, and then said:—

In no previous year, so far as I can gather from a reference to the printed records of the Society, has so much light been thrown upon subjects which are of the first importance in microscopy.

I propose, then, briefly to recall the evidences of progress in this part of our science, which the past year affords.

The Abbe Theory of Microscopical Vision.

As a notable feature may be mentioned the greatly increased interest which has been awakened in the important contribution to the theory of the microscope, originated by our illustrious Fellow, Professor Abbe. Although those views are now several years old, and were brought before the Society so long ago as 1877 by our then Treasurer, Mr. J. W. Stephenson, the recognition of the extraordinary nature of the experiments was until lately confined to a very small circle. Both in this country, and in Germany and America, however, the past year has seen a great extension in the number of those who have followed these experiments, and who have appreciated the important bearing which they have on microscopical vision.

I have used the term "extraordinary" because I think that everyone who has seen these experiments will readily agree that it is extraordinary, in every sense of the word, to find, that merely by excluding a greater or less number of the "diffraction" images found at the back of the objective, a great variety of entirely different appearances are presented by one and the same object—lines at a known distance apart doubled and quadrupled—or that objects in reality quite unlike can be made to seem identical—multi-sided figures giving images of squares. In short, the *same* objects may appear to be *different* in structure and *different* objects may seem to be *identical*, entirely according as their diffraction images are made dissimilar or similar by artificial appliances between the objective and eyepiece. The appearance of particular structure can even be "predicted" by the mathematician, before it has been actually seen by the microscopist.

The result of these experiments is to show that a distinction must be drawn between the vision of minute objects and what may be termed, for this purpose, "coarse" objects—*i.e.*, those which are considerable multiples of the wave-lengths.

The latter are imaged by the microscope, substantially in the same way as by the camera or the telescope, and their images correspond point for point with the object. We are, therefore, able to draw the same inferences as to the actual nature of such objects, as in the case of ordinary vision.

Minute objects, or parts of objects, only a few multiples of the wave-lengths, are, however, imagined in an entirely different way—viz., by the diffracted rays produced by the action of the minute structure. If *all* the diffracted rays from the object are reunited and reach the eye, an image of the real structure is obtained. If *some* only of the rays are transmitted, the image is no longer necessarily a true representation of the object, and the smaller the admitted portion the more incomplete and dissimilar the image. Now, as the objects become more and more minute, the diffracted rays are more widely spread, and fewer of them can be admitted by an objective even of largest aperture. The visible indications of structure in such images are not therefore necessarily conformable to the actual nature of the object under examination, and the only inference that we are entitled to draw from the image as presented to our eye, is the presence, in the object, of some of the many different structural peculiarities which are capable of producing the diffraction phenomena observed in the particular case.

Our veteran microscopist, Dr. Carpenter, C.B., has embodied, in the edition of his widely-known work published during 1881, a statement of the leading points of the diffraction theory, which is valuable as containing the results of his own matured views on the subject. He says (p. 187), "This doctrine, originally based on elaborate theoretical investigations in connection with the undulatory theory of light, has been so fully borne out by experimental inquiries instituted to test it, and is in such complete harmony with the most certain experiences of microscopists, that its truth scarcely admits of a doubt."

There are one or two points that require to be kept prominently in mind in regard to the diffraction phenomena in question; 1st, that they are not to be confounded with the so-called "diffraction band" observed round the outlines of objects illuminated by oblique light, nor with the "diffraction" rings displayed by brilliantly-illuminated globules; 2nd, that they are not confined to transparent objects illuminated by transmitted light, but are also produced by *opaque* objects; and 3rd, that they are not limited to lined or regular objects, but extend also to *irregular* structures or isolated elements of any shape; in fact, universally, to structures of all kinds, whenever the uniform propagation of the luminous waves is disturbed by the interposition either of opaque or semi-opaque elements, or of transparent elements of unequal refraction, which give rise to unequal retardations of the waves. They, therefore, apply not merely to the "resolving power" of objectives, but to their general *delineating power*—the power of the microscope to show things "*as they are.*"

The 3rd point is, I need hardly say, most important, and one which it will be very interesting to have more fully elucidated, having regard to Professor Abbe's statement that objects (such as the flagella of bacteria) which are only a fraction of a wave-length in diameter, will necessarily appear to us, not in their proper proportions, but with greatly *increased* diameters, and that very minute striations must appear as if the dark and bright interspaces were nearly of *equal* breadth, although in reality not so.

There are obviously many histological problems, such as the question of the structure of muscle, which a proper knowledge of this part of the subject may greatly help to elucidate.

The facts which we now have before us in regard to microscopical vision, are sufficient to justify the injunction of Prof. Abbe that "the very first step of every understanding of the microscope is to abandon the gratuitous assumption of our ancestors that microscopical vision is an imitation of macroscopical, and to become familiar with the idea that it is a thing *sui generis*, in regard to which nothing can be legitimately inferred from the optical phenomena connected with bodies of large size." That there must be a great deal more yet to be elaborated in regard to the origin and nature of the phenomena we have been considering, is obvious, and I hope that the attention of our own physicists and microscopists will be directed to a subject of such extensive practical bearing, not merely to the theoretical microscopist, but to the large class of practical histologists who are entirely dependent upon the microscope for the accuracy of their observatfons.

The Aperture of Objectives.

The "aperture question," as we all know, gave rise, several years ago, to a somewhat acrimonious controversy, not in the "Proceedings" of the Society, but in the unofficial section of its then *Journal*, and doubtless there were some Fellows who, at the beginning of last year, regarded with no little apprehension the prospect of a revival of that controversy. But, notwithstanding the warmth with which it was debated in its new form, no one will, I am sure, deny the very great value that the renewal of the discussion—between Mr. Crisp and Mr. Shadbolt—has been in bringing to the light what had previously been confined to a few. If any one does not now comprehend how an immersion objective can have an aperture greater than that of a dry objective of 180°, at least it cannot be any longer charged against this Society, that means have not been provided to enable him to do so.

The essential difference between the old and the new view of aperture is simply, that the former considered only the rays which *enter* the objective, while the latter deals with those which *emerge* from it.

The disadvantage of the former method, which estimated the incident pencils entirely by their angles, has been its inevitable tendency to give a fictitious importance to the angle of the entering pencil, which was supposed to have a special virtue of itself, in the delineation of objects. Naturally, therefore, the same angles, whether in air or any immersion fluid, were considered to produce an equal effect, and the advantage of immersion objectives was rested on minor points.

An estimation of the emergent beam, however, must obviously give the same result as one of the incident beam (assuming them both to be correctly made), it being of course impossible for anything to emerge that has not been first admitted. But to quote Mr. Crisp:—"The great and obvious advantage in dealing with the emergent pencil is that it is always in air, and so the perplexities are eliminated which have enveloped the consideration of the admitted pencil, which may be in air, water, oil, or other substances of various refractive indices."*

The subject of aperture is not, in reality, a difficult one, and any intricacy in which it may seem to be involved will be found to arise from the necessity of clearing away some of the old entanglements, such as the curious mistake involved in the "hemisphere puzzle" and similar matters. Looked at *de novo*, there are two simple stages in the aperture question.

(1) To appreciate that, in using the term "aperture," we use it not in any artificial sense, but as meaning opening and nothing else—defining, simply, the capacity of an objective for receiving rays from the object and transmitting them to the image.

(2) That the aperture (as so defined) of an objective is determined by the ratio between the diameter of the emergent beam and the focal length of the objective. According as this ratio is greater or less, so the objective will receive and transmit a larger or smaller portion of the total quantity of rays presented to it.

The emergent beam of an air objective of 180° angle cannot exceed in diameter twice the focal length; that of a similar water-immersion objective may be one-third larger, and of an oil-immersion half as large again, and the relative capacities of such objectives (with equal angles) to receive and transmit rays will always be as 1, 1⅓, and 1½.

It cannot be too carefully borne in mind that it is not a question of this or that theory, but the ordinary laws of geometrical optics, which determine that, all other things being equal, one objective will receive and transmit a greater quantity of light than another, and, therefore, has the larger or smaller aperture, according as the diameter of the beam emerging from it is greater or smaller.

As fellows of this Society we may, I think, be proud of the able communications, relating to this subject, which were published last year in the April and June numbers of the *Journal*.

Numerical Aperture.

The abandonment of the angular notation for aperture necessarily follows, as soon as the correct view of aperture is appreciated; for when we know that the apertures of three objectives are, for instance, as 98, 126, and 138, no one would insist that they should be designated 157°, 142°, and 130°. A notation can have no title to be considered a scientific one, which denotes things as the same when they are really different (60° in air and oil) or different when they are the same (180° in air and 82° in oil).

Until, however, the "law of aplanatic convergence" had been demonstrated by Prof. Abbe, no principle had been established by which the ratio between emergent beam and focal length could be conveniently denoted.

---

*By Prof. P. MARTIN DUNCAN, M.B. Lond., F.R.S., &c. (Annual Meeting, 1882.)

* As pointed out by Mr. J. Mayall, jun., at the commencement of the discussion, if 180° in air is equivalent to 82° in glass, the 140° in glass of the immersion lens must represent something *more*. The fact is, however, so constantly misinterpreted, owing to the supposition that when the immersion fluid is introduced the effect is only that the 82° is no longer compressed by the action of the plane surface of the lens, but is allowed to expand to 140°. This is one only of the apparent difficulties that obscure the proper estimation of the incident pencil, and which are avoided in dealing with the emergent beam.

It would not be possible for me to condense, without a sacrifice of intelligibility, the steps by which he subsequently showed, in a very beautiful manner, that the ratio in question can be expressed by the product of the refractive index of the medium in front of the objective, and the sine of half the angle of aperture, that is by $n \sin u$.

Taking for our *unit* the capacity of an objective for collecting the whole hemisphere of rays from an object in air (i.e., the case of a dry objective of 180° angle) we obtain the "numerical" notation, which, commencing with the lowest numbers advances as far as 1·52 with oil-immersion objectives, and by the use of which not only are apertures compared in the same medium, but in different media also, and we see whether they are smaller or larger than the maximum of a dry objective.

It is gratifying to find that the reproach hitherto attaching to microscopists, for the use of a misleading notation, is, thanks to the efforts of this Society, being rapidly removed, and that the initials N.A. are no longer so mystic a symbol as they have been. I understand that many of the opticians have decided to use the numerical notation in future issues of their catalogues, which is a step in the right direction, which we shall hope to see generally followed.

Whilst on this subject I may point out how important it is that in observations with high-power objectives, their aperture as well as magnifying power should be stated. Whether a large or a small aperture has been used, may make a very material difference in the value to be attached to the results described.

The "Homogeneous Immersion" principle.

The utility of homogeneous immersion objectives being established beyond doubt by practical experience, it is interesting to note that the origin of the principle is very fully recognised by Prof. Abbe to be due to our esteemed Fellow Mr. J. W. Stephenson.

The two essential points in homogeneous immersion are, 1st, the increase in aperture obtained by the use of a fluid of high refractive index and, 2nd, the enhanced optical performance arising from the total suppression of spherical aberration in front of the objective. Prof. Abbe states that although Amici first applied oil immersion, he failed to recognise the specific advantage of an immersion fluid being as near as possible in refractive and dispersive powers to the crown-glass —*i.e.*, "homogeneous." He finished his lenses and then sought for oils and mixtures of oils of various refractive powers for obtaining the best correction. It was Mr. Stephenson who, in his first communications with me, expressed the opinion that doing away with the anterior aberration would improve the defining power, and especially would afford very favourable conditions for further increase of aperture."

The importance of this system will be appreciated when we remember, in regard to the first point (the increase of aperture), that the theoretical resolving power of an objective is thereby raised from 96,400 lines to an inch, which is the maximum of a dry objective, to 146,528 the maximum of an oil-immersion objective, the illuminating power being also increased from 1 to 2·25: while as regards the second point, we are able by the homogeneous-immersion method to reduce the problem of correcting a very wide-angled objective to the much less difficult one of correcting an objective of *moderate air angle*. Our lamented president, the Rev. J. B. Reade, declared in 1870 that "the ghost of aberration will never be entirely exorcised even by cold water." But there appears to be good ground for believing that oil has practically accomplished that object.

During the past year several kinds of fluids for homogeneous immersion have been brought before the society, such as chloral hydrate and glycerine, iodide of zinc and glycerine, and gum-dammar and cedar-oil. Two other vegetable products have also reached us, "tacamaque" and the gum-resin "oliban," or "incense," both dissolved in cedar-oil. While the dammar is claimed to be unchangeable, and to be in refractive and dispersive powers very near that ideal of a good immersion medium, "fluid crown-glass," there is evidently room for further research in this direction, particularly for a fluid which will not attack the various varnishes in ordinary use.

Lastly must be noted an important advance in practical manufacture by the construction, by Messrs. Powell and Lealand, of a homogeneous-immersion objective of the large aperture of 1·47 N.A. out of a possible 1·52. As long ago as 1850 one of my predecessors in this chair expressed the belief that objectives had then "nearly, if not quite, attained the limit of perfection," and whilst it will be prudent even at this much later date to avoid any assertion of finality in the present, or scepticism as to the possibilities of the future, it must be admitted that, so far as regards aperture and resolving power, we have arrived at a point beyond which it will, to all appearances, be difficult to advance, at any rate not without serious restrictions in the use of the objectives. Whilst it might be possible to work front lenses for objectives out of diamond, and so to increase the aperture to 2·5 N.A., and the resolving power to 241,000 lines to the inch, it must be remembered that it would be essential at the same time to provide an immersion fluid, slides, cover-glasses, and illuminators of the same refractive index as diamond also.

(*To be continued.*)

SCIENTIFIC NEWS.

THE approximate position of Comet Wells, on May 10 will be R.A. 23h. 33m., N.D. 74° 35' for Greenwich midnight.

Dr. J. Cossar Ewart, Professor of Natural History in the University of Aberdeen, has been appointed to the Chair of Natural History in the University of Edinburgh, vacated by Prof. Ray Lankester before he had actually entered upon the duties of the office. Prof. Cossar Ewart is an Edinburgh man, and for a few years held the post of Conservator of the Zoological and Anatomical Museums in University College, London. He organised the zoological station on the coast of Scotland, near Aberdeen.

Mr. Eugene Kästner, the inventor of the electrical thermophone, died recently at Strasburg, in the thirtieth year of his age.

The Select Committee of the House of Commons, having passed the Bill for the construction of an electrical railway under the Thames, between Charing-cross and the London and South-Western Railway, at Vine-street, Lambeth, there is a probability that we shall soon have another attempt to tunnel under the river in full swing. The subway was made at so small an outlay that the scheme for an electrical railway promises to be a success.

There seems small probability of the search parties finding Lieut. De Long and his section of the crew of the unfortunate *Jeannette* alive. The news of the burning of the *Rodgers* will help to discourage the old method of Arctic exploration, and draw attention to the plan of establishing depots and advancing by degrees.

One of Mr. Edison's assistants says that the large dynamo now running in London has a resistance of ·002 of an ohm, and that on this resistance Mr. Edison is able to convert 125 horse-power of energy into electricity with a minimum loss, and to avail himself of 97 per cent. of the electricity outside of the machine.

A new insulating compound has been introduced, which is said to be as efficient as gutta-percha or ebonite, and much cheaper. It has been patented by Dr. Fleming, and has been tested by, amongst others, Sir W. Thomson, Mr. Preece, and Mr. J. F. Moulton. It is understood to be a compound of sawdust, cotton-waste, paper pulp, and other fibrous material, which is so treated that it can be worked into any shape, and be made impervious to moisture or acids. The new compound has been named insulite.

In the course of a lecture delivered last week at the Crystal Palace, Mr. E. Bright stated that an electric railway, about thirty-six miles in length, had been projected for a district in the South of England, where abundance of water for driving Gramme machines could be found.

Apropos of the Crystal Palace Exhibition, notice has been given of the "last weeks," the increasing length of the days robbing the electric-light engineers of much of their opportunity.

We have the fifth annual report of the Hackney Microscopical and Natural History Society, and are pleased to see that it is steadily increasing in numbers, while its finances are in a satisfactory state. Dr. M. C. Cooke is president, and Mr. Collis Willmott, of the Triangle, Hackney, hon. sec.

At Llancaiach recently a fine seam of the red-ash house coal was struck in a trial pit near the Park quarries. The entire seam is 7ft. 8in. thick, with about 12in. of rubbish between the two coals. It was struck at a depth of seven yards, and it is estimated to extend over nearly 100 acres.

On the South Carolina Railway kaolin, mixed with plaster of paris and jute fibres, is used for coating locomotive boilers. The kaolin is said to preserve the iron from corrosion, while the coating is more effectual than the ordinary wood lagging.

The Abbé Moigno says that the results obtained at the Palace of Industry in the experiments with electric light in conservatories were not favourable. The naked rays were found, as discovered previously by Dr. Siemens, to be injurious to the plants, and when passed through glass globes, did not appear to affect them. The Abbé finds no proof that nocturnal illumination is beneficial to plants.

At a meeting of the Victoria Institute, on Monday, Prof. Reinsch stated that he had examined with the microscope no fewer than 2,500 sections of coal, and had come to the conclusion that coal had not been formed by the alteration of accumulated land plants, but that it consisted of microscopical organic forms of a lower order of protoplasm, and, although he carefully examined the cells and other remains of plants of a higher order, he computed that they have contributed only a fraction of the matter of coal veins, however numerous they may be in some instances.

The prizes offered by the promoter of the Naval and Submarine Exhibition have been awarded as follows:—For the best means of saving life in cases of shipwreck, to Mr. Roper, for his bridge life-raft, one hundred guineas; for the best contrivances in the shape of cork mattresses, hammocks, cushions, &c., for supporting individuals in the water, to Messrs. J. and A. W. Birt, fifty guineas. The exhibition will be repeated about May, 1881, and particulars can be obtained of Mr. Samson Barnett, jun., 4, Westminster-chambers, S.W.

For mountain observation of meteorological and other phenomena, a recent arrangement at the top of the Puy de Dôme seems well-adapted. Round the observatory tower, a continuous circular terrace, with balustrade about 40in. high, has been formed, giving a full view all round. The balustrade is divided into 360°, the numbers being cut in stone. North is 0°, east 90°, and so on. More than 300 localities have already been referred to this graduation. Two telescopes are mounted on chariots, which run on rails, and may be brought to any divisions of the circle, facilitating the view, which embraces some seven departments. Mont Blanc can sometimes be seen, at a distance of 280km. (say, 175 miles). A vocabulary gives all the places visible from the summit, and the places in each vertical plane passing through a degree are indicated. Further, geographical maps are constructed, having Puy de Dôme as centre, and a number of concentric circumferences with radii, indicating distances. With this system the path of thunderclouds, and various other phenomena, can be easily observed with great precision.

It is known that the action of the brain causes a rise of cranial temperature. M. Delaunay (we learn from *Les Mondes*) finds from experiments on himself during sleep, that, reciprocally, an elevation of cranial temperature stimulates the action of the brain. Dreams are usually illogical and absurd. M. Delaunay, by covering his forehead with a layer of wadding, gets sane, intelligent dreams. He has also experimented on modes of lying, which favour the flow of blood to particular parts, increasing their nutrition and functional activity. He has observed that the dreams one has while lying on one's back are sensorial, variegated, luxurious. Those experienced when on the right side are mobile, full of exaggeration, absurd, and refer to old matters; but those produced when on the left side are intelligent and reasonable, and relate to recent matters; in these dreams, one often speaks. The observations, according to the author, agree with what we know as to the seat of sensibility, of motility, of intelligence, &c., and the comparative psychology of the right and left brains.

It is a common notion that sunshine affects the draft of a chimney, exerting pressure against the rising smoke, and this idea might seem to be favoured by the mechanical effects of light discovered by Mr. Crookes. Herr Kohlrausch has recently, in Carl's *Repertorium*, described experiments in this relation made with a delicate means of measuring pressure—a thin piece of straightly-corrugated copper plate, fixed by two sides in a frame, and, through a needle, affecting a mirror by its movements. The instrument was fixed in the side of a wooden case, having vertical iron tubes connected above and below. The sun's rays, Herr Kohlrausch says, exerted no influence amounting to a few millionths of an atmosphere. He dismisses the idea in question as erroneous.

Various hollow glass objects (beads, pearls, &c.), are now prepared with the aid of Balmain's luminous paint, by a German firm, Schellhorn and Söhne, in Lauseha, Thüringia; so that, after exposure to strong light, they shine in the dark. Two methods are patented, some particulars of which are given in the *Deutsche Industrie Zeitung*, No. 15.

Among novelties recently shown at the annual *séance* of the Paris Physical Society, was a one-liquid battery of M. Aimonnet, which, with 32 elements in a case about 24in. long, 16in. broad, and 8in. in depth, worked a Cloris-Baudet motor, giving a force of 608 kilogrammetres, used for turning copper. A Gramme motor, driven by Faure accumulators, worked a powerful pump. The arc light given by the Salignac regulators was remarkable for its intensity and fixity. In the vestibule were 30 accumulators (600 kilogs.), feeding an arc lamp of 100 burners, and on the staircase 40 accumulators (60kg.) working 40 incandescent lamps. In one of the halls optical phenomena were projected on the ceiling, a method which would often be quite sufficient.

An electric railway is to be made in the picturesque valley of the Brühl, near Vienna. It will extend from the railway-station of the sulphurous baths of Merdling to the hotel known as the Zwei Raben, near Meierei, in the Hinterbrühl, which is annually frequented by thousands of tourists. The length will be nearly two miles.

The telephone system in Vienna (according to a German electrical journal) is only about three months old; but the number of subscribers in communication is 224, and it will soon be 250. This is a more rapid rate than in Berlin, where the system was begun in April, 1880, and the subscribers now number 668. We note that a full account of the telephonic system in Paris appears in *L'Electricien*.

Attention has lately been called by M. Roland to an animal of the rodent order, which is met with on the banks of American rivers, and which he considers well suited for domestication. It is about the size of a pig, and is called the *cubiai*, or the water-hog It is not an aquatic animal, but defends itself from its enemies by plunging into water and remaining there a few seconds. It lives among the reeds, and comes out morning and evening in search of its food, which consists of herbs and roots of all sorts. Its large incisors enable it to cut the hardest woods with ease. Taken young, it is easily tamed, and does not leave the house; it knows its master, and likes to be caressed, and it is very cleanly in its habits. Its skin forms supple and permeable leather, and the flesh is good eating. Without requiring more care than rabbits, it will furnish as much flesh as a sheep, than which it is less subject to disease (though the flesh is less delicate). The apathetic character of the animal enables it to utilise all that it absorbs, so that there is no need to fatten it, and a large number may be kept in a small space. It is not afraid of cold; in very hot weather it lies in water among the reeds.

A singular accident from electricity lately occurred at a corn-mill in Pittsburg, U.S. The mill is lit with the electric light, and the generator is surrounded by a barrier 4ft. in height. A workman leaned on the balustrade, but immediately he jumped up with a cry, and falling into the arms of the engineer, who was behind him, expired. It seems proved that the engineer, who had been making experiments, had stretched a conducting-wire from the machine to one of the other conductors, and along the base of the barrier; and it is supposed that the workman, leaning on the barrier, had touched the wire with a lamp he held in his hand, thus closing the circuit though his body and the ground. Since, to supply the 16 lamps of the mill, a tension equal, at most, to 800 or 900 volts was required, the accident shows that currents of tension approaching 1,000 volts should never be manipulated without special precautions being taken in insulation of the conductors.

On the occasion of the Venus transit in 1874, Prof. Tacchini suggested to Père Lafont the desirability of erecting a solar observatory in Calcutta by way of supplementing European observations under better conditions of climate. The necessary funds were supplied by private subscriptions and by a grant of 15,000 francs from the Government of Bengal, and in less than two years a large dome was constructed, having a splendid Steinheil telescope (9in.) with a Merz equatorial base, and a large reversion spectroscope (one of Browning's). An excessive exposure to the sun's rays compelled Père Lafont to desist from his observations. The work was proceeded with by Pères de Clipperen and Campigneulles, who began the daily registration of sunspots, protuberances, &c. They publish the results from time to time in a series of plates or diagrams.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. PASSMORE EDWARDS.

⁂ *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."
—*Montaigne's Essays.*

DE MORTUIS NIL NISI *VERUM.*—THE LATEST ADVERTISEMENT OF THE COMMITTEE ON SOLAR PHYSICS—OTTO STRUVE 266 (COMA BERENICES)—μ^1 BOÖTIS—RIGHTS OF WAY, AND CLOSING FOOTPATHS—TESTS FOR A 3IN. TELESCOPE.

[19991.]—SINCE my last letter was written death has removed one of our mightiest intellects from our midst. I am, of course, referring to perhaps the greatest and most philosophical naturalist the world has yet seen—Charles Darwin. With what pride must not every Englishman ever regard him! To anything like mean, sordid, or selfish notions he was an absolute and utter stranger. His long and honoured life was wholly given up to the steady, patient, persistent study of the history of organised beings. That faculty of observation cultured and developed by his voyage in the *Beagle* 51 years ago, never afterwards slumbered nor slept; and the pure love of Truth constrained him to persist, through years and years of patient and persistent observation, for the purpose of arriving at it. It would be difficult or impossible to estimate the kind and amount of research embodied in such works as the "Origin of Species" and "The Descent of Man"; or even in his books on plants and earthworms. Moreover, the writing of the word "research" just now, suggests to me to recall the fact that he never went begging to Government to "endow" his investigations, or to grant him pecuniary aid in any shape or form. Like the really great discoverers in all ages and in all countries, he worked at his own cost and charge. He had faith in himself and in his cause; and had infinitely too genuine a love for Science for its own sake to use it for huckstering purposes, or for downright mendicancy. Such men as Charles Darwin are the very salt of the scientific earth. Alas! that they should be so relatively rare. Happily they leave their immortal work behind them, and their names are familiar to untold generations who follow them. Assuredly thousands will mourn for Darwin, who never beheld his face in the flesh; for of him may well be repeated the words of the Psalmist, "Know ye not that there is a prince and a great man fallen this day in Israel?"

So it would seem that an Eclipse Expedition has been despatched at the national cost, at the instigation of the "Committee on Solar Physics." It is to consist of that remarkably well advertised gentleman who seems, for some occult and inscrutable reason, to be always sent out to observe Eclipses (possibly in the hope that he may ultimately succeed in finding something out, if he only tries often enough!) and of Dr. Schuster. It is needless to add that the "expedition" received a parting puff in a daily contemporary, in which the "fine Roman hand" of the writer was but too distinctly perceptible. Luckily, that thoroughly competent astronomer, Mr. A. Cowper Ranyard, has gone out, too (it is needless to add *not* at the public charge), and that he takes with him a most complete and elaborate set of apparatus for Solar photography. He is to join M. Bischoffsheim's party. Other observers are also *en route* for Egypt. Now, the results of these separate expeditions will be awaited with keen interest; because if it be found—as I have little or no doubt whatever it will be found—that the unsubsidised and voluntary observers do all that, and more than is accomplished by the *Arcades ambo*, who made such a dismal fiasco, at a huge cost, in the year 1875, then I venture to think that the tax-paying public will have a distinct right to know at whose instigation and by whose authority Messrs. Lockyer and Schuster have been despatched on this errand. The initiated, of course, know that the whole thing is an advertisement, and an attempt to galvanise the Solar Physics Committee. If the nominees of this paltry little ring succeed in doing more than the unsubsidised observers, whose thought for themselves is subordinated and lost in their zeal for the advancement of Science, Mr. Mundella may, perhaps, be imposed upon a little longer. If not, then those at whose cost and charge the observers have been despatched to Egypt may conceivably claim, like the Cornishmen in the ballad, to "know the reason why."

In compliance with the request of Mr. Simms (letter 19936, p. 150), I availed myself of the opportunity afforded last night, by a few rifts in the clouds, to look at OΣ 266 (Coma Berenices). The driving moonlit cirrus haze prevented anything like an attempt at measurement; but my querist is certainly right as to the present distance of the components of this star, which is rather over 1·5″ than under it. I just turned the telescope on to μ^1 Boötis too; but failed to detect any abnormal faintness in the companion. It decidedly suggested no idea of a 10th magnitude. It may not be a very brilliant specimen of its class; but I should certainly rate it as of about the 8th magnitude myself. Of course, its bluish-lilac colour does not offer such a contrast to the background of the sky as the light of a white star of the same size would do.

In reply to query 46721, p. 183, highway boards, as such, have no power to agree, either with a landlord or tenant, to stop up a footpath over which the public possess a "right of way." The sole means of stopping a public highway is under 5 and 6 William IV., c. 50, ss. 84 et seq., which empowers two justices to stop up unnecessary highways, and divert and turn existing highways, so as to make them more commodious to the public, upon the requisition of the inhabitants of the parish in vestry assembled, through the Surveyor of Highways. The dedication of a road to the public constitutes a highway; and this is presumed if the owner of the soil throws open a way, and puts up no gate, bar, or other visible indication of his intention to exclude the public. In the case of Jarvis v. Bingham (and others) the Courts have allowed such presumption where the way had been only used four or five years and was actually in an unfinished state! Sixty years' uncontested user would indubitably establish the right under the Statute of Prescription; and I fancy that 12 years now would do so with equal certainty; especially, as I have just said, as only four or five years enjoyment of a right of way by the public has been held to be sufficient.

It is not very easy to comprehend what "Wykehamist" means (in query 46740, p. 183) by asking for tests for a 3in. telescope which can be found "without the use of a Star Map": because this may either indicate that he possesses a fair naked-eye acquaintance with the Heavens—or that he doesn't know a single star in the sky. However, he may try γ Leonis, ε Boötis, δ Serpentis, and σ Coronæ. If, though, your correspondent will only study your back volumes, he will find tests for telescopes of every size, sort, and description (including scores for 3in. ones) given over and over again.

A Fellow of the Royal Astronomical Society.

ASTRONOMICAL.

[19992.]—EYEPIECES.—Anybody who has a few astronomical books and has studied their utterances, and particularly their diagrams when referring to eyepieces, must have been struck with the idea that the subject is often very inadequately treated. I must say that, as far as my reading and observation extend, in no single work has the matter been dealt with and illustrated in a satisfactory manner.

Even in such a well known and useful work as Chambers' "Astronomy," we have a diagram of a Huyghenian or so-called negative eyepiece, and also of a Ramsden or positive eyepiece, but the paths of the rays are represented as being identical in both cases. At the same time we are informed that in the Huyghenian the image is formed between the two lenses composing the eyepiece, while in the Ramsden one it is in front of both, which statement is, no doubt, correct. By what perversity of ingenuity, then, are the diagrams made to contradict the test in the manner they do?

The path of the converging rays from the object glass through a Huyghenian eyepiece I take to be as I represent them here (Diag. 1), where R shows the converging beam, and E the eye of the observer. In the Ramsden form the ray path is something like this (Diag. 2), where F is the focus of the object glass, and E the eye as before. Will somebody kindly correct me if I am in error, and supply diagrams of other forms of eyepieces? While on this subject I may say that in Herschel's "Telescope" the diagrams seem to me to be, as one of our friends once said, when writing about another matter, "by no means inviting in their simplicity," and what another one might call a "caution." In Guillemin's "Heavens," edited by Mr. Lockyer, and revised by Mr. Proctor, we have a picture of the "Theory of an Astronomical Telescope," with the rays positively diverging from the centre of a convex object-glass. "My friends, these things ought not so to be."

FIG. 1

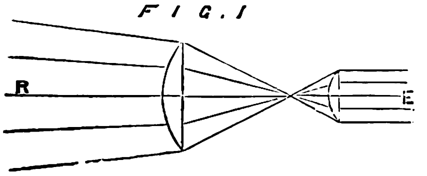

FIG. 2.

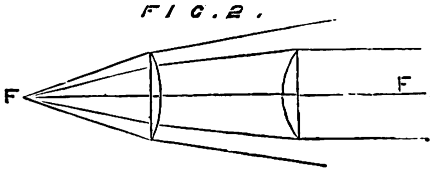


Powers Used.—We are favoured in this paper with a good many original observations and drawings of planets and double stars; but I wish that all the observers would give the focal length of the object-glass or mirror used at the same time that they give the power of the eyepiece. What would be even better than that, would be the adoption of the 6ft. focus plan as a standard to which all powers should be reduced. Seeing that the same eyepiece magnifies twice as much upon a 6-ft. focus as it does upon a 3ft. one, and that the focal lengths are very seldom given us, and the distance upon which the magnifying power is measured is never given us, the advisability of some uniform plan is tolerably evident if the pictures and observations are to be comparable with each other, or indeed to have any value at all.

Ascalon.

AURORA, APRIL 16TH—SUNSPOTS.

[19993.]—On the eve of Sunday, April 16th, there occurred one of the most brilliant exhibitions of the Aurora Borealis ever witnessed in these parts.

The Aurora began to manifest itself soon after sunset, and from that time on to midnight the northern heavens were the scene of most vivid illumination.

At 9 p.m., while observing some double stars in Leo Minor and The Lynx, I became aware that a bright haze was filling the field of the telescope to such an extent as to make it difficult to pick up faint stars. Removing my eye from the eyepiece, I at once saw the cause of this.

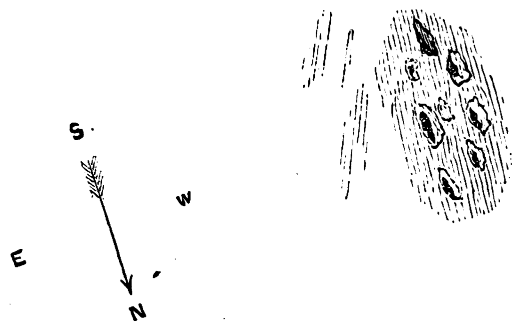
The Aurora, which but a few minutes before had been nothing but a faint phosphorescent glow along the northern horizon, was now rising a well-defined band of soft, even light. This band continued to rise until it spanned the heavens like an arch, the bases resting on the horizon at the N.W. and the N.E. points, while the centre was 25° or 30° above the horizon. Having risen thus, it remained stationary at about 9·45. Below and above this arch the heavens were as dark as ever; but about 10 p.m., spires of light began to shoot upwards to the zenith and downwards towards the horizon.

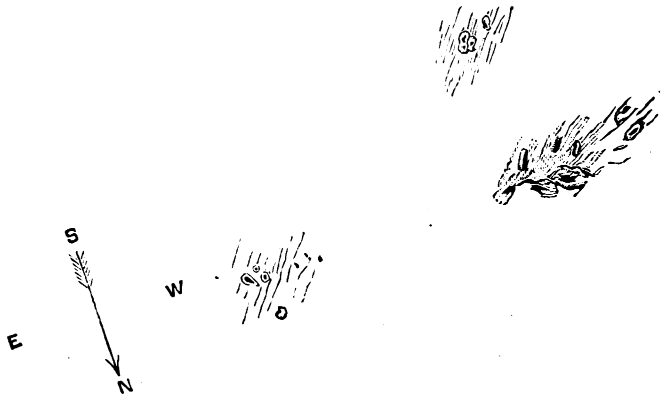
For more than an hour this continued; spire succeeding spire, flame succeeding flame, banner succeeding banner with great rapidity; while ever and anon large openings seemed to appear in the sky through which the light streamed with redoubled vividity.

At 11.15 the central portion of the arch began to reassume its quiet glow, while the bases began to brighten.

It now seemed as though a mighty wind had sprung up from the North, and was driving these bright bases to shreds, sending them through the air like flames or waving curtains. These, as the wind seemed to bear down upon them with fury, would bend before it like growing wheat; then, as it passed, straighten up again and glow with vivid tints of red, carmine, and green. Again they would fade away, but only to come back brighter than before. This continued until the flames had been driven quite to the S.W. and S.E.

At this time its appearance was such as to convey the idea that the upper strata of the atmosphere were on fire, and burning down through, and bright enough to read a newspaper. All this was doubtless caused by some tremendous action in progress on the Sun. While observing the Sun on the 14th, I saw some very large spots, and its face was dotted with spots of greater or less extent in both zones. On the western limb there was an aggregation of very large spots (of which I send a drawing), and the region all about was in a very agitated condition. Unfortunately I did not observe the Sun on Sunday, but to-day (Monday, 17th), I see the whole surface is entirely changed. The large spots on the western limb have disappeared, as also the chain of spots which encircle the disc on the southern zone, while towards the centre of the disc are a number of new ones (of which I send sketch), in the northern zone.





Perhaps—if such has not been done ere this reach you—some of your readers, who have well-appointed observatories, will give us the measurements and position of these spots.

Will "F.R.A.S." please accept my earnest thanks for his answers to my inquiries? So far, I have only been able to try γ Leonis and ζ Cancri, which I divided; γ Leonis being the easiest. I will try the others as soon as possible, and let him know the result.

Would he be so kind as to tell me what star atlas he refers to, when he says, "90 Leonis and 66 Cancri?" What is the best atlas for the amateur? I have Webb's "Celestial Objects"; but, though it is undoubtedly a most excellent work, I cannot see how I am to use it without R. A. and Decl. circles, and also all the star atlases referred to.

Perhaps I am dull of comprehension, and if some one will infuse a little, I shall be most grateful. **W. C. Herbert Bridle.**

1018, Wood-street, Philadelphia, Pa.

SCIENTIFIC RESEARCH AND THE ROYAL SOCIETY.

[19994.]—Permit me to amend a short sentence in my letter on Scientific Research, as I fear it is not so clear as it might be, the subject-matter being somewhat difficult. It is said that the "drop" phenomenon is owing solely to the *size* or *linear dimensions* of the source of the light, whether of the sun, or the flame of a rushlight. It should be that the "drop," as seen between two meeting bodies, whether of the Sun and the planet Venus, in a transit, or between the finger and thumb, or between two meeting penny-pieces held up against a sheet of white paper, is due, and due solely, to the *size of the eye-pupil*, and to that alone. Diminish this to the size of a needle-point hole in a thin metal plate, and the "drop" totally disappears; the meeting discs of other bodies being then seen to meet and touch each other, with clear and sharp outlines. It may be added that the pure and simple "black-drop" can be seen only between two *dark* objects against a bright light, as between two meeting planets on the sun's disc, could such an event occur. **C. B. A.**

THE COMET WELLS.

[19995.]—Ever since April 9th this comet has been observable with so small an aperture as 1¼in. and a power of 20; it was, however, only just within the reach of such an aperture on that date. Its appearance was that of a seven-and-half magnitude star a little out of focus, only distinguishable as a comet by averted vision, when a faint nebulosity was discernible on the preceding side. But by moving the telescope, so that the comet was viewed in various parts of the "field of view," the tail was made apparent to direct vision by steady gazing. It is almost needless for me to mention that the comet was only to be found by means of an equatorial.

On April 20th it was easily within the reach of such an aperture, being about three times larger than on April 9th, and by the 21st it had become so much brighter that according to Dr. Copeland it was "readily found with a good opera-glass."

We may, therefore, expect shortly to have the comet a naked-eye object, probably by the time these lines are in print.

Should the comet be as brilliant as it is expected to be, a splendid opportunity will be afforded us of adding to our spectroscopic knowledge of these, the most mysterious bodies with which the astronomer has to deal.

London, April 28. **B. J. Hopkins.**

A COMPACT FORM OF BUNSEN'S BATTERY.

[19996.]—I have made a very compact form of Bunsen's battery, and having used it a good many times, and it having thoroughly satisfied me, I thought perhaps it would not be amiss if I sent a description of it for the benefit of our numerous electrical friends.

The containing-vessel is an oak trough 19in. × 6in. × 4½in. outside diameter, and is made of ½in. stuff. It is divided into 12 compartments or cells by 11 partitions of ⅛in. deal, which slip into shallow grooves cut in the sides. Care must be taken that they fit very nicely, or they will leak.

The inside must be well waterproofed by giving it four coats of Japan black. For the first two coats a little turpentine should be added to the Japan, to make it soak into the wood. The outside may be French polished or varnished, and when a couple of good strong handles have been put on the ends this part of the job is finished; now you must go to the electrician's and get a dozen flat porous cells, 5½in. by 3¼in. by ¼in., two dozen zinc plates, 6in. by 3in. by ⅛in., and one dozen carbon plates, 5½in. by 2½in. by ⅛in. (these I had to have cut expressly for me, and got them with the rest of my things at Dale's), with a dozen ball-pattern clamps to fit. Now solder 6in. of 22 copper wire on to each zinc; now amalgamate them, and then put one carbon in and one zinc on each side of a porous cell, and put them in the outer trough. Now connect the two wires from the zinc of cell No. 1 to the carbon of No. 2, and so on through the whole series, leaving one zinc and one carbon for connection. Now charge the porous cells with nitric acid saturated with bichromate of potash (this is necessary to prevent it fuming), and the outer cells with sulphuric acid 1, water 10, and you will obtain a current of enormous power, very suitable for the electric light, for, with a good lamp, it will give a power equal to about 75 candles. It requires 2lb. of nitric acid (1s.) and 1lb. of sulphuric (1d.) to charge it, and with this charge it will give a constant current for about four hours. I would have sent description of the lamp I use with it, only I fear I have trespassed too much already.

H. S. B.

ELECTRO-MAGNETIC MOTORS.

[19997.]—EVER since the discovery that soft iron could be magnetised and demagnetised very rapidly, endeavours have been made to construct an effective engine for working purposes; and the increasing interest which at the present time is taken in the sciences connected herewith renders every attempt to stray from the beaten path worthy of investigation.

It seems, however, almost a forlorn hope, when we compare the cost of zinc with coal. But in competition with human and animal power, the case does not seem so hopeless when we consider that the food (which is the source of power) is also comparatively expensive. And hopes are further strengthened considering what Faraday says ("E.M.," Vol. XII., p. 106), that "the electrical relations of one drop of water equal a powerful flash of lightning," and that the power of a flash through 50 feet is equal to 12,220 horses, and the initial explosive force is equal to 300,000,000 tons. Here it is evident that explosive forces cannot be made to equate with correlated forces, which they supplement, and they elude our grasp.

It seems natural that an armature attraction (so long known) should be thought to be the most suitable means to utilise the discovery referred to; but seeing that it is known that battery power is being wasted to produce an average force far inferior to that at contact; and *that*, far less frequently in a given time than the nature of the case could admit of, great improvements are required.

In the presence of further light, I make bold to say that such a method is not the right one; and, moreover, I say that the power resides in the magnet itself; and that our efforts should be to contrive to use the *direct* force of the magnet (not acting at a distance) which can be proved exists.

Now, it is known that iron when magnetised, shortens by a small portion of its length, which is restored upon cutting off the current. This fact is, I believe, not generally known, and often considered doubtful. That such, however, cannot be but a fact, I have settled in my own mind, in this way: 1st. That anything can only produce motion in another thing at a distance by means of an intervening medium (in this case ether). 2nd. That anything can only produce motion in another thing when it is itself in motion.

But the difficulty lies in the application of so small a motion to practical purposes. This could not be done in the ordinary methods in use for such an object: the motion would be lost in what I may call the slack.

Although the motion is so small, we have two other circumstances in its favour (like the pawnbroker, 2 to 1). 1st. The power is very great; imagine the power required to compress a bar of iron (cold) the hundreth of an inch, or less. 2nd. It is known that magnetising and demagnetising, which corresponds with the shortening and lengthening, can be done with the utmost rapidity; in my opinion only limited by the number of vibrations corresponding to the musical note produced by striking the end of the bar.

But however an engine may be contrived, it is certainly necessary to avoid slack and friction as much as possible, and in order to give an idea of the elementary application of the power to other parts required to complete a machine, I describe Fig. 1, which represents a flat bar of soft iron riveted in many places to a like bar of brass, and wound round them a proper quantity of covered copper wire for the current, which flowing will cause a contraction of the iron bar, and deflection of the compound bar, becoming again straight when the current ceases. The bar is fixed at one end to a base or upright. Here is absence of slack or friction.

To manage a rapid cessation of current, I would suggest Fig. 3, which represents a circularsaw circumference with fine teeth (made of brass), which, rotating, breaks and makes contact with a suitable weak spring.

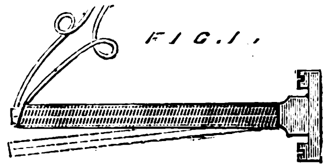


FIG. 1.

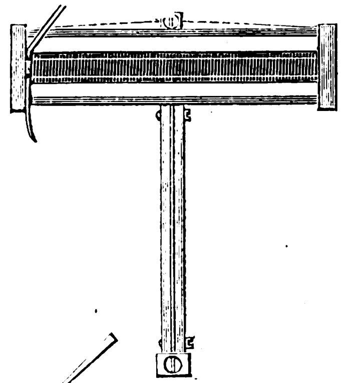

FIG. 2.

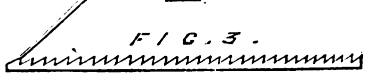

FIG. 3.

Fig. 2 represents a round bar of iron, surrounded by a parallelogram of gun-metal, in union, as if one piece. When the current is in the coil (shown) the outside bars are expected to bulge a little; but, nevertheless, a great increase of the motion compared to the iron bar. So far, I have had Fig. 2 made and laid aside for two years, and in the absence of a battery have been unable to test its performance. The lower part of Fig. 2 suggests a further increase of motion.

In conclusion, these ideas being only in their infancy, it is to be hoped that some of our readers will advance towards a perfect machine.

Barry-road, S.E. **J. H. Huxley.**

THE TELECTROSCOPE — DYNAMO-MACHINES—HEAT EQUIVALENT.

[19998.]—THE telectroscope, described in letter 19941 by "W. L." is certainly most ingenious, and I believe in theory is all right. In practice I am afraid the inertia of the moving parts connected with the Nicol's prism would render it impracticable. Those who know the difficulty of making a galvanometer with extremely light needle deat beat, will appreciate this objection.

With regard to "W. L.'s" first question, the changes of resistance of selenium attain almost the maximum instantaneously. The latest proof of this will be found in *La Lumière Electrique*, No. 16, April, 1882, p. 380—an account of experiments by Bellati and Romanese, showing that 1-1,000th of a second suffices to produce almost the total effect.

As to the second question, the resistance of selenium can, I believe, be altered 50 per cent. by bringing from darkness into a very strong light, assuming 50 per cent. to be what we work upon. If the selenium cell have a high resistance compared to the rest of the circuit, the resistance of the whole circuit may be altered nearly 50 per cent.; hence the whole current may be altered nearly 50 per cent., the resistance of selenium being about 10 per cent. that of iron, although the cell in this case must be very small (in theory a point), it might be possible to obtain the above result; still I think the objection on the ground of inertia would be almost insuperable. Now to turn to another subject. "Humble Bee" has stated that a current can be produced in a wire moving in a uniform field. "Conrad" objects to this. Now both are right. Whilst "Humble Bee" refers to a straight wire moving perpendicular to its own length and to the lines of force, "Conrad" thinks of a coil moving similarly. A coil moved similarly would have an electromotive force generated in the wire on each side of the coil; but these would be in opposite directions, and thus neutralise one another. A single wire can only be made to produce a current by letting the ends slide on two rails of metal joined at the end, thus virtually forming a coil, one side of which only moves, and thus the electromotive force in this side is not neutralised. By sliding the wire along we increase the area inclosed by the coil, and thus add lines of force to the coil or subtract, according to which way we move the wire.

In conclusion, I should like to ask a question. Will any one be kind enough to tell me the heat equivalent of one ampère per second through one ohm, as determined by experiment—not calculated?

Ll.B.A.

THE TELEPHONE RECEIVERS OF JOHNSTONE-STONEY AND OF PREECE.

[19999.]—MR. GEORGE TOLMAN is singularly unfortunate in his telephonic inventions. The forms of receiver referred to in his letter (19987, p. 177) as having been invented and used by him in November, 1880, had all been previously publicly described—the first two by Johnstone Stoney in the letter referred to in my previous communication (letter 19986, p. 177), the last by Mr. W. H. Preece in a paper "On some Thermal Effects of Electric Currents," read before the Royal Society on 27th May, 1880.

Johnstone Stoney says: "A spiral wire . . . was wound closely so that the spires were in contact or nearly so. One end of the spiral was fixed, and the other end attached by a thread to the middle of a . . . drum-head. A slight tension was put on the thread to draw the spires of wire slightly asunder. The spiral wire was then made part of a circuit, including one or two cells of Grove's battery and a line wire going to another room. The apparatus could obviously be rendered more efficient by using . . . a coil consisting of a number of concentric spirals not quite in contact, so as to allow small motion to exist. The induction might be still further increased by using a spiral of two wires, so that a powerful local current might be kept up in the alternate spires, while the varying line current is passing through the intermediate one. Another improvement would consist in using iron wire wound in a sufficiently loose coil. The self-magnetisation of the coil would co-operate with the electric induction to heighten the effect."

Preece says: "It occurred to me that if a long wire of small diameter and high resistance were attached to . . . the centre of a disc (such as one of those used for telephones . . .) and it formed part of a circuit conveying telephonic currents, sonorous vibrations ought to be reproduced." Experiments were made with wires of platinum, aluminium, palladium, tin, copper, silver, and gold, all under tension. **Alfred W. Soward.**

ELECTRIC-LIGHTING DANGERS.

[20000.]—WITH all due deference to "Sigma," for whom as an electrician I have the highest respect, I think he rather overrates the importance of the statement he refers to in his letter on the above subject. Mr. Johnson is certainly reported to have said that he would pass the "whole of that enormous current through his body." Still, it is to be remembered that his audience were not all electricians, and to go into the question of relative resistance of his body compared with that offered by the lamps and conductors would have been confusing and useless; what he wished to demonstrate was simply the inability of a low-tension current, as that generated by Edison's machine to do what the high E.M.F. in those of Brush and others have done—*i.e.*, give a fatal shock; and if in explaining this in popular language he allowed a technical inaccuracy to creep in, it hardly merits so severe a denunciation as "Sigma" would inflict.

No tyro in electrical matters would suppose that an E.M.F. of 110 Volts (or thereabouts) could send a current of 1,000 ampères through the resistance of the human body, and no one among the uninitiated will be in the slightest degree enlightened by "Sigma's" letter.

Suppose, then, we ask Mr. Johnson to reconstruct his unfortunate sentence, and make it run, "the whole current which that enormous machine could send through his body," and I think it will meet all requirements.

In conclusion, let me state that I am not in any way interested in the company concerned, and have never seen either Mr. Johnson or the machine.

Liverpool. **G. A. Moore.**

MEDICAL REPLIES.

[20001.]—VARICOSE VEINS (40673).—This is a permanent infirmity, due to congenital weakness in the fibrous coat of the veins, causing gradual stretching of the vein-tube with pain, swelling, and sluggish circulation in the parts affected. It is aggravated by much standing, by corpulence, by constipation. It is most frequent in the lower limbs, because there the veins have to support a long column of blood, and is more often found in the left leg than the right. Such occupations as do not throw strain upon the weak vessels; mechanical support to the legs by means of bandages, or elastic stockings, or adhesive plaster, and the prevention of constipation are the means of relief. I am not aware that climate is of consequence to such sufferers.

KIDNEY DISEASE (46667).—"B.D." who "has always lived freely, and smoked considerably," now has a series of symptoms for which he should get carefully examined by a physician. There is no means yet discovered by which a man who has "rotted his timbers" by "living freely" and smoking considerably can get a new set of timbers put into him. If he leaves off drinking and smoking he will stop the rotting process, and, if not gone too far, sound medical advice will show him how to tide along and make the best of such stock of vitality as is not yet used up. And medicine may help him. But his case is not one that can be served further by letter writing.

SCROFULA (46707).—This is too large and varied a subject to write upon usefully, as now requested. The forms of degeneration known as scrofula are endless, affecting as they do more or less all the organs of the body, and in very various ways. Querist probably has scrofulous disease of the glands of the neck—a disease in which earthy deposit takes place in the substance of the lymphatic glands. This slowly enlarges the glands to a chain of almond-like tumours, and when a little cold is taken, or the deposit softens, there ensue a series of abscesses. These abscesses discharge matter, and—so soon as all the scrofulous deposit has been got rid of—they heal up, leaving unsightly scars. The longer these abscesses are in clearing out the deposit, the greater will be the permanent scarring and deformity. Local applications, of which occasional dressings with a thin layer of soft-soap is one of the most useful as a domestic remedy, will often hasten and facilitate this discharge. But much depends upon improving the general health, so as to prevent further deposit, and make the blood so healthy as to quicken the healing process. Damp houses and damp clayey localities are prejudicial. Sea air, sea voyages, change of climate, and dry dwellings are advantageous. Open-air occupations, flannel clothing, such food as I have indicated in former letters—in fact, such hygiene, regimen, and diet as will keep the bodily health at its best, are the foundation of the treatment for such cases. Here, again, medicine also will do much; but I can only advise the sufferer to consult some good physician in his neighbourhood, who can personally examine him and realise his condition. Unless vegetarianism is distinctly beneficial, my opinion would be against it in your case. If thin in person you will find the fat bacon, milk and porridge diet useful. Abstain from alcohol and tobacco.

BROWN MARKS ON SKIN (46671).—Many such marks are cured by applying to the skin a lotion composed of an ounce of borax to a quart of water. The lotion should be dabbed into the skin every night at bedtime. If, however, the spots are of the nature of lepra or psoriasis, they will not go away without appropriate constitutional treatment. **James Edmunds, M.D., &c.**

Grafton-street, Bond-street.

"ENGLISH MECHANIC" MICROSCOPICAL SOCIETY.

[20002.]—SOME few weeks ago, a letter appeared in the ENGLISH MECHANIC in which it was proposed to establish a Microscopical Society amongst the readers of this journal, to be called the "ENGLISH MECHANIC Microscopical Society." It is gratifying to find that several of "ours" have already signified their willingness to help in getting up such a society, and it therefore only remains for those interested who are ready to become members to drop a line to either of the undermentioned, who will be very glad to receive any suggestions bearing on the matter. The proposed society could be worked somewhat as follows, subject, of course, to such modifications as might be deemed expedient, viz.:—

Admission to be by a small entrance fee and annual subscription, to defray necessary expenses.

A certain proportion of the members to be chosen annually to act as committee and honorary secretary.

Proper rules to be drawn up for the guidance of members.

Each member to contribute a stated number per annum of slides for circulation.

Boxes of slides, &c., to be sent from member to member at regular intervals. Note-books to accompany slides for receiving notes on the objects sent, or on any other matters interesting to the members generally.

The above is merely a bare outline of what might be done. It would be for the members themselves to say how far the idea should be extended. After a while the society would be found to be a pleasant source of recreation and mutual assistance, and could be made extremely useful in the way of naming and exchanging specimens, &c., &c.

Those favourable to the scheme will greatly oblige by communicating their ideas to

N. C. Sutton, 5, Courtenay-terrace, Portslade
near Brighton; or
F. Cowley, 106, Western-road, Brighton.

WENHAM'S UNIVERSAL INCLINING AND ROTATING MICROSCOPE.

[20003.]—THE readers of the ENGLISH MECHANIC are, I am sure, much indebted to the Editor for the publication of the figures and description of Wenham's new microscope in the issue of April 21. We are thus enabled to understand, in some measure, the scope of design of the microscope that most perfectly realises the modern ideal—especially after the numerous and splendid models of stands by Beck, Bulloch, Grubb, Ross, Swift, Tolles, Watson, and others, that have appeared from time to time in the pages of the "E. M."

I venture to offer a few observations in supplement to your published description, premising that I have examined the instrument carefully. I also premise that sundry of the movements are practically the same as those in Watson's microscope (devised by Mr. Moss, of Macclesfield), published a few months ago in the "E. M." As it is known, however, that the original models of both stands were in process of construction at the same time, neither party being aware of the other's design, they may both be regarded as original; my observations will, therefore, not include any direct comparison between them.

Dividing my remarks under four headings—(1) On the general design; (2) The fine adjustment; (3) The stage; (4) Minor items—

(1) The general design is the most ambitious hitherto constructed. Here are no half-measures. Mr. Wenham has grasped the idea of centralising the whole of the movements round the axes of the object to be viewed, and has developed it thoroughly. In Grubb's substage-arc, Nachet's double-sector substage, Zentmayer's swinging tail-piece, and Tolles's vertical disc-carrier for the substage ("Tolles-Blackham" microscope), combined with the rotating stage, we have devices enabling us to obtain every obliquity of illumination (within certain limits imposed by the construction). But for range of effects obtained with the minimum labour to the worker, Mr. Wenham's new microscope presents advantages over all previous constructions. He makes the focal point (*i.e.*, the object) the point of intersection of the three axes of motion by which the object can be presented to a fixed source of illumination at all degrees of obliquity. When utilising the movements to obtain obliquity of light, the observer knows exactly the direction of the change he is making. Every position can be registered, and the results repeated at pleasure. Moreover, within considerable limits alterations of the greatest possible delicacy in the obliquity can be made without removing the eye from the eyepiece. For example: Taking Fig. 2, "E. M.," April 21, p. 144, as the normal position for central light, by removing the condenser, clamping the tail-piece to the sector, and directing the mirror in the axis, the lateral inclination of the limb proper, carrying the optical tube, will at once give the range of oblique light from the nadir of the object, to within a few degrees of its horizon; or if the hemispherical lens be applied in the stage, in immersion-contact with the base of the slide, obliquity of incidence from 0 to 90° on a dry object (*i.e.*, in air) will be comprised within the lateral inclination of the limb, about 41°; for this inclination will utilise from 0 to 41° of the spherical surface of the illuminator, and the corresponding rays emerging into air above the plane surface will be at all obliquities from 0 to 90°. As regards dark-field illumination, the new stand gives the amplest facilities. With any objective—dry or immersion—the dark-field can be obtained. Even with the objectives of highest aperture—the homogeneous-immersion $\frac{1}{8}$ths, of Powell and Lealand, having 1·47 N.A.—the dark-field would be obtained by the lateral inclination of the limb, or by swinging the mirror on the tail-piece, 76° from the normal position, using the hemispherical immersion illuminator. On the whole, it appears to me that the combination of movements radially with the object itself as the centre, as embodied in this microscope, furnishes us with the most efficient means yet devised to utilise the resolving power of our finest objectives—to develop the finest images they are capable of producing. I commend the general design because I foresee that in the hands of the averagely skilful manipulator, results which have hitherto been regarded as extremely difficult, and obtained somewhat hap-hazard, will be brought within the compass of everyday ability. If the microscopist cannot now control the oblique light to his will, he must not blame his microscope.

(2) The fine adjustment is very conveniently placed, so that it can be worked on either side of the nose-piece. But the mechanism is lacking somewhat in delicacy. To my touch the movement was not so smooth as in a fine adjustment on a similar principle made by Swift. If the pinion of the fine adjustment projected slightly beyond the present milled heads, and were tapered conically, an extra sized milled head might be readily slipped on when required for very careful focussing—as generally adopted by Tolles. At present, too, one notes that the two milled heads of the fine adjustment and those of the coarse adjustment come together too closely in racking up the optical body, which might occur either in using 4in. or 5in. objectives, or in using the super-stage. If one required to rack out the optical body entirely, it would be necessary to remove the milled heads of the fine adjustment—which seems to me by no means an admirable or convenient arrangement. The great variety of movements in the new stand necessitate the adoption of a fine adjustment that will work equally well in all positions. Doubtless, Messrs. Ross found difficulties with the "Zentmayer" system that compelled them to experiment in new directions. I earnestly hope, however, that they will not rest satisfied with their present system, but innovate until real success is attained. A thoroughly efficient fine adjustment that will permit the free use of the "correction" collar of the objective without rocking, is one of the mechanical problems of the day still unsolved.

(3) With reference to the stage, the mechanical rectangular motions appeared to me rather too rapid, and I could wish (as suggested by your contributor), that Tolles's plan of giving rigidity to the fixed ring carrying the rotating plate, &c., by thickening the exterior flange vertically, and above the general plan of the stage, towards the shoulder, had been adopted. A clever mechanic like Wenham cannot fail to appreciate the merit of Tolles's plan,—Tolles who is regarded across the Atlantic as the microscope optician *par excellence*.

(4) As to minor items, I would suggest that the "iris" diaphragm beneath the achromatic condenser and the rotating disc of central stops, &c., might advantageously be replaced by the simple disc of central apertures, as in Powell and Lealand's condenser. The "iris" never acts centrally enough for delicate work with the condenser. The centring motions of the substage did not appear to me quite up to the mark—I found loss of time and general sluggishness of action in the movements. The modifications which Messrs. Ross contemplate making in the base-plate, &c., to enable the mirror to be slid in a rotating plate in the centre, and so that a lamp can be carried on the swinging tail-piece or at the lower end of the sector, are all commendable, and will get rid of what now appears an enormous area of blankness in the basal disc.

In the above remarks I have used some freedom of criticism—not, however, in an unfriendly spirit to the inventor of the new microscope. We have many of us come to regard Mr. Wenham as the type of a practical mechanician from whom improvements in the construction of the microscope are to be expected. Let me urge upon him to focus his attention on the fine adjustment, and thus crown his efforts by making the most perfect all-round microscope that has ever been seen.

F.R.M.S.

RAILWAY BRAKES.—THE WESTINGHOUSE AUTOMATIC VACUUM.—TO "A RAILWAY SERVANT."

[20004.]—THE Westinghouse patent, No. 1735, dated May 13th, 1873, contains, among many other improvements in details, a valve apparatus for, and is the earliest patent in relation to, automatic brakes. The system, as at present designed, is almost identical with the Westinghouse automatic air-pressure brake, and has a triple valve, auxiliary reservoir, and brake cylinder, modified to suit vacuum action. As in all vacuum brakes, the cylinder and reservoir are necessarily larger than in the compressed air brake; and the weight of the parts, with the exception of the main brake-pipe, is considerably in excess of that of the corresponding parts in the automatic air-pressure system, though not so great as in the Sanders and Bolitho apparatus, as used on the Midland Railway, one great advantage being that the heavy and expensive rocking shafts are dispensed with.

As mentioned in my letter, page 156, the hose connection between the vehicles is made by means of the Westinghouse universal coupling, which can be used either with air-pressure or vacuum, and will be understood by reference to the annexed illustrations.

Fig. 1 shows the main brake-pipe, tap, hose-pipe, and coupling, as seen upon the end of a vehicle. Fig. 2 gives a section of the coupling, and also the internal wire-coil *b*, used to strengthen the hose-pipe.

It will be seen that the cap 1, at the back of the coupling, presses the flexible diaphragm upon the internal cage 2, which, in its turn, holds in its place the packing-ring 3, at the face of the coupling, a spiral-spring 4, has the effect of pushing the packing-ring outwards, thus insuring a perfectly air-tight joint; a small hole 5, is drilled through the cap 1, to allow the pressure of the external air to act on the diaphragm, and assist the spring.

Large numbers of vehicles may now be seen on different railways fitted with the hose-pipes of both air and vacuum systems; this is of great convenience in the interchange of rolling-stock, but it necessitates double expense, and the adoption of universal couplings as above described, will avoid the duplicate cost.

In my letter, 19924, page 130, I pointed out the very great advantages to be derived from the use of a triple valve. As before stated, the Westinghouse Automatic Vacuum Brake, being provided with a triple valve and a pump, instead of ejectors, obtains results superior to the existing vacuum brakes. It has been perfected in order that railway companies who desire may possess a better vacuum-brake than those hitherto placed before them; but of course no improvements in details can overcome the inherent defect of all vacuum brakes having but a low pressure available; they must, therefore, always remain inferior to the automatic air system.

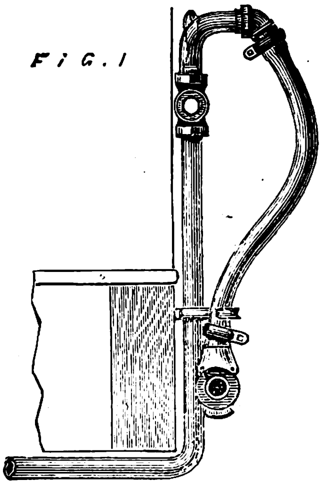

FIG. 2

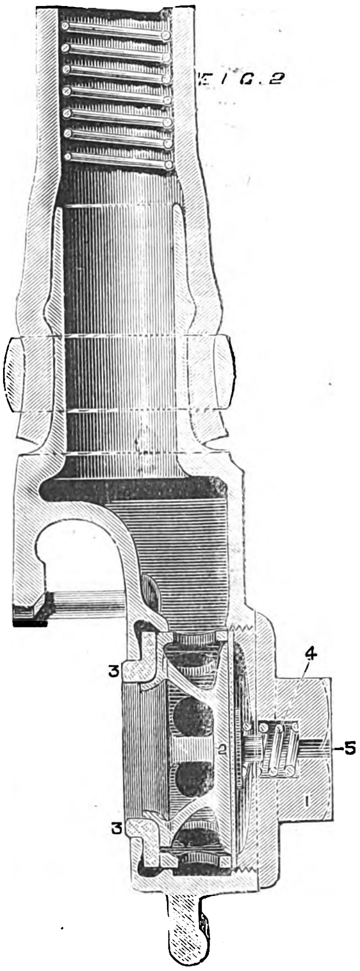
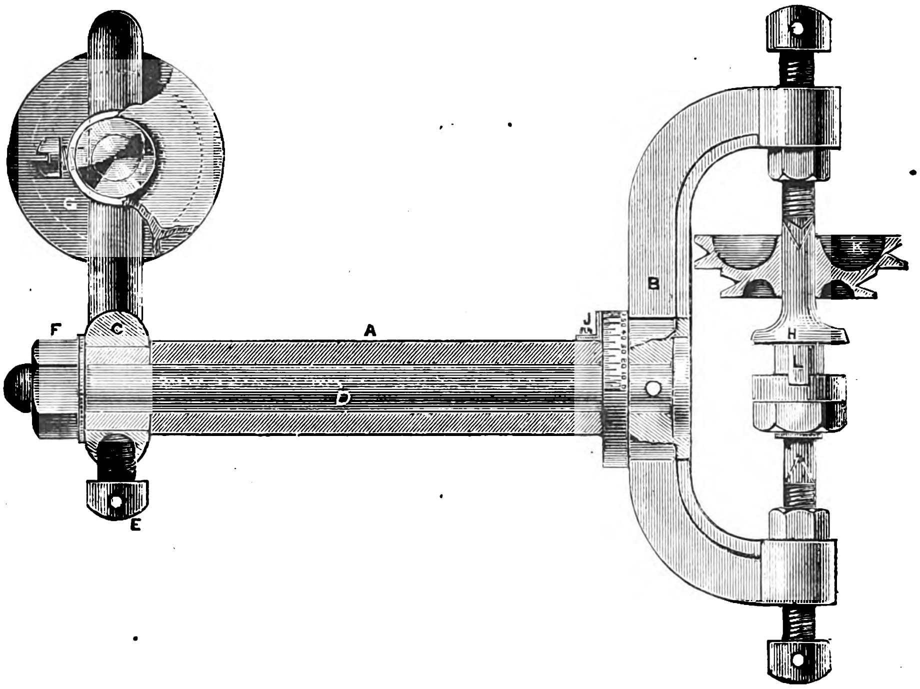


Clement E. Stretton.

Leicester, April 28.

CUTTING FRAME.

[20005.]—I HEREWITH send sketch of my cutting frame which I have had in use about eight years, and which I think is an improvement on "F. W. G.'s," and of which Mr. J. Evans mentioned in his letter. It will be seen that it can be set at any angle. Description: A is a piece of ¾in. ron square, with a hole bored through to fit D and urned down one end for C to work on. B is a gunmetal frame with an index plate cast on and divided as a sector from 0 to 90, so you can find the angle of the work to be cut. Then unscrew the nut F, and set it by the steel pointer J, then tighten up F, then slacken out E, and put on the cord, and it will soon find its position; then tighten up E. You can regulate the guide wheels G up or down. I have broken one of the wheels away to show, and I have broken the boss of B away to show the head of bolt D. The pin is to help hold it from turning round. H is the cutter-bar, with a slot L, 3-16in. by ⅜in. to take fly cutters. The collar I has a groove cut in half its depth, so as to grip the cutter: but circular cutters can be used by fitting a piece in the slot so as to form a feather on one side to keep the cutter from slipping. K is the speed pulley in section just driven on tight. I have not broken the division-plate, but kept it whole to show the divisions. When the cutter-bar is perfectly upright the pointer J should stand at 90°. The sketch is one half real size.

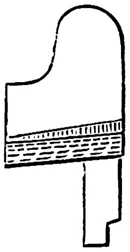


I am now making one for a gentleman, and should be pleased to show it when it is finished to any of my fellow-readers, or give any information if necessary. I have several different heads to take the place of B when required. **C. E. Sibley.**

29, Woodville-road, Mildmay-park, London, N.

UNIVERSAL CUTTER.

[20006.]—IN reply to Mr. J. H. Evans's letter 19950, I know that in using the universal cutter for cutting spirals it is usual to set it at an angle. But for this work I use, instead of it, a drill, the shape of figure, in the drilling instrument, and it cuts very clean and rounds off the corners as well. Sometimes I use a large step drill. **F. W. G.**



ORNAMENTAL LATHE-THREADS—ERRATUM.

[20007.]—IN my last letter (19973) by some oversight, at page 173, the woodcuts, Fig. 2 and Fig. 3, have had their angles interchanged, and need correcting with the pen in order to be brought into accordance with the description, which will be found in the third paragraph of the text. Fig. 1 shows accurately the deep Holtzapffel-thread of 50° angle. Fig. 3, with its full triangles at an angle of 60°, indicates the shallow Holtzapffel-thread. Fig. 2 was intended to show the Whitworth-thread in triangles of 55°, but rounded off one-sixth at top and one-sixth at bottom, as shown by mistake on Fig. 3. Fig. 3 was intended to show the American thread in triangles of 60°, but truncated by horizontal planes to the extent of one-eighth top and bottom, as shown by mistake on Fig. 2.

There are other well-known sets of screw-threads whose data would be of permanent value if put upon record in the ENGLISH MECHANIC. Such threads as those of Clement exist in dividing-screws and other valuable apparatus; but if their data are published, I do not know where to find them. I know that "J. K. P." has a very fine set of Clement's original steel hobs, and that upon screw-threads he could supply authentic and valuable data, which may drift into oblivion unless put upon record. Perhaps "J. K. P." will favour us, 1st, with any such data which he may be possessed of; 2nd, with an expression of his opinion upon the screw questions which I, as a mere dabbler in amateur mechanics, have ventured to raise.

To anyone interested in following up the screw question from a mathematical standpoint, with a view to establish a system of screw-threads, of which the pitch will be a definite fraction of the diameter of the cylinder on which it is cut—thus forming a universal and natural system of screws—I would recommend the perusal of a learned and valuable treatise (Systematique des Vis Horlogères) by Professor Thury, of Geneva, published by H. Georg, à Geneve.

James Edmunds.

PROPELLERS.

[20008.]—IT has occurred to me to suggest a plan of propeller, of which I made a small model many years ago, which may be described as having the motion somewhat of the connecting or coupling-rod between the side pair of driving-wheels of a locomotive engine. Look at these as a train passes: they appear to rise and fall most gracefully, but in reality they rise forward, fall, and retire.

If, therefore, there were two pairs of cranks working at each side of the vessel, with a framework acting as a coupling, and to this framework were attached suitable floats (there might be a dozen, forming a set of boxes without top or bottom), which would each inclose for the time a large mass of water, the dead-weight and resistance of which would, doubtless, by its reaction give a good progressive tendency to the vessel. I would propose to work these with slow but powerful motion. It has always appeared to me that there is a vast waste of power in the enormous speed at which both paddles and screw are driven. If, for instance, a rower were to drive his oar through the water at the same proportionate speed and force, the chances are he would soon either break his oar or kill himself for his trouble, but the boat would not gain the speed he would expect. I believe a vastly-larger blade—in fact a continuous blade, strengthened by tie-rods and guides from the shaft, so that the diameter would be as great as the beam of the vessel, would be the correct thing for a screw-propeller, and would be obliged if you would allow the subject to be discussed in the ENGLISH MECHANIC AND WORLD OF SCIENCE, by those who are more competent to form a correct opinion. **Milford.**

IRON MOULDING NO. 2.

[20009.]—As promised in my last, the subject for the present paper is "Screw Propellers." After having examined the drawing and the loam-boards, the moulder prepares for a start. First, by making a plate to build it on, if there is none already. The size to make it will be about one foot larger in diameter than screw. The building-plate may be made circular if the screw is small, and can be dried in the stove. If large, and to be dried in the pit, or on the floor, it is best to make it with three or four blades, according to number required. Or, if the moulder prefers a separate plate for each blade, will, in a great many cases, be superior, as they are easily shifted from place to place; and, besides, if the mould is made to answer when built, each blade can be lifted separately from its bed and dried in the stove, which is very convenient, as they take up little carriage room; and, besides, the drying in the stove is superior to the pit, and less fuel is required. We will assume the screw is about 16ft. diameter with four blades. There will be a circular space required, about 20ft. diameter, to work in. Concerning the pitch, size, and shape of propeller, are matters for draughtsman and pattern-maker. The screw we will commence with will be what is known as a plain screw, or constant pitch throughout. It is the most simple made, and one often in use. Some propellers are made with two or more different pitches, which will be spoken of as we get along.

The one we are commencing shall be built so that each blade, if convenient, can be taken off its bed and dried in the stove, or without being moved, and dried where built. The first thing to be done is to lay down a plate about a foot larger in diameter than boss of propeller, with a round hole in the centre of it to admit of centre of cross for the spindle to work in. Have the ring bedded solid, and either clamp or bolt the cross to it, so that the spindle will keep firm and steady till the job is finished. Having put the spindle in its centre, on the arm of it you fasten a parallel board about 10ft. long, taking care to set it at right angles to the spindles, so as to have the surface that it sweeps straight. This board, when secured in its place, is for forming the bottom of boss of screw, and also a bearing or surface about 12in. outside of the mould proper to lay a template or guide on (resembling in shape a wedge) for another board to work in, which will be explained further on. Take now some loam and brick, and on the centre plate build up to within ½in. or ¾in. of face of board; on the face of bricks rub on some soft loam till it is a little higher than face of board, which is now made to revolve, and you have the form of the bottom of boss with a print for centre core. The same operation is gone through with outside bearing. For a sketch of mould in present state see Fig. 1. A A, brickwork; B, point of centre core; dark lines, loam. The board is now taken off, and after the loam has become stiff another board is made fast to spindle to build the boss, or, properly speaking, to build a pattern of boss (see Fig. 2). It matters little how it is built so that the outline is good, as it is afterwards pulled down. You now space or divide the outside bearing into four. On one of these lines you place the guide, having a centre line on it corresponding with one on the bearing. When in its place a weight is put on the bottom of it to keep it steady and secure until the face of one blade is finished or swept up. A parallel board is now secured to arm of spindle (and I should mention that in this part of the job the arm requires to be in the form of a right angle). On account of the model of boss having been built first, the one end of board is made fast to arm, while the other rests on the guide (see Fig. 3). To the top of spindle is attached a small pulley, over which a rope works, at one end of which is a counterbalance weight, *w*; while the other end is attached to the arm or board, so as to facilitate the sweep in its passage up and down the incline plane. The arm in this part of job is not made fast, but the spindle is. The arm revolves, and should move freely up or down the spindle, as required. Having got the arm in working order, you now commence to build the blades, which I shall reserve for the next paper. **Foundry.**

FIG. 1.

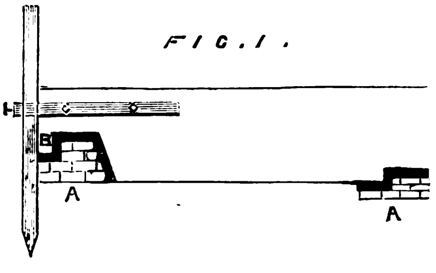


FIG. 2

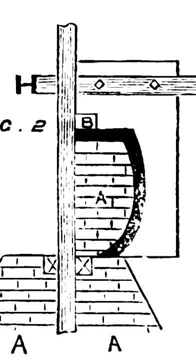

FIG. 3.

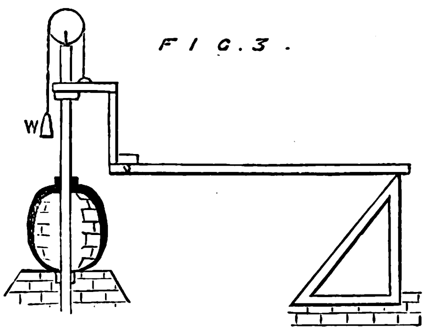


SOAP-ANALYSES AND FATTY ANHYDRIDES.

[20010.]—In answer to query 46698, page 183, ordinary fixed oils and fats are salts of the triad organic radical glycyl, C_3H_5, which performs the same function in the oil that the metal bismuth does in nitrate of bismuth. Thus, nitrate of bismuth has the constitution:—

$$\left.\begin{matrix}\mathrm{Bi}'''\\(\mathrm{NO}_2)_3\end{matrix}\right\}\mathrm{O}_3$$

while olein, the chief constituent of olive oil, is—

$$\left.\begin{matrix}(\mathrm{C}_3\mathrm{H}_5)'''\\(\mathrm{C}_{18}\mathrm{H}_{33}\mathrm{O})_3\end{matrix}\right\}\mathrm{O}_3$$

The process of ordinary saponification consists in the decomposition of the oil by caustic alkali, with consequent formation of glycerine and a soap or salt of the alkali-metal. Thus, the following formula represents the saponification of olein by caustic soda:—

$$\underset{\text{Olein.}}{\left.\begin{matrix}(\mathrm{C}_3\mathrm{H}_5)'''\\(\mathrm{C}_{18}\mathrm{H}_{33}\mathrm{O})_3\end{matrix}\right\}\mathrm{O}_3} + \underset{\text{Caustic soda.}}{\left.\begin{matrix}\mathrm{Na}_3\\\mathrm{H}_3\end{matrix}\right\}\mathrm{O}_3} = \underset{\text{Glycerine.}}{\left.\begin{matrix}(\mathrm{C}_3\mathrm{H}_5)'''\\\mathrm{H}_3\end{matrix}\right\}\mathrm{O}_3} + \underset{\text{Sodium oleate.}}{\left.\begin{matrix}\mathrm{Na}_3\\(\mathrm{C}_{18}\mathrm{H}_{33}\mathrm{O})_3\end{matrix}\right\}\mathrm{O}_3}$$

If the sodium oleate, or "soap," be treated with hydrochloric acid, as occurs in the course of an analysis, free oleic acid is produced, together with chloride of sodium. Thus:—

$$\underset{\text{Sodium oleate.}}{\left.\begin{matrix}\mathrm{Na}\\(\mathrm{C}_{18}\mathrm{H}_{33}\mathrm{O})\end{matrix}\right\}\mathrm{O}} + \mathrm{HCl} = \underset{\text{Oleic acid.}}{\left.\begin{matrix}\mathrm{H}\\(\mathrm{C}_{18}\mathrm{H}_{33}\mathrm{O})\end{matrix}\right\}\mathrm{O}} + \mathrm{NaCl}$$

Calculating from this formula, it will be found that dry sodium oleate yields 92·76 per cent. of free oleic acid, and similarly the alkali of the soap would be stated at 10·20 per cent., so that the analysis would be:—

Oleic acid	92·76 per cent.
Soda (Na_2O)....	10·20 "
	102·96 "

Here there is an error of nearly three per cent. in excess caused by assuming that the soap contains oleic acid; whereas, if it be regarded as containing oxide of sodium, the fatty constituent should be stated as oleic anhydride $(C_{18}H_{33}O)_2O$, which differs from oleic acid by the elements of water; 564 parts of oleic acid correspond to 546 of oleic anhydride, and so 92·76 per cent. is equivalent to 89·80 per cent. This, with the 10·2 per cent. of Na_2O, adds up exactly to 100 0. The proportions of anhydrides corresponding to palmitic and stearic acid are not greatly different from the above; hence, the necessary correction of the observed weight of fatty acids to the corresponding quantity of fatty anhydrides may be made by multiplying by the factor ·97—100 parts fatty acids representing approximately 97 parts of the anhydrides. In properly stated soap analysis the percentage of fatty anhydrides is given in the body of the report, with a note or reference to the corresponding amount of fatty acids.

Sheffield, April 29. **Alfred. H. Allen.**

STRING VIBRATIONS.

[20011.]—It is a curious thing, that two strings in unison and on the same violin will not sound louder than one string. I have never had this accounted for; perhaps the following may be a step in the right direction—remembering that where there is a mystery, it is best to go out of the beaten track, because there are always two sides to every question:—Take a lady's U-shaped hairpin, 'twill suit our purpose better than a tuning-fork, push one end in a piece of wood (say, the end of a shelf in a greenhouse) in this position ⊃ so that the upper arm will be free to move up and down or vibrate—push it in about 1in. with a pair of pliers; press down the free arm and let go, a dull thud is the response, but you will see it go up and down past its stationary centre, forming a figure which becomes an oval when started out of a straight line. Now tie a piece of white cotton near the round part of the ⊃ that is fixed in the wood, vibrate it as before, and the cotton has all the appearance of being electrified; it seems to be attracted and repulsed by what some would say is a current of electricity. Who knows what electricity is, or what sound is? I leave this thought, and next I tie a glove-button to 10in. length of the cotton. When I vibrate this, as before, through the ⊃, I get a vibrating-string with no sound; it is, in fact, a negative vibration, in opposition to the positive vibration of the ⊃ or tuning-fork. I only mean that one sounds and the other does not. But a change has taken place; the vibrating-string is divided into two parts, forming two bow-like segments. Without the button-weight the vibrations were dispersed without form, but with it they are collected together. This shows, however, that vibrations do not produce sound, but that sound produces vibrations dependent on weight. We shall see the effect that weight has on sound presently. You see the two parts with the weight of button. Now, slightly pull the piece of cotton hanging below the button—viz., put on more tension, when the string will come out in one bow form, as a violin string, but without any sound. Next, lift the button slightly, and the string divides into three parts—more slight, into four parts—the less weight the more divisions. This is very plain, but infers a different state of things to that inferred by standard books. There is only a thud from our primitive tuning-fork or hair-pin. Can't we make it sound? Take a violin bow and vibrate the under arm that is in the wood (soundboard); vibrate it about 1in. off the wood: you only get a nasty mixture of harmonics, because there is not sufficient weight to collect them together, but pull the cotton and out comes the true sound.

I infer from all this that harmonics are produced on the violin by a change of weight—viz., the tension is altered from end to end to different parts of the string. And that pressure on the string acts as a lever placed under a tension bar (a rod of iron, a stick, or any lifting arrangement.) But I need not go into this. Now let us take two strings on a violin, the D and G, or covered string. When I put my third finger on D, I get the upper note to the open G—viz., an octave; but look at the silver string, it is divided into two parts. How is this? Why, the weight of third finger acts on the unison lower string through the bridge, and changes its tension. This, however, takes away some of the weight belonging to the D string, and it does not sound so loud as any other note, say those produced by first or second finger, which would not be in unison with open G. If I want the upper G to sound as loud as the other notes, I must stop the open G from vibrating, and directly I put another finger on it, and only allow the stopped D to vibrate by itself, then the upper G is as loud as the other notes. This, then, is the reason why two strings will not sound louder, because one takes the weight off the other.

My great rule is this, "That an open string does not form itself into parts," although this is implied in all class books. **Fiddler.**

Patterns for Moulding Name-Plates.—In the *American Machinist*, Mr. G. B. Foote gives the following ingenious method of obtaining patterns for moulding name-plates, &c.:—First. Set up a card with suitable type; if you have an engraved trade-mark or cut of medal, put it in the card as set up. Then, after the forme is made up, justify it, plane down, &c., press it into a sheet of hard rubber of proper thickness which has been softened by heat; let the rubber cool under pressure until hard, then file off the face of the rubber until you get down to the level of the impression of the face of the letters, &c. You now have apparently a flat piece of hard rubber. Now put this on a flat heated surface, and the face of the letters, &c., will rise up, showing a reversed impression of the type, beautifully adapted as a pattern for moulding. This pattern can be bent to any shape for attaching to a curved surface.

REPLIES TO QUERIES.

⁂ *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[35398.]—**Jenny Lind Engines (U.Q.)**—I am much obliged to "Carstairs" for the information on p. 109. The description given of these engines agrees with what I have seen on the North Staffordshire line. I was under the impression they were "Jenny Linds" when I wrote the query; but I wanted proof. What number was the M. S. and L. "Carstairs" refers to? I remember seeing two engines on the M. S. and L. of the "Jenny Lind" type; but having four-coupled trailing driving-wheels, and the wheels had round spokes. They were numbered 55 and 59. Can "Carstairs" give the date of their construction, or of that class? I believe the "Jenny Linds" came out in 1847.—R. N. H.

[46095.]—**Preserving and Arranging Fossil Shells.**—"Mollusca" might possibly find the following arrangement suitable. First, the cabinet may be made 42in. by 24in. (and capable of extension in height). The drawers must be such as to receive fair-sized fossils, but must not obstruct the light; thus, the sides and back may be 1½in., and the front 3½in. deep. The front of every third or fourth drawer may be 5in. deep to accommodate any extra large specimens. To get maximum depth, have only *side* slides. Next, as specimens must be readily transferable, use boxes, and to prevent them being jarred or from rolling about, line all with cotton wool (pink). One sheet of grey drawing-card (4d.) will make 48 boxes 2½in. sq.; thus, bend a piece of zinc into the form of a very acute V, equal in depth to the side of the box, and by inserting the card, bend up by pressure on the table. Next, snip out with scissors four little triangular pieces from the creases on two opposite sides, making two (opposite) snips much larger than the other two: this will make the intervening side slope. The ends of the unsnipped sides will then overlap, and may be secured quickly and neatly with stationer's brown sealing-wax. The object of the sloping side is to inscribe the formation, locality, and name of specimen. The advantage of making the boxes one's self is that you can suit your own requirements as to size, height of sides, and economy. The boxes, for sake of uniformity, should be multiples of the smallest. Specimens too large and heavy for these boxes may be mounted on card-covered boarding, and pinned in place. As to classifying, the method adopted at the Jermyn-street Museum, of placing strips of wood, labelled, at the head of each fam., class, &c., is very good, as, by running the eye up the columns, you see at once the grade of any particular specimen. I was told by a professional collector that glycerine and gin formed a very good preservative compound. I should be very glad to know myself whether this is better than gum.—Pholas.

[46381.]—**Three-Legged Gravity Escapement.**—"Alfojoe" and E. M. Nelson do not seem to be aware that they have been disputing about an escapement which was superseded at least 23 years ago, by the double three-legs of the Westminster clock, which was put up in 1859. I cannot now refer to any but the sixth edition of Sir E. Beckett's book, but I am sure that the Westminster escapement has been described in four or five editions, and in the *Encyclopædia Britannica*, and also the four-legged one for small clocks or regulators. I concluded when I saw the one which "Alfojoe" copied from the copy of the original three-legs in "a book by J. W. Benson," that it must be an old book, written soon after Sir E. Beckett's first publication of that escapement, nearly 30 years ago; but he now says it is only seven years old, which is an odd commentary on his remark on the high authority of Benson as a writer on clocks. No doubt Mr. Nelson is right in saying that the late Astronomer Royal preferred an escapement which he had invented and published above 50 years ago, for the standard clock at Greenwich; but I have never been able to learn that it was preferred by anybody else. I remember and have found a letter in these pages, just two years ago, from "C. A. T.," and, I think, others also, saying that the writers had themselves made gravity escapement regulators from Sir E. Beckett's book, and found them most successful. "C. A. T." said: "the rate had been simply perfect," but "the beats not so equally loud," as he wished for astronomical purposes. Mr. Nelson mentions pin-wheel escapements with train remontoires as better; and certainly no recorded rate ever equalled that of the "Dent and Denison" clock in the 1851 Exhibition; but remontoires—at least the best—have been abandoned on account of their delicacy, and the practical equality with them of these later gravity escapements—not spoilt by the errors which he rightly censures in the late Mr. Cooke's supposed "improvement" of them. It is quite true that their great and unquestioned superiority is in turret clocks, but equally true that the "four-legged gravity" in regulators may be at least equal to a much more costly and delicate dead-escapement clock.—Horologus.

[46395.]—**G. W. Tank-Engines.**—I wish to ask "Clyde," if "Hesiod" (G. W.) is not of the same type as 2042, illustrated on p. 87, and if so, if he has not omitted the *original* date of their appearance, which I understand was 1849? Clark's "Railway Machinery" of 1855 has an engraving of one of that class.—R. N. H.

[46396.]—**Terrestrial Eyepiece.**—To "Paugul." — The eyepieces alluded to are seemingly of the usual character supplied with terrestrial telescopes. The lenses C and D are probably one-half the sum of their focal lengths apart, and the lens A just within the focus of the object-glass, so that the emergent rays cross immediately in front of B. This would cause the central rays to diverge; but they are nevertheless brought to a focus midway between C and D. No doubt this appears incongruous to "Paugul," but he can easily verify its correctness by a little actual experiment. It is very easy to quote a string of optical truisms, and so account, in an off-hand manner, for all the phenomena of refraction; but it is much better to practically apply these precepts before doing so, and this, as it seems to me, is just what "Paugul" has neglected, when he says, "The position of the diaphragm is wrong; it should be at the point where the rays cross where the image is formed." Now, he is apparently not aware that between C and D the rays do not cross at all, nor that he is describing two different kinds of foci which cannot be formed at one and the same time. The focus caused by the crossing of the rays is simply a round spot of light, and there can be no image until these rays have become palpably divergent, or until they have been collected by another lens. This may be very easily demonstrated by holding a piece of white paper at the outside focus of D, when the white spot of light will show that here the rays do really cross, and that an image of the object is not formed until some distance from the focus. He may also notice that the conjugate foci of this spot, and that of the image between C and D, do not accord with what he evidently conceives to be their theoretical position.—Aldebaran.

[46424.]—**Circular Saw.**—I see "Circular Saw" is not exactly satisfied with "Pattern Maker's" reply. I think if he will act on my advice he will have no occasion to be dissatisfied. In the first place, he must not expect to accomplish, at his first, second, or third trial, what it has taken a saw-straightener his lifetime to learn. What I would recommend him to do is to go to a sheet-iron warehouse and get three half-sheets of iron, say, one 24, one 18, and one 14 gauge, next get a heavy iron block, say an anvil with a good round face, i.e., not hollow, as a worn anvil gets; next, a fair-sized hammer, take off your coat, and turn up your shirtsleeves, then take one of the sheets (it does not matter whether it is the thick or thin one) in his left hand, and the hammer in his right, throw it across the block, and hold it at such an angle as the eye can look over the edge and scan the surface. You will notice that it is warped and buckled in all forms—anything but perfectly flat—some places rising up, others going down into valleys. Now, what you want to do is, by hammering around the edges of the valleys, to stretch and thus relieve the buckle, and you must try by this means to get all the little inequalities into one great hollow, rise, or buckle, and then by the same method around the edge, to bring your sheet perfectly flat. When you have got one right, then try the next, and then the next, and if you can succeed in all three thicknesses, try your saw, and not before. I would caution you, in straightening the sheet iron, to finish straightening the first before you touch the second; and if you can succeed, you will be able to do what hundreds of sheet-iron workers can't. I would also advise "Circular Saw," as he does not know a saw-fettler, to take it to his ironmonger for him to send it to a saw-maker, so he may have his saw to do his sawing, for it may be it will require straightening again against the time he has straightened his three pieces of sheet-iron, and certainly he ought not to touch his saw before he has done so.—Working Tom.

[46440.]—**Analysis of Soot.**—The ammonia is the only valuable constituent of soot; that is estimated as sulphate. An analysis gives 43 parts organic matter, containing nitrogen ·21, sulphate of ammonia, 12·7; carbonate of lime, 10 6; insoluble silicious matter, 15; oxide of iron and alumina, 6·5; carbonate of magnesia, alkaline salts, &c.—Sabbas.

[46443.]—**Handel Organ.**—An account of the alterations and repairs to the Crystal Palace organ will appear soon in the *Engineer*.—J. W. W.

[46445.]—**Gazogene.** — Try whether you can stop the leak by grinding the two parts together with a little fine emery and oil.—T. P.

[46448.]—**Powder - Mixing Machine.**—You can make one either by adapting a sieve, or by having a pan in which arms revolve. Should advise you to see some of those made by machinists, and you will be able to give an idea of what is wanted; for one that would do for mixing manures might not be exactly adapted to mixing the substances sold as fruit-salts.—Nun. Dor.

[46454.]—**Gas from Wood.**—This query is unanswerable without knowing the kind of wood, whether wet or dry, and what "gas" is meant. The ash would be charcoal, plus the mineral constituents—valuable as a dressing for the ground, if for nothing else.—E. G. M.

[46458.]—**Fernery Pipes.**—There is no help for it but to polish up the pipes, or to allow them to become discoloured. They are easily cleaned with oxalic acid; but perhaps they would look better when thoroughly discoloured than when perfectly bright.—Nun. Dor.

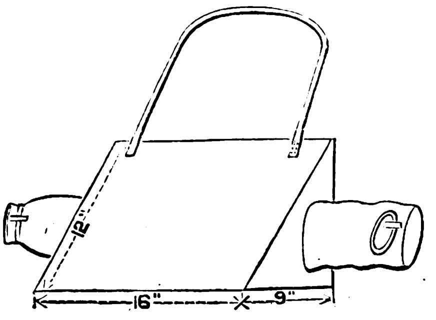
[46490.]—**G. P. Joints.**—There is nothing very remarkable about these joints. The wires are twisted together and soldered (using rosin as the flux), and are then covered with guttapercha strips, which are melted together by the aid of a warm tool, and pressed into shape with damp fingers. Culley, "Practical Telegraphy," pp. 169 *et seq*, gives full and explicit directions for making joints, to which I would refer the querist, if he wishes to excel in this work, as applied to long telegraph lines, where every little detail is carefully studied. I don't know whether a later edition than the seventh of Culley is out; but, in that, he refers to Chatterton's compound as one component of the insulating covering.—Nun. Dor.

[46493.]—**Lathe.**—To "Sunlight."—I wish for correct sizes and weight of 5in. lathe, gap-bed and screw-cutting, to cut square bars, 1in. by 1in., with circular saw. I hope you will send sketch of drilling-frame, and spindle for drilling holes in hubs of bicycle for ordinary lathe, with slide-rest not backgeared, 5in. centre.—Long Tom.

[46497.]—**Fortified Cities.**—Several fragments and lengths of the walls of Limerick yet remain. Near one extensive portion, a beautiful bronze statue to Sarsfield, who so bravely defended those walls, has just been erected. There are also some towers and parts of the ancient walls of Waterford remaining, interesting as having been built by the Danes, and resisted the efforts of Strongbow. I have also seen portions of the old walls at Fethard, Cashel, and Clonmel in county Tipperary, and at Youghal and Kilkenny. In many Irish cities, fragments of their walls, castles, and towers yet exist, and may be studied.—E. B. F.

[46497.]—**Fortified English Cities**—Perhaps the following may assist "Antiquary." Stafford was anciently encompassed with walls having four gates. They were demolished by Sir W. Brereton, General of the Parliamentary forces in 1643. Coventry was also protected by walls, which remained till 1661, when they were almost wholly destroyed by the Earl of Northampton. The walls of Worcester existed till 1651, when they were thrown down after the battle of Worcester, wherein Charles II. was defeated by Cromwell. Leland says in his Itinerary:—"Shrewsbury is strongly walled and defended with water, which is to be counted in manner for the towne ditch.... The walls are more than a mile in compass." "Oswestry was formerly surrounded by strong walls, which were a mile in compass, having four gates, also strengthened with a ditch. The gates remained till 1783." "The towne of Ludlow is well walled, and by estimation a myle in compass. There be in the wall five gates—Broad Gate, Old Gate, Gaolford Gate, Corve Gate, and Mill Gate. The castell hemmeth in part of the towne, and standeth on a strong rocke, well ditched between Corve Gate and Mill Gate" (Leland).—Student.

[46510.] — **Photography.** — The following arrangement may not suit large plates, without some modification; but I find it very handy with the cabinet-size and smaller plates I work with. The dimensions must be regulated to suit size of plate-box, and dark slide when open. My dark slide is a single one, so I find the following suit me perfectly. I procured two stout tradesmen's show-cards. One, for the bottom, I cut 16in. by 9in.; the other, for the front, is 16in. by 12in. I hinged these together along a pair of their 16in. edges, by glueing with pieces of tape, so that they open and shut like a book. They are then covered with a black bag, as shown in the annexed figure. There is no need of cardboard at the back. The front cardboard is kept up by its being slipped within a tape that is sewed to the inside of front of bag, about 4in. from top. I rather think this front cardboard could be dispensed with, if the top were kept stretched from side to side, by a piece of stiff cane, or other suitable material. The front, back, and bottom of bag are made of one piece of black stuff, with the seam underneath. I have the seams sewed, but probably elastic glue would be a safer fastener. When the first bag, with its ends and sleeves, is complete, another one, identically similar, is made to cover it. The inner and outer bags are not sewed together anywhere except at the outer extremities of the sleeves. One or more bags could be made to cover these, if thought necessary. I have found two bags quite safe, but am thinking of adding an outer cover of mackintosh to keep out wet. This would give additional security against light entering. The sleeves should be wide enough to admit plate-box and dark slide, and long enough, say, 12in., to reach the elbows. The indiarubber sleeve-bands are attached, as shown in the figure, so as to slip off easily when inserting or removing the plate-box and slide. The tape that goes round my neck is sewed to the outer bag only. It is essential that stitches should nowhere go through both bags, except at the ends of the sleeves. The bags are made of the stoutest black twilled calico. This costs 6d. a yard. It is quite easy to know the coated side of plates by touch alone, but the less fingering they get the better. Damp or dirty fingers would probably ruin them. It is well to carry a second plate-box into which to put plates that have been exposed. Each box should have a distinctive mark. After a little practice plates can be changed as safely, and very nearly as quickly, as in a dark room. I think windows unnecessary. It must be nearly impossible to see the inside through them, and they are liable to be broken. I have seen plans for changing bags in which there is only one hand inside; but it is a manifest advantage to be able to use both hands. This is the reason why I suspend my bag from my neck, as it leaves both hands free. I recommend all plates to be examined in the dark room for defective coating or other flaws previous to going out. I usually retire to a shady place when changing, but I have tested my bag in sunshine and found it light-tight. —W. H. S. W.



[46512.]—**Boring Horizontal Bar for Steel Core.**—Many thanks to "Jack of All Trades," but what I want principally to know is the manner in which an ash bar 9ft. long is bored for the steel core. A sketch of the drill would also oblige.—J. Wilson.

[46531.]—**Yacht's Deck.**—"Working Tom" should be careful how he advises; the idea of putting deck planks 6in. wide into a twenty-tonner is absurd; at the very most they should be only 3in. in the widest part, and taper fairly at each end; aft they will all reach to the archboard, but forward they will of course be cut short by the round-in of the bow. The proper method of laying a yacht's deck is by dowels and scant nails: that is to say, to fit the first plank (and of course begin at the side), put the dowels into the covering board, half their length, then mark their positions by pulling the plank to them; bore your holes, then tap the plank all along till it fits the inside of covering-board nicely, then fasten by nails driven obliquely through the edge of the plank, not down through; then repeat the operation with every plank. In this way no nail holes or anything of the kind will show, and when planed down will look nice and neat; 3 by 1½ in the middle will do very well. The plan proposed by "Working Tom" might do for a flat or collier, but not for a yacht. If "J. J. A." takes my advice, he will not attempt to lay his own decks. He will be better off by getting a yacht-builder to do it for him; it requires great care to lay decks.—W. R., Liverpool.

[46542.]—**Broken Steam Gauge.**—To "Sunlight."—As you say the tube can be soldered, will you please send sketch of a mercury vacuum-gauge as you promised? Also I see in the "E.M." of Dec. 30, 1881, a model steam-gauge. Will you please say what kind of rubber diaphragm it is? whether it is rubber such as we use for steam joints or not.—Gauge.

[46589.]—**Sack-Marking.**—I have used boiled linseed oil and best vegetable black for sack-marking many years, and find sacks sent for repairs after long usage with the mark nearly as good as ever; the preparation should be fairly thick, and a little driers added if you are not sure of the oil being right; the brush should be used with little of it on at a time. It does not require much to mark a hundred sacks. With reference to stamp or plate, some twenty years back, we used a stamp with wood letters fitting in a frame, but it soon dropped, as no advantage. I prefer using oilcloth. As for Farmer's waggon-sheets, cut like a stencil plate when not more than three hundred marks of one kind are needed; it yields to the sack better than a plate. The very large sack-makers use steam printing presses, but I do not know their price and construction.—Thos. M. Hewitson, Birmingham.

[46617.]—**Sewer-Gas.**—"C. G. H." can ascertain if his drains and house-pipes are defective by pouring some strong-smelling volatile odorous material through an opening, which should always exist for this very purpose, outside, and letting someone else smell about suspected places inside. —Bor.

[46627.]—**Measuring Polarisation in Battery.**—The only means we have of estimating the amount of polarisation is by interposing in the circuit any one of the forms of galvanometer. The measurements can be made, and loss due to polarisation tabulated.—W. J. Lancaster.

[46630.]—**Steam-Launch.**—I am sorry I cannot answer your query to my own satisfaction. There are, however, many willing contributors to "ours," who will have pleasure in giving you every detail you require. I should be sorry to mislead you on any point, and I feel that I am not sufficiently conversant with the subject of your query to give you a satisfactory answer.—W. J. Lancaster.

[46642.]—**Drilling Fluid.**—"Kismet" will find, I think, that nothing will beat soap and water; some use soft soap, others common yellow soap, for turning wrought iron. For steel, train oil is better, and is certainly cheaper, than olive. For boring steel, I have lately adopted paraffin, as it "seeks" into a hole so much better than a thicker oil. If much oil is used, it is worth while to catch turnings, borings, &c., in a suitable vessel, and let the oil drain off, when it may be used again and again. I also catch my soapy water, it saves a good deal of cleaning up after its use.—Bor.

[46649.]—**Mounting Micro Lenses.**—You may use either 36 or 37 threads to the inch for micro objectives. The lenses must be mounted with Canada balsam, and eyepiece lenses may be carefully rolled into their cells. In mounting achromatic combinations great care is necessary to get each combination perfectly true, and this can only be done after some experience. I shall be pleased to give you any assistance I can through our pages. —W. J. Lancaster.

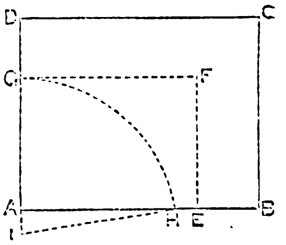
[46658.]—**Date Marks.**—I send "Alpha" the following marks and dates of the London Assay Office, which is now in its 23rd cycle. Each cycle is composed of 20 years, and each year is denoted by a letter of the alphabet, which is different every year. The letters used are:—A, B, C, D, E, F, G, H, I, K, L, M, N, O, P, Q, R, S, T, U. The 1st cycle commenced in 1438-9, and had 3 stamps—1st, Leopard's head; 2nd, date mark; 3rd, maker's name (the letters used being Lombardic capitals), and ended 1457-8. Cycle 2 began 1458-9 and ended 1477-8, but the stamps and letters for it are unknown. Cycle 3 commenced 1478-9 and ended 1497-8, and had 3 stamps. 1st, The leopard's head, which was crowned in 1477; 2nd, date mark; 3rd, maker's mark (Lombardic letters). Cycle 4 began 1498-9, ends 1517-8, has 3 stamps. 1st, Leopard's head, crowned; 2nd, date mark; 3rd, maker's mark (black-letter, small). Cycle 5, from 1518-9 to 1537-8, three stamps, as last. No lion passant till 1545 used (Lombardic capitals). Cycle 6, 1538-9 to 1557-8, has 4 stamps—1st, Leopard's head, crowned; 2nd, date mark; 3rd, maker's mark; 4th, lion passant (Roman capitals). Cycle 7, 1558-9 to 1577-8 has 4 stamps—1st, Leopard's head, crowned; 2nd, lion passant; 3rd, date mark; 4th, maker's mark. No escutcheons had been used up to 1561, when the date letter was first put into a shield (black-letter, small). Cycle 8, 1578-9 to 1597-8, 4 stamps, as last (Roman capitals). Cycle 9, 1598-9 to 1617-8, 4 stamps, as last (Lombardic capitals). Cycle 10, 1618-9 to 1637-8, 4 stamps, as last, small italics). Cycle 11, 1638-9 to 1657-8, 4 stamps, as last (court hand). Cycle 12, 1658-9 to 1677-8, 4 stamps, as last (black-letter, capitals). Cycle 13, 1678-9 to March 1697, 4 stamps, as before (black-letter, small). Cycle 14, March till May, 1697, began letter A, then as usual, till 1715-6, 4 stamps. 1st, Britannia; 2nd, lion's head, erased; 3rd, date mark; 4th, maker's mark, which was the first two letters of surname (court hand). Cycle 15, 1716-7 to 1735-6, 4 stamps —1st, Leopard's head, crowned; 2nd, lion passant; 3rd, date mark; 4th, maker's mark (Roman capitals). Cycle 16, 1736-7 to 1755-6, 4 stamps as last; but after 1739, the initials of maker's Christian and surname (Roman small); there are 4 different shields used in this cycle for the date mark. Cycle 17, 1756-7 to 1775-6, 4 stamps as last; but after 1721 (I should have added the leopard's head was smaller than before) black-letter capitals. Cycle 18, 1776-7 to 1795-6, 5 stamps: 1st, leopard's head crowned; 2nd, lion passant; 3rd, date mark; 4th, after 1784, the duty mark of king's head; 5th, maker's mark (Roman small). Cycle 19, 1796-7 to 1815-6, 5 stamps as last (Roman capitals). Cycle 20 (Roman small), 1816-7 to 1835-6, 5 stamps as last; but after 1823, the leopard's head without a crown. Cycle 21 (black-letter capitals), 1836-7 to 1855-6, 5 stamps; but the Queen's head from 1837 in the place of the king's head. Cycle 22 (black-letter, small), 1856-7 to 1875-6, 5 stamps same as last. Cycle 23, 1876-7 to present time (Roman capitals) (the letter for the present year till 1st of June being the letter F). Some short time back I sent an answer to "ours," in which I gave a list of the assay towns and their separate marks; but not having the papers at hand, I cannot refer so as to give the exact date, but perhaps "Alpha" can do so. I have only given the date marks of the London office, but am afraid I have made this answer too long already, or I would have given the letters for the other eight offices, but will do so at any future time if the Editor thinks they will be of sufficient interest. In reading plate, the shield of the date letter must have the point downwards. Some workmen have had their work marked by a X or star near the maker's name to distinguish their particular work. The date letters are in parentheses.—J. Chamberlain.

[46651.]—**Problem in Mensuration (Nesbit's).**—The following is the way I worked the problem:—

```
                 A B and C D = 100.
                 B C and A D =  80.
                 I A         =  10.

   100  = A B or C D            100      10 = I A
    80  = A D or B C             80      10
   ----                         ----    ----
 2)8000                        2)20     100
   ----                         ----
   4000(63·245 = A H            10 I A
   36
   ----              A H
123) 400          63·245^2 = 4000
     369                      100
    ----                     ----
1262) 3100                   4100(6403 = I H or I G
      2524                   36
     -----                   ----
12644) 57600              124)500
       50576                  496
      ------                 ----
126485) 732400        12803)  40000
        632425                32409
       -------               ------
         69975                 7591
            Then 64·03 = I G or I H
                 10·   = I A
                 ---------------
                 54·03 = A G;
             And 80    = B C and A D
            Less 54·03 = A G
                 ---------------
```

Width of walk = 25·96 = D G and E B.



By using more decimals you can prolong the answer.—Sharples.

[46656.]—**Pitch of Propeller.**—The rule as given in Molesworth is as follows:—

$P = \frac{101\ V}{R}$. where P = pitch of screw in feet

R = number of revolutions per minute

V = velocity in knots per hour.

Or,

$P = \frac{88\ v}{R}$. where P = pitch of screw in feet

R = number of revolutions per minute

v = velocity in miles per hour.

—Dix.

[46651.]—**Problem in Mensuration.**—By simple arithmetic find that a walk 26ft. wide round two sides would occupy 4 sq. ft. more than the half area, and that the inner edge of this walk is 128ft. long; then if 4-128ft. or 1-32ft. or ⅜in. be taken from the 26ft., it will give the required width, and agree with the answer given in decimals.—W. W. S.

[46659.]—**Spongy Platinum.**—"G. F." would have done better not to have troubled about the "washing." I would suggest that he should add a little liquid ammonia to neutralise the solution, which is probably acid. Then add some more chloride of ammonium, evaporate to dryness, and fuse the residue in an earthenware assay crucible with an equal bulk of oxalic acid. The ordinary kitchen fire will do if no furnace is at hand. The fused mass of spongy platinum may be well washed. I often prepare it in this way, both for use as such, and for the sake of the recovery of platinum used in my assays of potash and ammonia salts.—EXPERIMENTER.

[46660.]—**Sutton's Secondary Battery.**—You say that you have bent the plates "into a spiral, with indiarubber between top and bottom to prevent contact." If by this you mean that the indiarubber entirely covers the plates, I should say that is the cause of failure. If I made one on the spiral principle, I should use felt, or some other porous substance, as a separator. Indiarubber is non-porous. Some time ago I made a cell on the parallel plate plan, with only about half the lead-surface of yours, which answered well, and had plenty of power to drive a medical coil. At the end of a week it had not entirely lost its power.—J. HEZMALHALCH, jun., Fellisclifle, viâ Leeds.

[46664.]—**Resistance of Electric Lamps.**—Many thanks to the gentlemen who have so kindly replied to my query. As "Sigma's" reply contains the real answer, may I venture to make a suggestion to him? He is doubtless aware that amongst the visitors to the Crystal Palace Exhibition there are many busy men who have not time to study even his excellent book, but who are anxious to understand the elements of the subject—especially as concerns electric lighting. These persons have been informed in the ordinary colloquial way that the incandescence of the carbon in the lamps is due to the "resistance" which the filaments of that substance offer to the passage of the current, and they have also been told, as stated in my query, that the resistance of one lamp being 50 ohms, four in series would be 200 ohms, or if in multiple arc (is not "circle" more correct?) 12·5 ohms—presumably, as I said, for each lamp, simply because there was nothing to indicate that what was meant by "resistance" in this case was really increased conducting capacity. This resistance, in fact, has nothing to do with the lamps themselves, but is the resistance of the circuit. "Sprague's Electricity" was issued before much had been done in electric lighting, or there would doubtless have been a chapter on the subject; but when I tell my friends they can find all the principles clearly explained in that book, they reply pertinently, "We have not time to study the subject, but we would gladly endeavour to understand the rudiments—especially what electricians mean by ampères, volts, ohms, &c." The use of the expression "resistance"—though quite intelligible to those who understand the subject, is confusing to the tyro; and some recently published textbooks seem only to have been written to show what the writer knows, and not for the purpose of instruction. I do not suppose that is the intention, but it is the effect. In one I refer to the index for "resistance," and on turning to the page, discover that the paragraph is headed "conduction." Another reference shows that "resistance" is a tangible something which the current has to "encounter" and "overcome." In the same paragraph the water-pipe analogy is used, and it is said that if the pipe be a very "thin" one, the water will only slowly run through. Of course, it is clear enough to those who understand, but then there are thousands who want to know, who are simply puzzled by these textbooks. In the case cited, it is evident that the writer meant "small" by the word "thin"—the analogy having become mixed up with wires. However, not to ramble, I think I have shown where misconception arises, and I now arrive at my object, which is to ask "Sigma" if he cannot write us an explanatory article on electrical terms, giving examples of their application in practice. For instance, at the Palace, I have often heard the question, How many cells would it require to work one of these lamps? Supposing Swan's to be meant, I make out that one cannot be worked with economy, for the same battery plant would work five. Is that so—meaning the lamp which is supposed to have a resistance of 50 ohms? Another example may be given as an instance: a good deal is said about storage batteries, and people want to know how many Bunsen cells are necessary to charge a Sutton or a Faure secondary. I have heard it said, "one, if you keep it on long enough"; but if the E.M.F. of a Faure is over 2 volts, how can a cell, with an E.M.F. of only 1·8 volt, charge it? Another: Griscom's motor is shown driving a lathe, current being furnished by a bichromate battery. An example of the electrical terms or units, as applied to calculations of that kind, would be useful. I know I am asking for something very much resembling a "royal road" to knowledge, but I think "Sigma" will understand what is wanted, and I know that he can, if he will, put the information into just the form that is required by those who are too busy to make a study of the subject, but yet desire to understand with intelligence.—NUN. DOR.

[46669.]—**Patterns for Engines.**—To give you the proportionate sizes would take up much valuable space in these columns, that is, if fully stated. Briefly, for the 1⅜ bore engine, the cylinder should be 4¼in. long inside the covers; piston-rod, ¼in. diam.; connecting-rod, 9in. long between centres; crank-shaft, according to steam pressure, from ½in. to ¾in. diam.; nominal power, about 1-6th of a H.P. The 4in. bore and 8in. stroke engine should have the cylinder 10in. long between the covers. The piston-rod should be ¾in. diam., crank-shaft, 1¾in. to 2½in. diam. The proportion of the valve, ports, &c., must be determined by the class of engine, the proposed speed, and the pressure of steam. Put these particulars before me,. mentioning the names of parts you still want, sizes of, and I will tell you. Horse-power would be 1¼ nominal. I am assuming that the pressure of steam would be, say, 50lb. in the latter case. The first engine would be but a toy; whilst the 4in. engine would indicate probably more than 2 H.P.—SUNLIGHT.

[46672.]—**Binding Screws.**—I would strongly advise you not to attempt to make any substitutes for binding-screws. Dirty connections are the cause of more annoyance and trouble than any other part of the battery, and makeshifts are sure to come to grief just at the moment when most wanted. You can make good connecting screws of all kinds at a cost to yourself of twopence to threepence each, and I shall be pleased to give you instructions how to make a few useful connecting screws.—W. J. LANCASTER.

[46674.]—**Telephone.**—The induction coil is used in conjunction with a carbon transmitter. The secondary, induced by the primary, possesses properties not contained in primary current, thus it will go over longer distances without much loss, and it gives a smoothness to the sound at the receiver. I have used induction coils of every form with carbon transmitters, and find the advantages I have named; but I have not found such a marked difference as some have. You can make a suitable coil out of 2oz. of 18 primary, and 2oz. of 36 secondary, well insulating each layer from its neighbours, and more especially the primary from the secondary. Connect two wires from primary to transmitter, and from secondary to line and earth.—W. J. LANCASTER.

[46675.]—**G.N. Engine, 48**—No. 48 has outside cylinders, 18in. by 28in., and 8ft. 1in. driving-wheels. I believe all the 8ft. engines are the same as regards wheels and cylinders. No. 47 was the engine that was sent to the Darlington exhibition, and was built at the company's shops at Doncaster in 1875. It never runs to London. No. 48 was built also at Doncaster in 1874, and is No. 150 of their build. This engine was on the Leeds express when the latter ran into the Scotch express at Abbotts Ripton in Jan., 1876. Full dimensions of the class will be found in back vols.—MURANO.

[46676.]—**Focus of Lanterns.**—The only way for you to produce a large disc is to move your lanterns sufficiently far from screen You must, of course, remember that your light will enable you to obtain a disc about 12ft. to 15ft. in diameter, and beyond this it would be unwise to go, as the loss of light would more than counterbalance extra size of disc. It is always better to have a small disc well illuminated than a large one but dimly lighted.—W. J. LANCASTER.

[46676.]—**Focus of Lantern.**—The size of the picture of a lantern, as I have repeatedly stated in these pages, depends on the focus of the objective, and that only. If you want a large picture at a very short range from the screen, you must get a very short-focus objective or focus lens. The condenser has nothing to do with the question: it is simply a light gatherer. If I understand you aright, your present lantern has an objective of 4in. focus. Is that so? If it is, you can get a larger picture at the same range, or the same size near the screen, by using a 3½in. focus objective. Shorter than that I would not advise. If you do, you will find a want of focus and definition. I have lenses made specially for me that are 3in. focus only; but the definition is not equal to a 4½in. one, although no cost was spared. Large pictures at a short range mean very short-focus lenses, and consequent bad definition; and this is intensified by any attempt to depart from the exact square position relative to the screen. On the other hand, a long-focus lens will bear to work at a small angle, and gives splendid definition and depth of focus.—SUNLIGHT.

[46678.]—**High Temperature Fluid.**—Linseed oil boils, I believe, at 602° F. Would this do for your purpose? This is the nearest to 600° of any boiling-point I am acquainted with. If the vessel which is to contain the oil is perfectly smooth, the boiling-point might be raised a few degrees, and a temperature of 600° obtained without the oil boiling. Sulphuric acid boils at 640°: this, I suppose, would be out of the question. Then there is mercury, which boils at 660°.—W. J. LANCASTER.

[46678.]—**High Temperature Fluid.**—Fusible metal composed of lead 1, bismuth 2, tin 1 fulfils the conditions stated, and if its solidification at about 200° F. is no objection, might do. An alloy of bismuth 15, lead 8, tin 4, cadmium 2, melts at a lower temperature—said to be about 140° F.—J. BROWN, Belfast.

[46679.]—**To Mr. Lancaster.**—I cannot lay my hand on your original query. Will you be good enough to say exactly what it is you wish to do? I do not remember your first query, but shall be pleased to give you an answer when I know exactly what you wish to do.—W. J. LANCASTER.

[46683.]—**Magneto-Electric Machine.**—To MR. LANCASTER.—You have not one-tenth part the amount of wire on bobbins that you ought to have. I have repeatedly written that to get full power out of a core the wire on bobbin must be as deep in layers as the thickness of core. Now your core is ⅜in. diameter, then you must wind as much wire on as will make the whole just over 1in. diameter. Let the end nearest magnet revolve in a socket in connection with the framework of machine; the other end should be insulated from frame by a bush of boxwood or ebonite; then, of course, the spring must be screwed to frame, and touch round parts of axle twice during each revolution. A double magnet gives, of course, a stronger current; but a single magnet would give as much current as you would care for. You can make the spring out of any shaped piece of steel; the holes in the one you saw were there because probably the spring had been stamped, and originally belonged to something else. You can make a magnet-compound one out of bars of steel, coupled at one end with iron; but it would be a bad one. You can, if you like, make a magnet of a V form, the ends being riveted together; but this is not so strong a form as the horseshoe or U form.—W. J. LANCASTER.

[46684.]—**Photo. Background.**—You should buy a piece of "Avery's" background cloth. This you can have with a different colour on each side, dark and light, or dark and medium; in fact, any shade you like. It is remarkably cheap, and is the best background you can have.—W. J. LANCASTER.

[46689.]—**Focal Length of Photo. Lens.**—Take the solar focus and work from that. Thus: A lens of 12in. focus would give an image at 12in. of everything having parallel rays. Thus the sun's light would produce such a focus, and the most distant part of the horizon would produce an image in almost the same plane, while nearer objects would produce an image beyond that plane. In the case of a double combination, you must obtain its equivalent focus.—W. J. LANCASTER.

[46690.]—**Waterproof Cloth.**—Canvas can be made waterproof as follows: but calico will suit quite as well for this purpose. Give four or five coats of linseed oil, equal parts, boiled and raw. If colour is desired, one of the coats can be of paint, but it will be more pliable without paint.—D. BROWN.

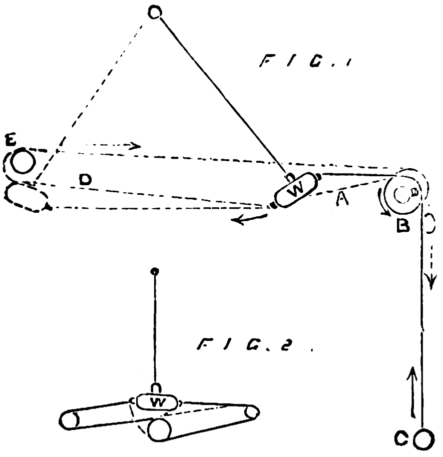
[46697.]—**Railway Grease.**—The querist is to some extent correct in supposing these compositions contain soap. I give the following from Barry's excellent work on "Railway Appliances," but the quality of the oil employed differs greatly on different lines.

	For winter.	For summer.	For very hot weather.
	lb.	lb.	lb.
Russian tallow ..	214	342	426
Palm oil	240	210	210
Soda	20	18	18
	Gallons.	Gallons.	Gallons.
Water	64	48	48

The great objection to grease as a lubricant is being applied from the top, it carries down with it any dirt or grit, and thus causes circular grooves to be worn in the journal. Oil is now considered to be a more efficient lubricant, after many severe trials.—A MEMBER OF THE SOCIETY OF ENGINEERS.

[46687.]—**Lifting Water by Motion of Ship.**—The height to which water will be lifted by motion of a ship going at speed of one mile per hour will be (theoretically) ·38in.; two miles per hour, four times that height; three miles, nine times; and so on, making the height at ten miles per hour 38in., and at twenty miles 12ft. 8in. Practically about 30 per cent. might have to be taken off the theoretical heights to allow for friction and bend in the pipe.—G. PINNINGTON.

[46687.]—**Lifting Water by Motion of Ship.**—"R. W.," in ENGLISH MECHANIC of 21st April, asks the height to which water could be raised according to the speed of the ship. This query does not intimate for what purpose the water is to be raised, but it has reminded me of an idea that I thought of when going to India in 1855—namely, of utilising the oscillating or pitching motion of a vessel by suspending a very heavy weight with room to swing from side to side. From this weight, W, there were to be two bands, one A, leading direct to a pulley on a shaft B, inside of which there was to be a ratchet acting on the shaft, so as to carry the shaft round with it. A band-spring or weight would carry the pulley back again on the return of the weight W. From this weight, W, there was to have been a second band D, passing over a fixed pulley, E, in the side of vessel, and thence to another ratchet pulley on same shaft as first mentioned, and rigged in same manner. It is manifest that at each sway of the weight W the shaft would revolve so many times, according to the diameter of the pulley, and work either a screw or pump, or punkah. Another and more compact arrangement is shown below. Each band works on a different ratchet pulley, having a ratchet working into the shaft, and reversed either by a spring or a separate weight, or by a band leading to the main weight W, but in a reverse direction.—Milford.



[46700.]—**Intensity Coil.**—There is some connection between the two sets of tin-foil in your condenser, which completes the circuit. Each sheet of foil should be a quarter of an inch smaller each way than the paper between it, and the two sets of connections kept some distance apart. —R. V.

[46702.]— **Mounting Oleographs.** — White linen is best for mounting. Strain the linen over a clean, flat board, fastening it down by a few small flat-headed tacks; tin-tacks will do. When strained free from any wrinkles, slightly damp the linen with a sponge with clean water. Let this remain a short time. Then paste the back of your oleograph, and rub it well down over the strained linen. Let this remain to dry overnight. After this, sponge gently over with vellum size, which is the best for the purpose. Let this get thoroughly dry, after which apply one smooth coating of white-paper varnish. Tack only round edges of linen.—G. Fryer.

[46708.]—**Rain-Water Tanks.**—Iron, galvanised, would keep the water clean and sweet; and I should recommend four supports unless you have very strong iron. Wood tank, lined with 4lb. sheet lead, will keep the water clean and good. Frost? No. As regards price, materials vary in different localities. You should ask your ironmonger what a galvanised iron tank will cost of the size you mention; then, for the wooden one, ask your carpenter to quote, and your plumber the price he will line it for, and, by comparison, judge for yourself. Durability: the iron one, if thoroughly galvanised, needs no further trouble or expense. Wooden one will require frequent coats of paint to keep from rotting. You may get a good cheap water holder by taking a quantity of oil-casks, and connecting together at bottom. Last a long while.—Working Tom.

[46712.]—**Yacht.**—If "Minum" will say what distance "house" is from the pond, and what means he has of transporting his proposed yacht, I will gladly help him.—W. R., Liverpool.

[46714.]—**Power of Engine.**—The rule that I generally use is as follows:—$A \times P \times V / 33{,}000 =$ actual h.p. Where $A =$ area of piston, $P =$ pressure per square inch, $V =$ speed of piston per minute. Making use of this formula in your case it becomes, therefore, $7{\cdot}00 \times 50 \times 200 / 33{,}000 = 2{\cdot}13$ actual h.p. I generally use 200ft. as the speed of pistons to my engines.—H. E. B., Ex.

[46714.]—**Power of Engine.**—Rule: Multiply area of piston in inches by pressure in lb. per inch, the product by the number of feet travelled by the piston per minute, and divide by 33,000. This will give h.-p. required. To find area of piston: Multiply the square of diameter of cylinder by ·7854. To find number of feet travelled by piston: Multiply the number of revolutions per minute by twice the stroke in feet.—E. S.

[46714.]—**Power of Engine.**—It is quite impossible, I regret to say, for me to give an opinion on the querist's engine, as he has not mentioned the speed, or revolutions per minute; but I append two rules that will enable him to easily calculate it out for himself. Let us take one rule, for instance, which is to multiply together the square of the piston's diameter in inches, the number of strokes per minute, the length of the stroke in feet, and the steam-pressure, together with the constant ·0000467, and the product will be the horse-power; or, to state it briefly, let us take C as the piston's diameter in inches, N the stroke per minute, P the pressure of steam, and S length of stroke, when the rule is $D^2 \times N \times P \times L \times {\cdot}0000467 =$ the horse-power. This is one way; but if the querist desires something that, perhaps, looks simpler, then he may multiply the area of the piston in square inches (which, in his case, is 7·068 square inches) by the effective pressure of steam, which is only to be ascertained by the indicator; then multiply that by the speed of the piston in feet per minute; divide this product by 33,000, and the quotient is the power, less friction.—Sunlight.

[46716.]—**Sound in Pipe.**—Local circumstances in so many cases greatly control the question of sound transmitted by a water-pipe. If it be a noise due to the transmitting power of iron, then a remedy would be to have a joint in the pipe, with pretty wide flanges, and between them a thick rubber ring. This would make a watertight joint, and, at the same time, abolish the noise, in a great measure. Would this be practicable?—Sunlight.

[46717.]—**Gas-Engine.**—To "Sunlight."—The sliding light of a gas-engine is one of the difficulties, and a great one, too, of the compression-engine. I will, however, briefly tell you that the description to which you refer of Crossley's patent, No. 2,177, of 1877, of the igniting arrangement is, to my mind, an absurdity. Not only so, but I have never met with an engine so fitted, and I do not think any were ever made on that plan. Therefore, you have been following a bad plan, to say nothing of the question of infringement. It is an exceedingly difficult matter to first get a good ignition and one certain of action, and yet be clear of infringement of existing patent-rights. And, apparently you have overlooked the operation and effect of the parts mentioned at Nos. 5 to 35, p. 9. As it is a special point of the patent, I hardly feel justified in saying more than that you have no doubt misinterpreted its meaning. And that, hence, it is quite impossible for you to get ignition. Broadly, the question you really want to know is, how to get the same pressure behind the light as before it. As far as the specification in question goes, I cannot venture to say anything, as I should be doing what I take to be a wrong to the patentees. And let me add that you are apparently most clearly infringing their patent as it stands. As it is held to be an infringement to make even one article or motor even for one's personal use. There are many points at issue that I should not care to mention publicly. I have myself a variety of plans, several of which depend entirely on the arrangements of the slide itself for their action, and not in any way depending on the grooves or channels on the valve-face. I need hardly say that these are, with other points, fully patented. The only thing I can do to help you is, that if you advertise your address I might be able to give you some assistance by private letter and in confidence, that I should decline to make public. As to the launch, I know the suction-gear you name; but it could not be applied to the purpose named, for several reasons. I carefully thought out the matter; but so far, insuperable objections came in against suction-gear. One very potent reason is that the engine, the screw-shaft, and the reversing motion must all be in the same horizontal plane. —Sunlight.

[46718.]—**Varnish for Venetian Blinds.**—Use what is called "church" oak varnish; as to the mode of application, with a 00 or 000 varnish-brush; varnish costs from 8s. per gallon upwards, according to quality and maker.—Hampstead.

[46721.]—**Right of Way.**—It would take many pages fully or even clearly to answer these wide questions. If the footpath has become a public highway it can only be closed by taking the proper steps under the statute 5 and 6, Wm. 4, ch. 50, and upon an order made by the justices in Quarter Sessions. But there are rights of way which are not highways. A right of way arises either by grant of the owner of the land or by prescription—*i.e.*, user, for more than twenty years. Rights of way are of endless variety, and depend upon the purposes for which they are used, the neighbourhood, and other facts, so that a general definition is as impossible as it is useless.—Fred. Wetherfield, Solicitor, 2, Gresham-buildings, Guildhall.

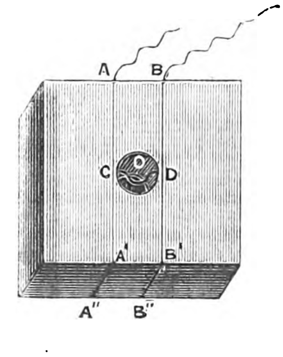
[46724.]—**Concrete Walls.**—We find nothing beats Portland cement concrete. One sack of cement to $\frac{3}{4}$ of a cube yard of gravel or broken stone. Yours will not want washing. See that there is some of all sizes, so as to fill up all cavities: if not, add sharp sand to make it do so, or a few ashes are good when above damp lime. We find ground lime to be a failure. If you like to write I will answer same. Be sure you have stones of all sizes, so as to have no cavities.—H. Booker, Sidcup, Kent.

[46725.]—**Plumbers in Paris.**—The English plumber can work his way in Paris as in England, and with the same success. The streets are not paved with gold, but where there's a will there's a way.—P. J. Davies.

[46726.]—**Paints for Spanners.**—Use black japan, and put into a japanning oven to dry. Put it on either with a brush or your hands.—Working Tom.

[46727.]—**Firing Gunpowder by Electricity.** —All you need is a small battery. One cell even will be sufficient for home experiments. What is needed is a short length of very fine iron wire, as fine as a human hair. If you take the two wires from your battery, and round one of them give the fine iron wire a few turns so that it is held fast, and then apply the other battery wire to the iron wire held in tension, you will quickly find what length of wire the battery will render red-hot. There is no need of an induction coil at all. —Sunlight.

[46727.]—**How to Fire Loose Powder by Electricity.**—The following is a good and effectual method. Take a piece of wood, about 1in. square by $\frac{1}{2}$in. thick. Make niches A′ A″ and B′ B″, about $\frac{1}{4}$in. apart. Also make two corresponding niches at the opposite end at A and B. Next, in the centre of the piece of wood, bore or scoop out a small hole O, say, about $\frac{1}{4}$in. wide.



Then fix two pieces of copper wire in the niches by bending them round and knocking them in in the position seen in the figure. Next, at the centres of these two wires, solder a piece of thin platinum across, about $\frac{1}{2}$in. long, and bend it down into the hole. The points where it is soldered are seen at C and D. The wire may be obtained for 2d. a foot at any good electrician's. Then fill up the hole with gunpowder, and paste a piece of paper over it to keep the powder in. Lastly, solder two wires to the wire at A and B to serve for heading wires. A couple of bichromate cells should fire this fuse. The poles, of course, are to be connected with the two leading wires. To fire the loose powder, the fuse should be inserted in the middle of the heap. Its action is that the current in its passage through the platinum wire (which must be very thin) heats it red-hot, thereby igniting the powder in the hole. No induction coil is needed. The dimensions of the fuse may be smaller than this.—W. H. L. H.

[46731.]— **Moulder's Blacking.**— I hardly know what "P. C. M." wants to know; is it how or what the blacking is composed of, or is it how does the moulder mix it for use? For very best work I have seen blacklead—servants' friends—as sold by the ironmongers, used; next, a cheaper sort of plumbago, and a cheaper sort for big work is the charcoal blacking, that is, ordinary charcoal ground as fine as flour. The moulders mix it for use as follows:—Take a bucketful of clean water, some potter's clay to thicken it, and put in a few handfuls of the above blacking. Proportions are all rule of thumb.—Working Tom.

[46732.] — **Micro. Fungi.** — Usually opaque. Some are soaked in spirits of turpentine, and mounted in balsam; others, without the soaking, in glycerine jelly.—John Alex. Ollard, F.R.M.S., Enfield.

[46733.]—**Screw Propellers.**—Your question cannot be definitely replied to as it stands. Every vessel almost needs a special size and pitch, so that there is no general size and pitch for all purposes. Certain rules—such as the draught of water aft, and other considerations—govern the size of the screw, whilst the speed of the engines and the lines of the hull are the data on which we go for determining the pitch.—SUNLIGHT.

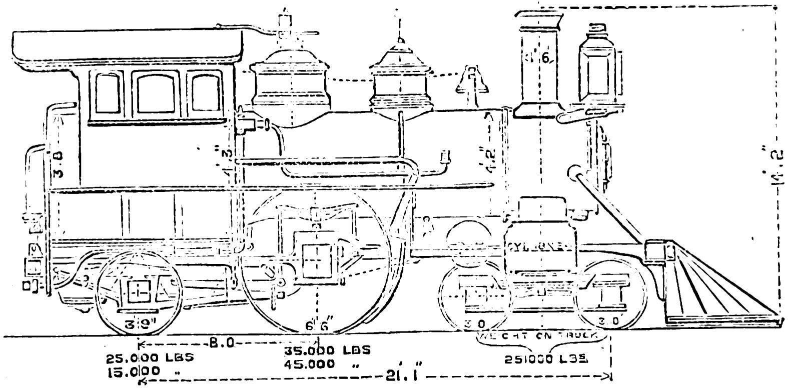
[46734.]—**M. R. Engines.**—All the engines "C. H." inquires about are six-coupled double-framed goods engines; 510 was rebuilt 1879: cylinders 16½ by 24 originally, 17 by 24 after rebuilding; 481 is a straight-framed engine of the same class, but I do not know the date. Most of the 480 class were rebuilt in 1878. The 430-449 class were built by the company in 1860, but most have been rebuilt; 395 was rebuilt 1878. Most of the 290 class of engines stationed at Birmingham were renewals of 1869 (such as 293, 297, 299): I have not seen 291, but perhaps it is one of these. The 270—289 class are nearly all rebuilt at various dates, mostly 1875-7. I do not know dates of those mentioned. I give dimensions of the old straight-framed goods engines—cylinders 16 by 24; driving-wheels 5ft. 2in.; wheel base 16ft. 6in.; grate area 14·5 sq. ft.; 180 tubes 2in. dia., ⅝in. clearance; weight on leading-wheels, 12 tons 6 cwt.; on driving wheels, 11tons 5cwt.; on trailing wheels, 8 tons 14 cwt. Dimensions given are those of the engine in the Exhibition of 1862 built by Fairbairn, Manchester. Can any reader give its number? All these engines which have been rebuilt have had their cylinders enlarged to 17 by 24. The boiler is also much larger. No. 429 engine belongs to a set of two engines built by Beyer, Peacock, and Co. in 1858, with Cudworth's fireboxes. They ran trials with two engines (426 and 427) built by the company in 1858, with the ordinary Midland brick-arch fireboxes. The result was in favour of 426 and 427. No. 428 eventually exploded at Nottingham in 1863, and was rebuilt. No. 429 was rebuilt in 1865. The fireboxes of both engines were changed to the ordinary Midland pattern.—METEOR.

[46735.]—**Eames's Locomotive.**—"Tyre" will find a full-page elevation of this engine about p. 412 of *The Engineer*, in the first half of 1880, and also a sectional elevation, &c., in *Engineering*, p. 265, March 24, 1882. I should here like to remark the engine in question was not, as some of the daily papers made it appear, built for the Eames's Brake Company; but for the Philadelphia and Reading Railroad Company, by the Baldwin Company, and bears date March, 1880. It has worked some of the L. and Y. trains; but with what success, if any, beyond the English locomotive, has yet to be stated.—R. N. H.

[46735.]—**Eames's Locomotive.**—This engine was purchased by the Eames' Vacuum Brake Company from the builders, Messrs. Burnham, Parry, Williams, and Co., of the Baldwin Works, for transportation to England, and what object they had does not appear, as the locomotive is fitted with the Westinghouse automatic air-brake, with the reservoir between cylinders and pump fixed on rear-end of firebox. It was originally intended for the Pennsylvania and Reading Railroad, to run on the Philadelphia to Bound Brook section. The engine, as will be seen from the tracing appended, is of the outside-cylinder type, with single driving-wheels, with a four-wheeled bogie in front and a small pair of trailing-wheels under the firebox. The load on the driving-wheels can be altered at will by the engineman by means of a lever (worked by a small vertical steam-cylinder) acting on the compensating-beam of the springs in such a way that the loads respectively of the driving and trailing-wheels may be altered from 35,000lb. on driving and 25,000lb. on trailing to 45,000lb. and 15,000lb. The trailing springs are somewhat curiously arranged, as will be seen on reference to tracing. They are placed in rear of the axle and the two ends of the frame as usual, while the centre of each spring is connected to the rear-end of a beam which passes over the corresponding trailing axle-box, and has its front-end coupled to the compensating-beam coupled to the driving-wheel spring. The heavier load that can be thrown upon the driving-wheels is for enabling it to start promptly on a gradient or with a heavy train. I append a few of the principal dimensions:—Diam. of cyl., 1ft. 6in.; stroke of cyl., 2ft.; length of ports, 1ft. 4in.; width of steam-ports, 1⅜in.; width of exhaust, 3in.; outside lap of valves ⅞in.; inside, 1-32in.; lead, 1-16in.; travel of valves, 5½in.; travel of eccentrics, 6¼in.; diam. of wheels, 6ft. 6in.; tractive force, $18^2 \times 24 / 78 = 99{\cdot}7$lb.; total wheel base, 21ft. 1in.; driving to trailing, 8ft.

Weight on driving-wheels ..	45,000lb. or	35,000lb.
Weight on trailing-wheels..	15,000lb. or	25,000lb.
Weight on bogie-wheels	25,000lb.	25,000lb.
	85,000lb.	85,000lb.

Diam. of barrel at smoke-box end, 4ft. 2in.; thickness of shell-plates, 7-16in.; length of firebox inside, 8ft. ½in.; width of firebox inside, 7ft.; thickness of firebox tube-plate, ½in; thickness of firebox plates, ⅜in.; diam. water-tubes forming grate, 1⅞in.; thickness water-tubes forming grate, ¼in.; pitch water-tubes forming grate, 2⅜in., number of boiler tubes, 198; outside diam.-tubes, 2ft.; length of tubes, 12ft. 2¾in.; length of smoke-box, 4ft. 2in.; height of chimney above rails, 14ft. 2in.; height of centre of boiler above rails, 7ft. 4in.; diam. exhaust nozzle, 4⅛in.; total heating surface, 1,400 sq. ft.; grate surface, 56 sq. ft.; the area through tubes, 3·5 sq. ft.; sectional area of chimney, 1·77; ratio of grate area to heating surface, 1 : 25; flue area (tubes) to grate area, 1 : 16; ratio of sectional area of chimney, 1 : 31·7. It will be seen from the above figures that the enormous grate area causes the ratios of flue and chimney to appear abormally small, although these areas are themselves amply large for the size of the boiler. The smokebox is very long, and is intersected a little above its centre by a wire network (3½ meshes to the inch), through which the blast-nozzle projects. The engine has no footplate in rear of the firebox, the stoking being done from the tender footplate. There is, however, a small footplate running along the side of the firebox, and on which the cab is built. One of the difficulties in introducing it in England would be difficulty of getting from side to side. The boiler is fed by two injectors, pumps being used. The smokebox is carried on four movable links, two before and two behind the firebox. These are the principal particulars and dimensions. For further particulars see *Engineering*, March 24.—E. W.



[46738.]—**Universal Brake Couplings.**—The East Coast and Midland Scotch Joint Stock carriages have already brake-pipes for air and vacuum. The West Coast Joint Stock has at present the chain brake, but is to be provided with the Westinghouse pipes, so that it can be worked on the Caledonian. The L. & N.W.R. don't seem to have fixed on a brake yet; when they do decide, it may be necessary to add other pipes to the Joint Stock. I cannot speak from experience about the brake worked through the buffers; but, on looking to page 4 of Mr. Stretton's little book on "Railway Accidents," of February, 1881, I learn that George Stephenson tried such a brake upon the Liverpool and Manchester, and Leicester and Swannington Railways in 1832, and he gave it up because he found a difficulty in setting the train back. The statement quoted upon page 177 is quite true, that the vacuum brake on the Midland leaks off in two minutes, and that it cannot be fitted to engines or tenders. *I do not consider* that it does fulfil the conditions, and should be glad to know the opinion of our correspondents. I quite agree with "Railway Servant," that ejectors, when running a stopping train, use quite 2lb. of coal per mile. I cannot say for certain how much a pump uses, but it is very little. During the next two weeks I shall work engines with both pumps and ejectors. I will take very careful notice, and report experience I gain in a letter to ours.—A DRIVER.

[46739.]—**Nitro-Glucose.**—Take equal measures of strong nitric and sulphuric acids, mix, allow to cool, and then stir in finely-powdered loaf-sugar. Nitro-glucose will speedily form in a stiff pasty mass, which should then be removed from the acids and well washed with water. Owing to its insolubility and impermeability, it is difficult to entirely free it from acidity; but if that is any objection, it may be still further purified by dissolving in alcohol, and precipitating by pouring it into water.—WM. ROBINSON, jun.

[46741.]—**Landscape Photography and Dry Plates.**—"Holiday Work" might resort to some of the old collodion processes, either with the bath or emulsion, and of which I think there are ample details in back volumes; or, if he likes to prepare his own gelatine plates, he can make them as slow as he thinks proper—it is all a question of "cooking." It is quite a mistake, however, to suppose that gelatine plates cannot be manipulated without an "inconveniently dark non-actinic light." It is simply a question of a little dodging, such as working with the back to the light; in a part of the room where no direct light from the window can fall upon the plates, or interposing an opaque screen between the light and the plates.—W. ROBINSON, jun.

[46741.]—**Landscape Photography and Dry Plates.**—In answer to "Holiday Work," I find in my experience that gelatino-bromide dry plates are the most simple and pleasant process of any I have tried. Plenty of light can be used if of the right kind; a ruby hock-bottle with a candle used inside gives a very pleasant light; these can be bought at most dealers in photographic apparatus. Plates can be bought about as sensitive as wet plates. I use Edwards' Glycerine Developers, give long exposures and slow development. On reference to my notebook I find the following: Waterfall near Wales, light moderate, time 3 p.m. Small stop, Dallmeyer's Rapid Rectilinear, exposure 35sec., very slow development; the result is all that could be desired, and splendid in detail. (The plate was an extra rapid).—JAMES PARKINSON.

[46742.]—**Daniell Batteries.**—To use Mr. Sprague's words, "the great drawback to this cell is that the copper salt passes by endosmose into the zinc solution; and suggests as a remedy the use of two porous cells, the space between them being filled with a strong solution of sulphate of zinc, and some zinc cuttings added to decompose any copper salt entering." It is almost a perfect remedy, but increases the internal resistance somewhat. You would not gain anything by using water instead of acid and water, or semi-saturated solution of sulphate of zinc.—AN ASSOCIATE OF THE SOCIETY OF TELEGRAPH ENGINEERS.

[46743.]—**Microscope and Magic-Lantern.**—Much has been written on this question in back numbers of this journal. I myself always prefer to use a proper lantern micro. objective; that is one constructed to utilise as much of the available light as possible, and not only this, but it allows the micro. attachment to be so arranged that the great condensation of heat on the slide is avoided. As you apparently do not know this, I would tell you that when using the lantern as an enlarging microscope, the slide is placed approximately where the focus lens usually is, and hence, being placed where the rays of light converge to a focus, great heat is also thrown on the slide, so much so that with the usual form, small animalcules are speedily killed by the heat of the water in the tank, or by the great concentration of heat on them, if in a cage. Not only so, but the heat damages the slides by starting the balsam, and sometimes even cracking the glass. With the objective from an ordinary microscope, the aperture is not sufficient to get the projection sufficiently well lit, and nothing but a lantern micro. will remedy this. The best of all micro. attachments is a form that has been introduced by Mr. Browning, of London, the definition of which is something splendid. But the high price of it, and the fact that nothing short of the oxyhydrogen light is of any use with it, preclude its use except by a few.—SUNLIGHT.

[46745.]—**Stopping for Decayed Teeth.**—"Murano" will find plain indiarubber tooth-stopping the most effective. It can be obtained at all chemists.—SEAWEED.

[46745.]—**Stopping for Decayed Teeth.**—If you cannot go to a good dentist, don't stop them at all. I had several teeth stopped with metal. The teeth decayed below the stopping, which became loose. Nothing would pick it out (being as hard as iron), and the agony was intense, as I could not cleanse the tooth out. No stopping is of any use unless the tooth is well and thoroughly cleaned out. Then use some soft stuffing. Keep your teeth well cleaned out and well cleansed, and attend carefully to diet (this is all important), and you will seldom have toothache. If you have, use carbolic acid and chloroform in equal parts. It need not be kept in the tooth for long, and should be carefully put in, to avoid burning the lips. I used to use it daily and hourly. To clean the tooth out use caustic. The taste is unpleasant before eating or smoking. I have also used nitric and hydrochloric acid, but they are painful. I am now a vegetarian, and suffer seldom from toothache.—JOHN ALEX. OLLARD, F.R.M.S., Enfield.

[46746.]—**Stopping for Decayed Teeth.**—Several years ago, finding some of my teeth were showing signs of rapid decay, I bethought me to stop them with an amalgam of silver, which I made by filing some pure or coin silver to a powder, and working it up to a stiff paste with quicksilver. After having scraped the cavities of the teeth to remove decayed and soft parts, and otherwise cleaned them out and dried with plugs of cotton-wool, I packed and pressed the amalgam in, and shaped off as nearly as I could to the original forms of the teeth. After it had set, which occupies about half an hour, or less, I had as good a biting and grinding surface to my teeth as could be wished for. Observe that this stopping should not be applied if the teeth are aching, or an exposed nerve left undestroyed. After several years, these stoppings show very little sign of wear. The only thing that detracts from universal use is that the amalgam turns black, so is rather objectionable for front teeth. For back teeth this discolouration does not matter. Only on one occasion have I found it necessary to remove the stopping from the tooth in which it was placed. Owing to subsequent decay, the cavity had enlarged and the stopping got loose. Toothache following from a severe cold in the facial nerves, I was constrained to remove it to get relief. It is out at the present time, but I intend, as soon as the nerves are in their normal condition, to stop the tooth with the silver amalgam. I must append a caution: Do not let the quicksilver touch any article of jewellery, or you may be caused vexation. White guttapercha makes an excellent stopping *pro tem.*; it soon wears away. Carbolic and other such diabolic combinations should be eschewed as much as possible; they invariably accelerate decay. Creosote notoriously crumbles up the molars.—ALFOJOE.

[46753.]—**A Water-closet Nuisance.**—I think that the rubber washer edges are loose; but try a small ball-valve with pea waterway. If you cannot get one, send to me, and I will let you have one cost price. I expect you have a very high pressure behind your valve.—P. J. DAVIES.

[46754.]—**Watch Repairing.**—To "ALFOJOE."—It gives me great pleasure to know that what I have written upon the subject of watch-cleaning, &c., has proved of service to "Country" and others. As regards the query put to me, there must be something defective in the action of the stopwork of the watch referred to, or through frequent breakage the chain has become too short, and is pulled out at the barrel-hocking before the fusee snail-point catches against the stop-finger attached to the top plate. These defects must be sought for, and you can ascertain which causes the trouble if you take the movement from the case, and with the eyeglass examine the run of the chain from the barrel to the fusee, and the action of the stopwork, whilst the watch is slowly wound up. If the chain is of the correct length, there should be fully a quarter of an inch of it upon the barrel when fully wound up and correctly stopped. If too short, it will be seen that the snail-point does not come up to the end of the stop, while the chain is wound off the barrel and pulls on the hook. To correct the chain, you must attach about an inch of the same substance and strength. This will allow the fusee to pass further round, and so make the stopping effectual. Should the fault prove to be in the stop-finger or its spring, it will be necessary to take the watch to pieces. Occasionally a little bit of bristle from the brush will get wedged between the chaps of the plate stud, or dirty oil may prevent free action, or the lifting spring may be too weakly set. In these cases the remedy is obvious. If you take the watch to pieces, put the plates together with only the barrel, fusee, and chain in, and set the mainspring up at the ratchet as usual. Then with a pair of hand-tongs or a small hand-vice, wind the chain from the barrel on to the fusee, and watch closely whether the stopwork fails or acts correctly. If it does not, try to ascertain the cause and so correct the error. I have occasionally found that two hook-holes have been made in the ring of the barrel because the first-made hole has been either too high or too low to deliver the chain correctly. If such is the case with this watch, you must try both, to ascertain which is the correct one. There is yet another chance that the fault may be caused by the lifting spring having shifted from its place, and so prevents the extreme end of the stop-finger resting against or near enough to the top plate, and thereby allows the snail point to pass by. It is needless to give sketches to illustrate my meaning, as five minutes' close study of the parts themselves should make all perfectly clear to you. Respecting the 'scape-wheel, by "fastening" do you mean "riveting" to the pinion? If so, you can do this with the little tool (Fig. 3, letter 19974) and a small round hollow punch, a portion of which has been cut away and the remaining part bevelled off from the hole outwards. By gently tapping the punch with a hammer, when the wheel is placed teeth up in the stake, and that screwed in the bench vice, the protruding part of the pinion is closed over the edges of the hole in the wheel and so made secure. Great care must be observed in riveting over, as a little excess to one side or another will throw the wheel out of truth. You must ascertain the correctness of this either in the calipers or in the depthing tool, which, in many ways, is the better tool for the purpose of trying the flatness or truth-in-the-round of all kinds of watch-wheels. If one side of the scape-wheel is found a little higher than another rivet that part a little more. When correct, finish off by rolling it in the centres of the turns by a horse-hair bow against a piece of Arkansas stone slightly oiled and held firmly at right angles to the teeth of the wheel, and so "tipped" up, and then with a suitable balance file thinned off equally. In my letter 19974, "Watch Mainspringing," read "turning" for "twining."—ALFOJOE.

[46755.]—**Enlargements and Developing-Tins.**—A very good and inexpensive method of enlarging will be found in the "Photographic News Almanac" for 1882 on page 54. Directions are sent out with each packet of paper. I have used tin developing-trays, for alum and fixing-baths, without the slightest trace of evil of any kind; but for developing coat with Bates' black varnish, after the manner of coating a negative; warm the tin first.—JAMES PARKINSON.

[46755.]—**Enlargements and Developing Tins.**—Block up all the window of operating room except a small space for negative, remove dark slide and focussing screen from camera, place back of camera against negative, focus image to size required on sheet of plain paper, and then take enlargement on bromo-gelatine paper. Leave developing tins alone; carefully dry them when done with, and they will most likely last your lifetime.—W. ROBINSON, jun.

[46756.]—**Bookbinding.**—Get your sheets of paper, cut them to the size required, glue one of the cut edges which you intend to form the back of book with ordinary hot, thin glue. When dry, stick on your end papers. Then, afterwards, paste your boards on, to form the cover. When pressed, glue a piece of bookbinder's cloth over the back with good hot glue. Paste on the marbled-paper sides. Let this dry. As the book has not been sewn, but merely glued at the back, you will be able to remove a leaf from it without loosening the others, providing you are not too rough in the way you go about it.—G. FRYER.

[46757.]—**Emery Wheels.**—To "SUNLIGHT."—Just fix on the size wheel you think would suit you; you would do well to write to one or two firms who supply the unmounted wheels, when they would not only quote price, but give the required speed. Having gone so far, I could then tell you speed of overhead shaft and size of pulley needed.—SUNLIGHT.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Since our last "R. N. H." has replied to 35398.

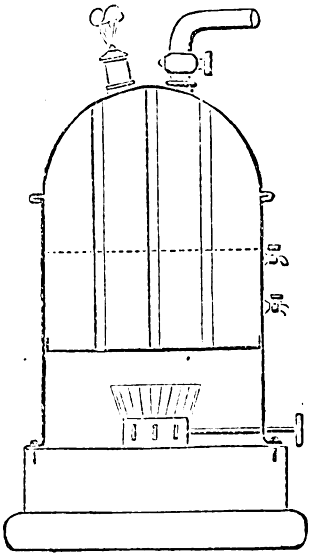
QUERIES.

◆

[46760.]—**Making Boiler.**—Would "Sunlight" or Mr. Lancaster please kindly explain the best means by which I can accomplish the following?—I want to make a copper vertical boiler as sketch. I have the dome or crown made of copper, semi-circular, like a deep copper scale. I want to make the sides come down below the bottom to form a support for boiler, and at same time suit as a furnace for burning spirits. Please say the best means to unite strongly and substantially the top or crown to sides and also the bottom. I have seen one similar which was brazed. Can I do this, or what way would you approve of—two or three brass tubes, vertical, to run through the boiler, and be expanded at crown and bottom, and I suppose a little solder, or brass, run round at the union of both metals? Crown dished out of the solid. What will be the best way to join the vertical seam of side? Copper crown is 7in. dia. by 20 W.G. Please say what pressure this may bear; I do not require it very great pressure. I shall have an ordinary model boiler spring safety-valve on it.—JUNO.



[46761.]—**Compensated Watch.**—I have recently bought a combination lever watch, Swiss make, in gold keyless case, with full plate, jewelled in 10 holes, with compensated balance. I found great difficulty in rating it. Since I brought it nearly to time I have been comparing it with a regulator clock controlled from Greenwich, and the following is the result:—

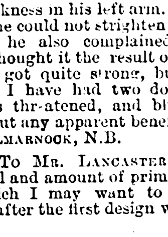
Feb. 4 .... 1m. 15s. slow.
11, 18, 25 .... 45s. slow each week.
March 4 .... 1m. 30s. slow.
" 11.............. 45s. slow.
" 18, 25, April 1.. 6m. slow in three weeks.

Was not observed in the interval. It appears from this that the normal rate, as rated, is to lose 45s. a week. What is the cause of the variations? Can it be rectified? There is a "ring" or "jingle" in the tick. It is steadily carried, never shaken in any way, or exposed to variations of temperature. It is a highly-finished one of the best of its class.—A. A. C.

[46762.]—**Sick Child.**—Would Dr. Edmunds kindly consider the following?—My little boy, aged 5 years, on recovering from influenza about three months since, showed signs of weakness in his left arm. On examination we found that he could not strighten it without pain at the elbow-joint; he also complained of pain in the back. Our doctor thought it the result of general weakness. He has now got quite strong, but the arm is no better—but worse. I have had two doctors, both say that joint-disease is threatened, and blisters have been applied freely without any apparent benefit. Is there no other remedy?—KILMARNOCK, N.B.

[46763.]—**Coil.**—To MR. LANCASTER.—What is the best length for a coil and amount of primary wire to give $\frac{3}{4}$in. spark; but which I may want to give 2in. by increasing secondary after the first design was complete?—T.

[46764.]—**Punches for Boiler-plates, L-irons, &c.**—Will some of your correspondents please give a sketch, with full-sized dimensions, of a common or ordinary punch, showing how it is held in the machine, an explain why it often makes such ragged holes in th plates. Some time ago an American, S. H. Jenkins, of



New York, introduced a punch which had cutting edges or teeth, something like inclosed sketch. Can any reader oblige with an accurate sketch, and say how it answered in practice? It claimed to clear out or rimer the hole after first punching it.—RIVETER.

[46765.]—**Periosteal Rheumatism.**—Some time ago I felt a stiffness in one of my elbows and thereupon briskly applied friction, but it still continued, attended with pain on moving the joint, and more especially in moving the muscles of the arm in putting on my coat. I subsequently tried counter irritants, but without success, and finally applying to a physician, was told that most likely it was the result of a strain, and a liniment was prescribed. It still continued as before, although attended with somewhat less pain. And now after having expended several guineas in doctors' fees, I am informed that it is periosteal rheumatism, and all that was lastly prescribed was "Fredricshall" water, for generally improving the system. Being now on the verge of 50, I should feel grateful if any fellow-reader of "ours" could advise me as to its removal.—R. A. V.

[46766.]—**Lathe.**—What is the correct size of round belt to drive a 6in. treadle lathe? And what is the dimension of a triangular band? How is the latter sort joined? Is it advisable to make a good lathe having both the bearings of mandrel coned one way? Are any made so by good makers that do not jump? Also, should the nose be screwed with a finer pitch than Whitworth's standard? If so, what is the ratio to the above mentioned? Is 1⅛in. the proper dia. of mandrel and loosehead spindle for 6in. lathe? Is there anything to supersede the emery-wheels used with overhead that will not injure good tools?—INVINCIBLE.

[46767.]—**Repolishing Ebonised Piano.**—One of Neumeyer's highly-polished ebonised pianos having become dull and scratched, how can the original brilliancy be restored? Or what is best plan to adopt to give a less brilliant but more durable surface?—CHESTER.

[46768.]—**Surveying.**—Would a correspondent to the "E. M." kindly give an easy and graphic method of finding the true meridian, latitude, and longitude of any place? The aspirant to be possessed of a theodolite, chronometer, and star-map, but to have no knowledge of the country. The same inquirer would also like to be informed of the method of determining distances by aid of micrometer attachment to telescope of theodolite, and the maximum error per mile arising from its use? Also, a good maker to whom to apply for surveying instruments to be constructed with suggestions of improvements?—YOUNG ASPIRANT, Tasmania.

[46769.]—**Silvering Mirrors.**—In No. 878, Jan 20, 1882, a process is described of silvering large mirrors. I have tried the process twice with rather disappointing results. The mirror, although quite perfect in most parts, in others is streaky and covered here and there with blackish dots. I would be obliged to some subscriber for some further hints on the subject. Solutions of perfectly pure chemicals were made up in the proportions described, and the face of the mirror, 2½ft. by 2ft., made chemically clean by washing in nitric acid, then in caustic soda, and water ammonia was added to the silver solution till the turbid appearance first produced had quite cleared; the potash solution was then added, and ammonia again till the solution was clear. Then a weak solution of silver added drop by drop till the appearance was decidedly turbid again. I then dissolved the glucose separately, but while this was taking place a film of evidently reduced silver rose to the surface of the silver solution. The glucose was now added to first solution, and the whole well stirred and poured into a wooden box lined with guttapercha. The mirror was then carefully hung on the surface of solution with about ¼in. betwixt bottom of box and and face of glass. I may mention that just before the solutions were mixed warm water was dashed over the face of glass. The basin in which the two solutions were mixed had a beautiful coating of silver all over the sides and bottom, although the mixing would not take longer than ¼ of a minute. The solutions were made up with water at about 180° F. The mirror was allowed to remain about 30min. in solutions. By that time all the silver had been reduced.—SIGNED CHEMIST No. 50.

[46770.]—**Cold-air Motor.**—Could some kind reader give me a description of Giffard's cold-air motor. I should be much obliged for a rough sketch? I wish to make one, and intend making it like one I once saw, but I cannot say now whether it was a patent or not. It was in the way of a steam cylinder with perforated ends and a piston, and was driven by steam-power.—SUMMIT OF ENGLAND.

[46771.]—**Zincography.**—Information wanted as to zincographic process. The way I work it is this:—Clean sheet of roofing zinc with fine emery cloth, write on lithographic transfer paper with litho. writing-ink rubbed down in water. When dry lay transfer face down on zinc, damp back well and pass through press, damp again and take off paper. Then smear gum-water over zinc with camel-hair brush, and having got printer's ink prepared on roller, pass same lightly over zinc. I got this recipe from a scientific paper. Result: Printer's ink smears irregularly over zinc plate, and does not catch to the writing as it should. What is wrong? Should zinc be treated with acid to bring writing up in relief?—A CANADIAN SUBSCRIBER.

[46772.]—**Steam Launch.**—I am building a small launch 16ft. on water line, by 4ft. beam and 3ft. deep from keel to rail, and am fitting it with a single cylinder engine 3in.×4in. stroke, and balanced to run between 250 and 300 revolutions per minute. The boat will have fine lines, as it is intended only for river work. What propeller will probably give me the best results, what diameter, a fine or coarse pitch, and especially whether two or three bladed? My own impression is, that a two-bladed propeller at this number of revolutions is the best; but should like to have the experience of others. Further, would a boiler having 1¼ sq. ft. of grate-area, and a total of 10 sq. ft. of heating-surface give ample steam? What is the best speed I can expect from this machinery?—SCREW PROPELLER.

[46773.]—**Prince of Wales Harp.**—Could some of "ours" give me full instructions how to make the above? What are the kinds of woods most suitable, the kind of strings and cost of same, how they are tuned, and a few hints on playing? I should like, if possible, the exact dimensions of two sizes—the smallest useful size, and the largest? But if this is not to be had, anything on this subject will be thankfully received by—W. WORLEY.

[46774.]—**Bristol and Exeter Locos.**—Will "Clyde" kindly oblige with dimensions of any of the other classes of Bristol and Exeter engines?—those of the 9ft. singles having already appeared in Vols. XXV. and XXIX. (I think), and he having supplied those of Old 69 class. There are, I believe, some 6ft 6in. coupled, and some 7ft. 6in. singles.—CARSTAIRS.

[46775.]—**Staining Walls, and Plain Decoration.**—Would any of your readers give me the proper ingredients to mix to get the following colours for bedrooms and sitting-rooms:—The colouring matter to be made from dissolved lime, whiting, size, and the stuff to give the proper tint. The colours wanted being salmon colour, pale light blue, with a greenish shade. Where could I get stencil plates to make a border for top of wall and at bottom near skirting? Is there any cheap work on plain house-decorating?—F. J. C.

[46776.]—**New Form of Cheap Battery.**—Will Mr. Hawkins (19957) kindly give approximate cost of six cells as described above—*i.e.*, cost of six quart jars, six smaller ones and ingredients? If the Swan lamp referred to is the usual 20 candle-lamp or a smaller one? Mr. H. says the six cells will sustain a good light for over eight days. Will Mr. H. kindly say how many hours per day he has allowed for lamp-burning?—R. D. T.

[46777.]—**Timber Loading.**—Will some fellow-reader give me some information on the subject of timber loading, the best way of going about it, and if it would pay to use a crane on wheels? If it would do so, what is the best crane to get, and the price? Of course I mean when hauling a lot of timber from one place. Would a crab be of much use? I understand the common way of loading timber by means of skids and rollers; but this is a very slow and clumsy method, and knocks the horses about a great deal before they really commence their work of hauling. Would one of the patent blocks suspended to tree—timber always being put under tree—be of much use?—JUMBO.

[46778.]—**Spectral Photography.**—Will any of your readers kindly inform me what apparatus is required for photographing the spectra of metals, &c., and what is the kind of spectroscope suited for the purpose? Also, whether the same spectroscope and apparatus could be used on a 9¼in. reflecting telescope for stellar spectral photography?—CINQUANTA.

[46779.]—**Bleaching Cotton.**—How can I bleach small articles made of cotton? Have tried boiling in water with chloride of lime. The colour is good, but the articles feel harsh and smell of the chloride. I want the cotton to feel soft. DIX.

[46780.]—**Water-power.**—1. What power could be got from a body of water equal to the fill of a 10in. pipe, having 35ft. of a face, by using a "turbine wheel"? 2. What power could be had by using an overshot wheel from the same fall? 3. What would be the probable cost of each wheel and where could they be got?—QUEENSLAND.

[46781.]—**Music.**—What books are most suited to the requirements of the First Bachelor Music, London University?—PENURIA.

[46782.]—**Explosion in Firebox of Loco. Engine.**—To "SUNLIGHT," OR OTHERS.—A rather extraordinary affair has lately occurred in connection with a burst and plugged locomotive boiler-tube. As the occurrence was quite unexpected, and not capable of explanation on ordinary lines, perhaps after reading the narrative you will kindly favour me and others with your opinion on the subject. It is briefly as follows: A loco. engine burst a tube at a distance from stables, and had it plugged at the nearest shops. On arrival home, the boiler was emptied of steam and water, and immediately filled up with cold to cool, and after an interval emptied again. The boiler-maker then began to extract the plugs preparatory to drawing the tube. But it seems there had been a very heavy charge of "something" in the tube, for no sooner was the plug slightly loosened with the hammer than it blew out with a report like a musket, and the discharge, whatever it was, took effect in the man's face and hands. Eyes very severely inflamed from the effects, hands and face specked all over with little black particles driven into the skin. Altogether, he had a very narrow escape. Now the tube was empty when the plugs were inserted, no water could be in it, or very little, if at all. And in the latter case the heat remaining in boiler after being cooled would not, I should think, be sufficient to vapourise it. What do you think of this? Tube burst just inside tube-plate, firebox end.—SCOTUS.

[46783.]—**Battery for Continuous Current.**—Will someone kindly give me particulars of an inexpensive cell suitable for maintaining a current for about eight hours per diem through about 100 yards of wire in a closed circuit, and how often such a cell would require recharging? My object is, that on the circuit being broken at any point, an alarm shall be given by a Leclanché battery being brought into action through the release of an armature or some other convenient means. The strength of the continuous current need not, therefore, be great.—F. H. B.

[46784.]—**Bicycle Making.**—I should be glad if "Sunlight" will oblige me with a sketch of frame for drilling hubs for front and back wheel. I have a small upright drill with rising and falling table, 8in. in diam. takes in 6in. I have also a small lathe, 5in. centre, 2ft. 6in.×2¼in. V. and flat-bed, single-geared, no slide-rest. Will "Sunlight" also oblige by answering the following?—1. What will be the right width between hubs for 50in. machine? 2. Size of back wheel? 3. What rake to allow from centre of spindle to centre in neck?—E. STEVENSON, junr.

[46785.]—**Churn.**—Would some of the readers of the "E. M." tell me what is the best sort of churn for making a small quantity of butter at a time, say from 1lb. to 4lb.? I have heard of a small American box-churn being adapted—also the atmospheric churn; but I have seen neither. Probably there are other sorts which have superseded them in efficiency.—TOPY.

[46786.]—**Ventilating Weaving-Shed.**—We have a weaving-shed which is very hot in summer, and we cannot do with the ordinary ventilators, because it injures the yarn, owing to the drying of the size. What we want to know is, whether there are any means of lowering the temperature or heat of the room without causing a draught or making the room dry?—MANUFACTURER.

[46787.]—**Condenser.**—To T. N. ANDREWS, Plymouth.—Will this gentleman kindly inform me as to the size and number of sheets of tinfoil used in the construction of the condenser of the coil described by him in No. 885 of this paper?—B. B.

[46788.]—**Varnishes and Stains.**—Can any reader tell me of a varnish or polish for small turned work? A dark yellow preferred, to be applied whilst the work is in the lathe, and dry at once. The wood used is ash. Also, what coloured matter is used on soft wood and beech to imitate mahogany for door-knobs, &c.?—WOOD-TURNER.

[46789.]—**Screw-Steamer.**—I am making a model yacht to be propelled by a screw of 2½in. dia. with three blades. The boat is 22in. long, 4in. wide, 5in. deep, made of zinc. The engines are two in number, 1¼in. stroke, ½in. bore—double-action oscillating. The boiler is made of brass, well stayed, 6in. long, 2½in. dia., and can be pressed to 15lb. per sq. in. I shall esteem it a favour if any kind reader will inform me whether I am correct in making it to the above sizes, and also if the engines are large enough to travel at a good speed, and at what speed?—PROPELLER.

[46790.]—**"Stirling Castle."**—I shall be glad if any reader can give me dimensions of the engines as well as the size of the above-named ship, which left last month for China?—PROPELLER.

[46791.]—**"Sahara."**—The Cunard's largest, which, I believe, is being constructed for the Atlantic trade. Can any reader give the dimensions of her as well as the engines?—PROPELLER.

[46792.]—**Aquarium Front.**—What should be the thickness of a plate-glass front for an aquarium, 4ft. × 2ft. × 2ft., depth of water 1ft. 6in., stout wood back, sides and bottom. What pressure of water would be on the glass?—STICKLEBACK.

[46793.]—**Glueing Belt Splicings.**—Will any reader kindly tell me what sort of cement to use for cementing the splicings of belts before they are sewn, and in what way it is used?—G. H.

[46794.]—**Model Beam Engine.**—I am about to make a model beam-engine 2in. stroke. Will "Sunlight" or any other kind reader, tell me the best way to get the parts drawn to scale?—more particularly the beam, size, and weight.—AMATEUR.

[46795.]—**L. & N.W.R.**—Will some correspondent kindly give the exact distance of Rugby and Northampton from Euston by the new route?—LORD OF THE ISLES.

[46796.]—**The New Bee Motor.**—Can any reader give a section of the new motor above named?—AMATEUR ENGINE DRIVER.

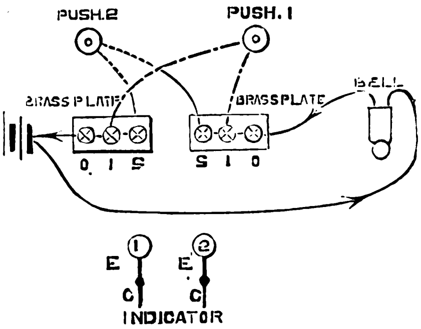
[46797.]—**Academy Boards.**—Are the Academy sketching-boards trustworthy for finished paintings on a small scale?—H. W.

[46798.]—**South African Railways.**—Could any reader of the "E. M." inform me how many miles of railway are in actual working order at the Cape at the present time? Also, how many miles are under construction, and the builders of their locomotive engines?—A DRIVER.

[46799.]—**North American Indians.**—Can any of your travelled correspondents give any information upon the Indians of North America, especially the tribes of the Apaches and Comanches? The latter tribe were stated about 30 years back to number about 100,000, and to live mainly upon the chase of the bison. Do they still inhabit Western Texas, or are they placed on reserves? And what is their means of subsistence now that the buffalo is extinct, at least, in that locality?—J. W. W.

[46800.]—**Engine Query.**—I am much obliged to "Labor Omnia Vincit" and "Sunlight" for their replies. The reason why I fear to apply high pressure to my engine is that there is a hole in one of the steam passages. It is stopped by soldering a plate over it and secured by screws. I think it would be quite safe at 20lb. pressure. I have not room for any but a vertical boiler.—ELEPHANT BILL.

[46801.]—**Sub-Circuit to Indicator.**—I have fitted up an arrangement as shown in diagram (where only two room connections are shown for simplicity) for making one bell serve for 12 different circuits. I now desire to arrange a sub-circuit from each room, wire to an indicator to show which room has signalled, but am at a loss how to do so, as it appears to me that one room push will throw all the sub-circuits into electric activity. Full lines on figure indicate part of circuit common to all rooms. Dot and dash line, room No. 1; dotted line, No. 2. Wanted description of connections to E, E', &c.?—BOB.



[46802.]—**Early Rising.**—Some time ago you had some ingenious ideas for getting up of a morning, but they all failed in one respect—viz., the noise comes to an end, and with me such would have no effect, as I should simply wake up, open an eye, listen to it; when over, go to sleep again. So I had an electric bell fitted up over my head. Push outside the door. When the push is applied it keeps on until I get out of bed, open the door, and take it off. It answers beautifully with one exception—I have no reliance that the push will be applied. Now would the following do?—A clock with a weight to it, underneath the weight lay the push-flat, so that the weight would ultimately rest on the push and keep the electric bell going until relieved. Say an alarm clock, so that the alarm weight set the bell going. Could not I have two sets of wires—one for the door, and one for the clock? I should be glad if someone with necessary apparatus could try it and gives details of same, or better invention?—JOHN ALEX. OLLARD, F.R.M.S., Enfield.

[46803.]—**Movable Bookshelves.**—Can any reader suggest a convenient form for such, readily removed from one house or part of a house to another? —B.

[46804.]—**Furniture Cleaning.**—I am asked "how to get off all that nasty black and rough stuff which oozes out of furniture (walnut especially) without injuring the French polish on the articles?" Brandy and spirits of wine have been tried without success. Can any reader assist?—B.

[46805.]—**G.E.R. Locomotives.**—Will someone give dimensions of the new six-coupled goods engines just out, designed by Mr. Bromley, and built by Kitson and Co.? I hear that they can take 50 loaded trucks of coal from March to Stratford—is this correct? Also, are the four-coupled engines, with inside cylinders, now in course of construction, being built at Stratford?—G. C. M. HALL, Colchester.

[46806.]—**Mounting Plate Machine.**—I have a plate 18in. diam., and wish to mount it as a Winter's or any other type of machine. Will Mr. Lancester, or any other kind reader, help me with a working diagram and instructions?—A BEGINNER.

[46807.]—**Royal Engineer's Department.**—Will "Unfortunate" kindly inform me if we may take two subjects in part (*a*) (*b*) (*c*)—viz., architectural drawing, &c., preparation of working drawings, or must we confine ourselves to one?—STARTER.

[46808.]—**To Mr. Evans.**—Would Mr. Evans be kind enough to fulfil his promise of giving a description of the compensating index for the oval chuck, a drawing to scale for, say, a 5in. centre lathe, and a separate drawing or two of any complicated part would, I think, enable anyone to try their hands at making one for themselves.—THOMAS S OW.

[46809.]—**Restoring Leather Bag.**—A deep red (nearly black) leather courier bag has become faded and spoiled by wear and damp. How can the bag be made to look less shabby?—M. C. H.

[46810.]—**Inhabited House Duty.**—Will Mr. Wetherfield kindly say, from the following, whether I must pay the above duty or can I claim exemption?—A house let weekly, gross annual rent £23 8s.; total amount of rates and taxes all paid by the landlord, £3 8s. 10½d.—LANDLORD.

[46811.]—**Revarnishing Dog-Cart.**—I wish to revarnish my dog-cart. How am I to proceed? What ought I to use for the woodwork, which is of a light colour, and how is the black varnish prepared that is used for the iron parts?—J. B.

[46812.]—**Ethoxo Limelight.**—I have made a hydrogen generator on the wash-bottle principle, but it does not saturate the oxygen with sufficient ether vapour. Could any reader inform me of a better principle? and oblige—ENGINEER.

[46813.]—**Dry-Rot.**—This has made its appearance in the framework of a cellar window. Is there any means of preventing its spread? I have given the frame a coating of red paint.—R. N. H.

[46814.]—**Caledonian Engines.**—Will "Carstairs" please give the date of the Cal. tank engines with outside cylinders and three axles, but running on four wheels, 4ft. 7in. diam. Had they saddle-tanks, and are they still working? Also, date of six-coupled outside cylinder goods? In each case, the earliest.—R. N. H.

[46815.]—**Paste for Pottery Transfers.**—Will any reader kindly inform me how to make paste for use with the tissue paper tranfers for pottery? I have been making it with flour and water, but it gets stale in a few days, and the print will not leave the paper well.—LITHO.

[46816.]—**Sulphate of Baryta in Glue-making.**—Can any reader tell me what use is made of the above? —CIVIS.

[46817.]—**Griscom's Electro-motor.**—Will some reader kindly give description, dimensions, and rough drawing of Griscom's electro-motor? Also, how to alter it so as to make it a dynamo machine?—A. E. HARRIS.

[46818.]—**Putting Chain in Watch.**—Will "A Fellow-Workman" tell me how to put the chain on in a watch? I have the other parts together, but don't know how to put chain on.—ONE LEG.

[46819.]—**Telescope.**—Why are not telescopes made with concave eyelenses, by which the image would be seen erect and the definition would be improved?—AQUA FORTIS.

[46820.]—**Piston Ring.**—Would "Sunlight," or others, tell me how to straighten a large brass piston-ring? It is twisted after hammering to make it spring. —R. Q.

[46821.]—**Clause in a Testator's Will.**—To MR. WETHERFIELD.—I give and bequeath to my said executors the sum of five hundred pounds, in trust to invest in their names, in Government securities or railway debentures, stock, and to pay the interest arising therefrom as soon as it shall be received by them, to my four cousins, A, B, C, and D, during their lives, in equal parts, and as each of my four cousins departs this life, I direct that one-fourth part of the said sum of five hundred pounds be divided equally and amongst the eight children of my brothers, W and J. One of the cousins is now dead, and the stock invested is much increased in value—whether does this increase be added to the eight children's share, or does it properly belong to the residuary legatees? Your opinion will greatly oblige—T. A.

[46822.]—**An Unpredicted Occultation.**—While examining Plato on the evening of 26th April, I observed the Moon approaching a sixth magnitude star, and on consulting the *Nautical Almanac* could find no mention of any occultation on that evening. I watched the star till it was occulted. The disappearance, which was instantaneous, took place at 10.54 mean time. I could find no star on my map corresponding to the exact position of the one occulted, the nearest being 9 Sextantis, and I should be obliged if "F.R.A.S." would kindly tell me whether this was the star or not.—ALCOR.

[46823.]—**To "A Fellow-Workman."**—Will "F. M." kindly inform me which is the most satisfactory way of weakening a powerful hairspring; it is a verge, and, though I have a pretty good stock of new ones, I can't find one the right strength. A sketch, with explanation will greatly oblige me. I am very much obliged to "A Fellow-Workman," also to "Alfojoe." I believe that all the watch-jobbing readers of the "E. M." thoroughly appreciate them both.—TED ARTHUR.

[46824.]—**Watch.**—Will "Fellow-Workman" or any other obliging correspondent instruct me how to fasten a flat crystal glass to a Geneva watch, which at present has an ordinary thin one.—G. FRYER.

[46825.]—**Electric Bell-ringing by Cylinder-machine.**—Will Mr. Lancaster please tell me if a 6in. cylinder electrical machine would produce enough electricity to ring a small electric bell at a short range of wire; if not, would he be so kind as to tell me how to construct a small machine (not very expensive) to do the work?—AN ESSEX BEGINNER.

[46826.]—**Dulling Brass.**—Will any reader kindly inform me what substance will give brass a permanent dull bronze colour, or a colour similar to that given to fishing reels which are made of brass? I want it for a landing net, the metallic parts of which are very bright. —FISHERMAN.

[46827.]—**Boiler Capacity.**—I shall be glad if any of your kind readers can tell me how to find the size of steam boilers of different horse-powers. I have seen in Molesworth's book, page 299, that 1 cube yard or 27 cubic feet is required for each horse-power, but the sizes given for boilers from 1 to 35 horse-power, on page 300, do not work according to this rule—e.g., Cornish boiler, 10 h.p.; should be 27ft. by 10 equal to 270 cubic feet. Now the size given for this is 16ft. long by 4ft. 6in. diam., which, deducting the flue, 2ft. diam., equals 204ft. only, and in vertical boilers there is less capacity still, so that I am in a fog how to make out which is right.—J. H.

[46828.]—**Guerin Brake.**—Will one of your readers give me the details of the Guerin brake, tried some years ago and reported on by Col. Yolland; also of a brake said to have been invented by a Mr. Robbins, and used for a little time upon the South Western line? Was Mr. McConnell the first gentleman to fit steam-brakes to engines and tenders? I should also like to know the construction of the Great Western vacuum brake. Unlike other systems the cylinder appears to move and the piston-rod to remain fixed.—A DRIVER.

[46829.]—**G.N.R. Slide-Valves.**—What lap and lead has the slide-valve of the G.N.R. passenger and goods engines? Has the goods engine any inside lap?—R. Q.

[46830.]—**Spring Pins.**—What is the best way to get the length of spring-pins?—R. Q.

[46831.]—**Photographic.**—Would any reader oblige with instructions for making a retouching desk for retouching negatives? and oblige—COLLODION.

[46832.]—**Value of Lease.**—Will some of your readers kindly oblige me, if convenient, what is the present value to sell of a lease £260 annual value, fixed for 18 years, safely secured? You will grant a favour to an old reader.—FARMER.

[46833.]—**Bumping Noise in Engine.**—Would "Sunlight" kindly tell me the cause of the bumping noise in my engine at the end of each stroke? It is a new one, six horse-power, but has never worked well from the first. It has been taken to pieces once, and fitted with new brasses in the main shaft, but it did not stop the noise altogether, and now it is as bad as ever, although the brasses are all tight without the least shake. I fancy the fault lies in the main shaft or else in the crank-pin. But I don't know how to prove it or to correct it.—ONE IN A FIX.

[46834.]—**Churchwardens.**—To MR. WETHERFIELD.—Has any alteration been made in the law of voting in the election of churchwardens since the year 1818? What is now the qualification for voting?—J. K.

[46835.]—**G.N.R. Engines.**—Would some of the readers of the "E. M." kindly oblige by giving general dimensions of the G.N. bogie that now takes Scotch mail? To the best of my belief, it runs only as far as Grantham and leaves King's Cross somewhere about 10 a.m. Are these engines generally liked, what brake is used, what rate per hour are they permitted to travel?—H. N.

[46836.]—**Chloride of Silver Cell.**—I have made a cell as follows:—A plate of zinc 3in. by ¾in., and a silver plate same size, the latter coated with fused chloride of silver, separated by a strip of stout blotting-paper saturated with a solution of chloride of zinc. Cannot get sufficient current to work a miniature coil, though a bichromate of above size does so powerfully. Am I expecting too much from so small a cell of the De la Rue type? Primary of coil is No. 22 B. W. G.—TOLEDO.

[46837.]—**Electro-Magnets, &c.**—Will an electrical correspondent kindly inform me what rules should be observed in working the above in order to insure the battery-power being properly proportioned to the requirement? I have heard that the magnets should be wound with wire offering a resistance equal to that of the line wire, and that the combined internal resistance of the cells in series should equal the resistance of the external circuit. Is that correct? If so, what is the internal resistance in ohms of a Daniell, Fuller, and Leclanché?—TOLEDO.

[46838.]—**Chuck.**—If it is not abusing "F. W. G.'s" kindness, he would confer a great favour by describing a good 4 independent jaws chuck, suitable for a 4in. centre lathe, and if accompanied by illustrations as good as those in his description of backstays in your last number, it would be of great advantage, I have no doubt, to many readers of the "E.M." who, like myself, are troubled with more ambition than money.—CHUCK.

[46839.]—**To Mr. Wetherfield.**—A. obtains goods, oilcake, &c., of two persons, B. and C. respectively, and consumes them upon a farm he rents. A. goes to America leaving the debts due to B. and C. unpaid. D., the father, puts an auctioneer in and sells the stock, &c. (cattle, implements, &c.), for rent and money lent. The auctioneer realises £300 more than the amount of rent and money lent claimed by D., who, however, takes the £300. When D. is asked to pay the debts due to B. and C., D. deputes a son, E., to tell or promise B. and C. verbally that if they will kindly wait a little B. and C. shall be paid. In the meantime D., the father, dies, and now the son E. refuses to execute D. the father's promise, and says neither he nor his father can be called upon to pay. By means of the auctioneer it can be proved that the father received £300 more than he was entitled to. What course ought to be taken by B. and C. to recover the payment of their debts? —NA F.

[46840.]—**Organ Reeds.**—I should be very much obliged to Mr. Dresser for a few practical hints on the treatment of organ reeds. I am quite sure that practice and skill are both required—but the practice I mean to have, and some skill I hope to get. An organ builder's help is a luxury that I am seldom able to indulge in; I wish I was. Meanwhile, I must try to do the best I can. My difficulties are: (*a*) a stoppage altogether, (*b*) a coarse grunting sound, (*c*) slowness of speech, (*d*) the tone as it gets near its pitch decreases in quantity and finally goes off altogether, (*e*) or else becomes horny and loses the peculiarity of a reed. Now who will throw some light on the mysterious subject, so that I may be no longer at my—WITS' END?

[46841.]—**Vacuum Pump.**—In No. 886, page 34, of the "E. M." is described a vacuum pump by Mr. Sutton. I have been trying some experiments with one made from that description, but with a reservoir of mercury raised by a pulley, instead of the pump that Mr. Sutton recommends, as I find it (the pump) would be very expensive to make. I find that when you once fill the bulb A with mercury, and empty it, you cannot get any further vacuum, on account of the vacuum in G sucking up the mercury in F; so that before you can get sufficient pressure of mercury in A to force the second quantity of air in it out through J, the mercury flows over into G. It seems to me that F should be at least 30in. high to prevent this. I may say I used a barometer-tube connected at I, and I got, by once filling and emptying A, a column of mercury of between 28in. and 29in. high. I shall be glad if any kind reader of the "E. M." can give me any advice as to where I may be wrong in using the pump.—J. R. EDDINGTON.

[46842.]—**Estimation of Tannin.**—Is there any other method than the tartar emetic and gelatine processes for estimating the quantity of available tannin in different substances; I have worked the gelatine process, but have invariably failed to arrive at an accurate estimate, and I find it difficult to obtain tartar emetic.—PRO BONO PUBLICO.

[46843.]—**Gas Inspectors.**—Could any of your correspondents inform me to whom to apply, or what steps to take to be appointed a gas-meter-inspector for a district? All gas-meters, when made, must be tested and stamped by an authorised inspector before being sold; also, all meters taken to pieces for repairs must be duly stamped afterwards before being used. Now, it is common in the district in which I reside for the gas-companies to repair their own meters, and then put them into use without being tested and stamped, as the carriage to and from the nearest inspector would be a very large item; the distance, I believe, is from 60 to 70 miles. The consumer, in this case, has no guarantee that the meter is correct.—GAS-METER.

[46844.]—**Clock.**—I have a very good clock beating and indicating seconds; but the minute-hand is rather loose, so that, though from 12 to 6 it indicates correctly with the seconds-hand, yet from 6 to 12 it is half a minute behind the time indicated by the seconds-hand. What can I do to remedy this, so that all round the twelve hours the minute-hand will indicate what the seconds-hand does, and advance with every beat of the pendulum. —WISEAF.

[46845.]—**To Mr. Davies.**—Will you kindly inform the musical part of the readers of the "E. M." the proper way to tune a piano? I have an old one I want to tune. I've put several new wires, which do very well; but what I want to know is this—which is the proper way to begin, from middle C or, as some say, tune from both ends to the middle? An answer to this, I think, will oblige more than one reader of the "E. M."—TED ARTHUR.

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden, London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade; to write to the Editor if he has any suggestions to make and to advertise in the paper when he wants work.

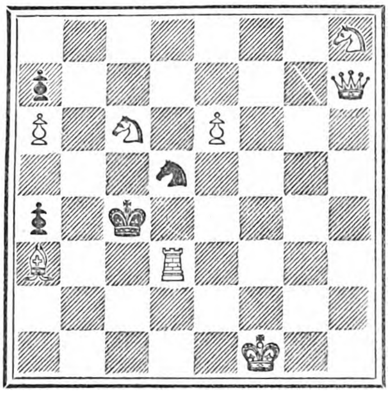
The charge for Advertisements for Situations is One Shilling for Twenty Words, and Sixpence for every Eight Words after.

CHESS.

All Communications for this department must be addressed to the Chess Editor, at the office of the English Mechanic, 31, Tavistock-street, Covent-garden, W.C.

PROBLEM DCCXLIII.—By J. A. Miles.

Black.



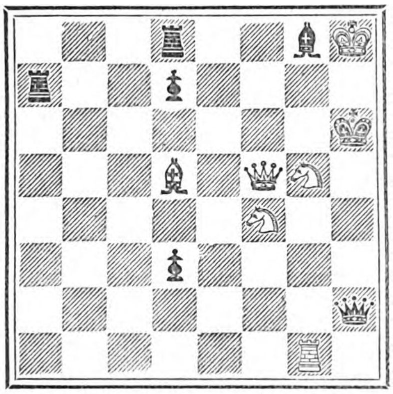
White.

White to play and mate in three moves.

PROBLEM DCCXLIV.—By W. A. Shinkman.

From *Brentano's Chess Monthly.*

Black.



White.

White to play and sui-mate in two moves.

Solution to 740.

White.	*Black.*
1. R takes P at Q 6	1. Kt takes R.
2. Kt to Q Kt 6.	2. Anything.
3. Mates accordingly.	
	1. Q Kt moves.
2. R takes Kt.	2. Anything.
3. B or R mates.	

NOTICES TO CORRESPONDENTS.

Problems received with thanks from J. A. Miles, H. J. C. Andrews, Sergt.-Major McArthur, C. R. Baxter, J. P. Taylor, and H. F. L. Meyer.

We have pleasure in drawing attention to the new edition of the "Chess Club Directory," just published. The thanks of the Chess world are due to Mr. Bland and his coadjutors for their zeal and ability in producing a work so needful and interesting. We have first a paper by the editor, giving a brief account of the principal matches in 1881. This is followed by an admirable paper by Mr. Potter, on the principles involved in successful play. Suggestive remarks succeed, by Mr. Andrews, on Problem Tourney Codes and Regulations. Mr. W. T. Pierce returns again to his favourite subject, "The A 1 Notation." His arguments are unanswerable; but, we fear, not convincing. Mr. Thompson once more waxes eloquent on Pawn on 8 in Chess Problems. There are also some lighter and amusing papers, and some capital verses by Messrs. T. P. Taylor and J. G. Cunningham. The list of Chess Clubs and resorts in England and Wales is very complete, and will, no doubt, be found exceedingly useful. In addition to all this, we have the Prize Problems in British Tourneys in 1881, and the laws of the game as established at the International Chess Congress, 1862 (has not the time arrived when these should be revised ?). The work is, therefore, of considerable value, and ought to become an annual; and thus a Chess landmark from several points of view. If we have any improvement to suggest, it is that a few more problems by leading composers might have been published with advantage. Also, some of the most notable games of the year. We are sure that no lovers of Chess would grudge the slight increase in price that this might have entailed.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or requies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, May 3, and unacknowledged elsewhere :—

P. Argall.—W. H. Harling.—W. A. Smith.—F. W. Reynolds and Co.—E. S. Hindley.—J. L. Gallard.—C. Nickalls.—W. Kitney.—Morris Cohen.—Jas. Roberts. —O. S.—Rev. T. Calliphronas.—Farquhar.—Railway Fireman.—Thirds' Practical Watchmaker.—A. H. B.—Darkness.—Young Wheelwright.—J. L. Davies.—Volvox.—Cumberland.—W. B. A.—A. Rigg.—Perplexed. —J. R.—Brickwall.—Blackwater.—F. G. du Pont.—H. Nolan.—Namdrah.—Anxious to Get On.—The Gas Man.—Kingsmill.—Poor Quill Driver.—E.—Orderic Vital.—Glow Worm.—Hugh Tunnadine.—Dispart.—Jas. Parkinson.—Collodion.—H. M.—Yoshi.—Fellow Workman.—An Old Subscriber.—J. T. M.—Gelatino Bromide.—Inquirer.—Krautbach.—F. W. G.—Foundry.—J. H. Huxley.

W. H. Skelton. (Are you not rather hard to please? So long ago as April 14 we indicated the course of comet *a*, and on April 7 our correspondent, the "Fellow of the Royal Astronomical Society," actually placed it, so that a little sweeping on any subsequent night would readily lead to its finding. However, as you appear to want the position assigned by the latest calculation, it is May 6, G. midnight, R.A. 21h. 59m., N.D. 73° 9′. Any other particulars of importance we may receive will be found in "Scientific News.")—Housewife. (Many remedies have been suggested in back volumes, but the best appear to be a hedgehog, and powdered borax mixed with sugar and bran.)—R. Dale. (We do not understand your difficulty. The scheme of tuning has been given many times, as well as the actual manipulation required.)—H. W. (A Swan lamp with sufficient current to keep it incandescent would do for the purpose; but we are afraid those to which you refer would not give light enough.)—J. T. Ingham. (The cause is clearly a radical defect of the instrument, and a practical man must be called in to examine it, as it is impossible to say whether it can or cannot be improved from a mere description.)—G. B. Taylor. (No, certainly not. You should study first principles.)—Swan. (It would be absurd to put such a question to Dr. Edmunds. They are known as *muscæ volitantes*, and are of no moment.)—Brakeblock. (The pressure on the drums of vacuum brakes cannot exceed 14lb. per square inch, and it is extremely doubtful if such a pressure as that can be obtained. Where do you find the statement that it is 30lb. per square inch ! 2. They are joined by an "extension" line between Bishop's-road and Gloucester road stations. 3. Practically identical. All the companies north of the Thames, we believe, except the North London, and that is practically connected by the North-Western. Such a question can be answered by reference to the time-tables.)—C. S. Cannell. (It will be time enough to publish the sketches and description when the machine has been made and found an improvement.)—W. G. E. (Change of air is the best remedy. Simple antimonial mixtures are preferable to the honey, vinegar, &c. If the cases are very severe, you should call in a medical man to *see* the patients.)—Douglas. (You could use the pipes as return, but not as line. See many places in back numbers.)—Teddy. (No cement; could be brazed, for which, see indices under head Soldering, and recent numbers; but it is a difficult job, and you would act wisely by getting it done by a skilled hand.)—Dry Plate. (See p. 124, No. 890.)—W. W. Jones. (Mitchell's "Manual of Practical Assaying," edited by Crookes, Longmans and Co., contains methods, but perhaps Bauerman's "Metallurgy of Iron," Lockwood and Co., will answer your purpose. A great deal of information on the subject can be found in back volumes.)—Pro Bono Publico. (There is Napier's "Manual of Dyeing and Dyeing Receipts," published by Griffin, and Crookes's "Dyeing and Calico Printing," Longmans, both of which are "illustrated" with specimens of dyed fabrics.)—P. Ingle. (The use of the acetic acid will do no harm, and very little good. A medical man would probably recommend cod-liver oil.)—Isle of Wight. (You are not entitled to any compensation under the circumstances.)—W. H. (1. Unsuitable; it cracks. 2. Do you mean *income* tax ? If so, No. 3. It is impossible for us to say if the assignment of H.'s policy was legally effected; but if it was C. is entitled to the amount insured for. Better show the document to a respectable solicitor.)—W. S. F. (Thanks for your kind offer of the photograph, but we fear we could not spare the space. Thanks also for congratulations. While "ours" retains good friends like yourself, its continued and increased success is assured.)—B. M. (We do not think Sir Edmund Beckett supposed his idea would much help people who use worn-out screws and badly-shaped screwdrivers; but with good tools and screws the inconvenience complained of occurs, and might, we think, often be obviated by the adoption of Sir Edmund Beckett's contrivance.)—K. Y. (If the "child" is 26 years of age, we do not see why her mother, or any one else, need be under any anxiety on her account, unless, of course, she is imbecile, in which case, if the matter was properly seen to, her maintenance would devolve on the person who adopted her.)—Alexander. (Directions for making blacking, soap, &c., have been repeatedly given in back vols.; but we do not think you can hope profitably to make and sell small quantities of such things in competition with the great houses that cover the field.)—A Two Years' Subscriber. (558 can be had post free for five halfpenny stamps; 565 is out of print.)—A Subscriber from the 10th Volume. (If the widower of the intestate's daughter is entitled to his deceased wife's property, of course the administrator of the estate now in course of administration is justified in including him. If the property is personal, no one can hinder the husband from disposing of it as he thinks fit, unless he was merely appointed trustee of his deceased wife's property for the benefit of their children)—F. Rowe. (If you refer to p. 178 you will find that Mr. Lancaster has injured his hand, and finds a difficulty in writing. No doubt he will redeem his promise as to the medical coil as soon as possible.)—Bullock. (You mean a magneto-electric machine, we imagine. See p. 470, No. 826, and look again under that head.)—Ovin. (There are no text-books which give detailed instructions; but in Nos. 517, 525, 533, 551, 573, you will find information that will help you.)—Lo Ko. (Try gymnastic exercises. No other safe way.)—A Country Watch Jobber. (If you are wise you will do nothing except on the advice of a medical man, for the most important thing is to find out what is the matter.)—Esimus. (Immaterial—half inch inside good size for the mercury tube. 2. No, the platinum becomes at its brightest just as it reaches fusing point. The carbon gives much the better light. 3. We really do not know. They are not suited to the work, and no electrician would think of using them for the purpose.)—Collodion. (There is no difference, for there is no such substance. Hyposulphite of soda is the common name for sodic thiosulphate. There is sodic sulphite and sodic sulphate, and you have probably confused the "chemist." Hyposulphite of soda is the commercial name of the salt you require.)—J. J. V. (We do not know the exact method adopted, but there is nothing new in the arrangement. Reeds were arranged vertically in American organs years ago by English builders, and they are placed in all sorts of positions by American builders.)—G. Fryer. (See "Joiner's" letter next week. You say there is an objection: two correspondents say there is not. Leave the matter now to the judgment of our readers.)—A. C. H. (It cannot be done as specified. The best way is to have a cistern raised some feet above the aquarium.)—Miner. (You require a battery, and you will be able to judge whether you can make one by referring to back numbers. See "Replies.")—Young Engineer. (All particulars of Whitworth's Scholarships are given in the "Whitworth Prospectus,' to be obtained from the Secretary, Science and Art Department, South Kensington.)—F. L. (It depends on the size of the machine and the energy put into it. In all probability, it is of use only for furnishing current for medical purposes, or for the usual experiments.)—David. (See p. 176, last paragraph.)—X. Y. Z. (See p. 431, No. 876.)—Tomtit. (For electric bells, kindly look through the last volume. You will find a new door-contact on p. 617, No. 884. Leclanché cells, or the tinpot battery recently described.)—Pongo. (Will not the clock described on p. 112, No. 785, suit? See the indices to Vols. XXX., XXXI., under heads Gravity Escapement and Clocks.) —Cat's Tail. (See p. 77, No. 705. Yes, a Leclanché.) —An Amateur Electrician, Dublin. (Yes, quarterly, 2s. 9d. 1. Drawings have been given in several serials and in some of the books. 2. Two at least. 3. We suppose, in the absence of the context, that it formed the negative plate of the battery. 4. We do not know. They are scarcely suited for arc lights. 5. About three-quarters of an inch, but there is nothing of the kind.) —Trydau. (As far as the, production of current is concerned, the crack would have no effect; but we should not like to be in the line of flight when you set your machine at work. Have you forgotten that it must revolve at a high speed, and that a crack, however slight, would be sufficient to condemn the casting ?)—A. H. Metz. (See p. 77. No. 705. You have merely to divide the alphabet between two needles. Yes, such a battery would do. Gas-carbon or coke, not charcoal. Use copper-wire, unless your line will be very long.)—Dolomite. (They would act correctly for a short time, but if the air could gain admission, the watery vapour would be condensed, and dust would find its way in. That is why the tubes are closed.)—J. S. (You can tin them by first washing with acid, rinsing in water, and turning into a pot containing cream of tartar, grain tin, and boiling water, but preferably by dipping them into melted tin, or if galvanised, into melted zinc. The baths of molten metal should be covered with sal ammoniac, and the nails be placed on a sort of sieve for dipping.)—Anti. (What is it you mean ? If a clock-work train for paying out magnesium ribbon as fast as it burns, you can easily make one from a cheap American clock.)—H. A. (If you cannot refer to our back volumes, procure Graham's lectures on Breadmaking, 1s., of the Society of Arts.)—W. J. P. (See p. 100, No. 836. You can go as third or fourth, as soon as you can get a berth; but you will find some difficulty in that. The only way to put in the twelve months is to apply to the master or owners of a steam-vessel.)—F. B. (Is it too much trouble for you to refer to a dictionary ? As all such solutions depend for their action on the salt, not on the water—as much as the water will dissolve is put in—that is, they are "saturated" solutions. About 4oz. will be required, depending to a certain extent on the purity of the salt.)—Dav. Stewart. (See p. 81, number for March 31 last. We remember nothing else, and doubt whether the process is of much practical use.)—W. Blow. (They are constructed in the usual way, but are, of course, very small. The second query is too indefinite. Several have been given in back numbers, many of which can be had.)—Bull-dog. (Procure a tube of moist water-colour lampblack, and thin with weak solution of gum-arabic.)—

FRIDAY, MAY 12, 1882.

LIGHTNING AND LIGHTNING CONDUCTORS.*

THE best method of protecting buildings from injury by lightning has been debated for years, but latterly a general consent has been given to the plan which provides a rod with points at the highest part, connects it with all the available metal-work of the roof, and then makes as perfect an electrical connection with the earth as is possible. Scarcely four months have passed since the issue of the report of the Lightning-rod Conference (see p. 441, Vol. XXXIV.), and we have the author of the first-mentioned work in the foot-note practically condemning the conclusions arrived at by the representative men who took part in the Conference. Major Parnell's book, apart from his hypothesis, will, however, be of use, as he has taken the trouble to collect a number of facts in reference to accidents from lightning without considering whether or not they support his views. The first part is a compilation of recorded facts and opinions, some of which are arranged in too unconnected a manner to be of any use; part the second is a superstructure of theory erected on the facts from the author's point of view, and the third part contains the author's recommendations. There is one advantage in reading Major Parnell's book, that when he comes to build up his theory he refers to the actual words of the authorities on which he bases his arguments, though it is awkward sometimes for the reader to be compelled to refer to the extract in order to arrive at Major Parnell's meaning. His case against lightning-rods is set out with some skill, though too much is made of points which have nothing to do with the question of the conductor itself; but his view may be gathered from the following passage:—"The advantages afforded by a lightning-rod appear to be summed up in the fact that, if it be in good condition, it tends by means of its point to furnish an outlet for any charge that may collect at the particular parts of the ground in contact with its root." Holding that view, he naturally considers that it is bad practice to lead the earth end of a rod away from the walls of a building, even when the object to be gained is a good connection with moist earth; for ordinary ground (moist earth) is not an accumulator of electricity like metal, and a rod so rooted taps a considerable extent of ground which has nothing to do with the protection of the building. The principal disadvantages appertaining to lightning conductors he enumerates thus: (1) The exposure of elevated metallic surface furnished by them; (2) their costliness; (3) the sources of failure to which, after erection, they are liable; (4) their tendency to disfigure the appearance of buildings. The last two "disadvantages" are both within control; cost is not an important factor, but it is essential to ascertain whether there is any disadvantage in exposing a metal rod capped with points which may be assumed to attract electricity from the clouds. Major Parnell holds that when a rod is well connected to the ground it constitutes a local plate, and the exposure of elevated metal must always be a great disadvantage, for it is impossible to estimate whether its tapping powers are on a par with its accumulative properties. In ground at no great distance from the rod a charge may accumulate, when the rod, owing to its metallic substance, extent, and elevation, becomes liable to be embraced in the explosion's line of least restraint. Thus, although itself a local plate, the rod accidentally acts as a local dielectric to the adjacent charged ground to which it is not connected, and instead of protecting the building positively attracts danger to it. The connecting of rods to water and gas mains is held to be simply giving them an additional outlet for the electricity tapped by them, and the building against which a rod so rooted is fixed is more exposed to injury than others; further, Major Parnell also holds that rods with roots laid in rivers, in wells, in moisture of any kind not immediately contiguous to the structure, are sources of danger to it, as the building thus "protected" is merely being utilised to tap the electricity of the water or moisture. Having demolished the rod by attacking its principle, it is only slaying the slain to attack the present system by pointing out the "disadvantage" of using copper, of the "expensive points," of the extension of the roots in the search for moist earth, and the risks run by the faults due to bad design and bad workmanship. The fact that the author does attack the details would appear to indicate that he has a lingering doubt as to the justice of his condemnation. The true function of lightning-rods is to prevent the building being struck, by presenting an easier path for the electricity; Major Parnell contends that their true function is to prevent explosions occurring at all, and he accordingly dispenses with the long stalk, which he holds causes the explosion, and adopts iron plates buried beneath the surface contiguous to the walls of the building, with points or short rods projecting about six inches above the surface of the ground. The instances recorded by Major Parnell in his table he afterwards groups, and in the fairest manner sets out those which tell against his view as well as those which apparently support him. In studying this question, it is obvious that a list of buildings to which lightning-rods have been fixed, and which have altogether escaped being struck, cannot be accepted as evidence, for it is impossible to prove that the buildings would have been struck if the rods had not been there. The most valuable cases are those in which buildings once struck have enjoyed a subsequent immunity after a rod has been fixed; for in them it is clear there is the liability to be struck. More important still are those cases in which buildings to which rods have been affixed have been struck more frequently since they were "protected"—though in those it is possible to imagine the rods were not in good order. It may be that the rods at the cathedral at Alatri, in Italy, were not of proper dimensions; but the fact is, that although the building has not been damaged, the rods have been struck five times in eight years; and in 1872, the water-pipes supplying the town, which passed about 11 yards from the earth-connections, were broken. The earth-connections, in this case, were 13ft. long, with points and copper wire twisted among them, the whole being buried in cinders. The cathedral stands on high ground, a solid calcareous rock being found a short depth beneath the surface. Father Secchi gave a description of this case, and attributed the failure of the rods to harmlessly discharge the electricity to defective earth-connection. In this case, however, it can scarcely be said that the rods attracted the lightning, as the cathedral had been frequently struck before, and that was the reason Father Secchi suggested the erection of the conductors. A clearer case is that of the Sorbonne, which was struck in September, 1880, shortly after the rods were erected, though it had never, so far as is known, been previously struck. As before, it was the rod that was struck, two out of six stems receiving the flash. In this instance, the main stalk was a rod of iron less than 6-10in. square, led into a pit at a great distance from the buildings. Here, it may be said, as is undoubtedly the case, that the rod was too small in sectional area, but it would also appear to be an instance of a rod attracting the lightning. The cathedral of Sienna, in Italy, although repeatedly damaged before the erection of the rod, has enjoyed immunity ever since. A similar history belongs to St. Mark's, Venice, which, prior to 1766, had been frequently struck and damaged. In that year a conductor was erected, and the building has not been struck since. Similar instances are on record; so that while it is clear rods do protect, and have protected, in certain cases, it is needful to inquire how they were erected before condemning them in those cases in which they failed in their mission. Major Parnell concludes that lightning-rods, owing to their roots and points, have a tendency to protect the constructions to which they are affixed, especially ships; but that owing to their stalks they have a tendency to injure constructions, and have frequently done so. To this last statement it will probably be replied—only when the conductor was not of a suitable kind, and was improperly erected. Major Parnell's work would have been incomplete without the practical measures he advocates; but we suspect that architects will pay little attention to directions which involve the abolition of all metalwork on the outside of their buildings, except near the ground, and which include the disuse of wooden roof coverings.

Amongst the means suggested by Major Parnell for avoiding lightning strokes, is the use of grates on the ground-floors of country houses, with wide vertical horns to sink into the soil, and numerous ornamental pointed projections on any portion above ground. His principal idea, however, is the use of the electric tap, instead of the conductor, which is formed of plates of iron, each ¼in. thick, 4ft. long by 6in. wide. Into that, 1in. from the edge, are to be riveted two wrought-iron rods ⅜in. in diameter, sharply pointed, and 12in. long. These plates are to be laid flat, at a depth of 6in. around the building, with one edge touching the wall, if possible, thus leaving the points projecting for 6in. at intervals of 2ft. These plates would be applied only to the prominent features of a building—*e.g.*, the tower of a church, and their cost is estimated at 1s. 6d. per foot run; but it is obvious that the electric taps might take the form of ornamental castings, with vertical webs for making the earth-connections. It must be confessed that Major Parnell's system is economical, as compared with the present arrangements; it remains to be proved whether it is equally efficient.

Of the second work mentioned in the foot-note there is little to say, save that it is intended by the translator to form an appendix to his treatise on lightning conductors. It is a classical pamphlet on the subject, issued under the authority of one of the most distinguished scientific bodies in the world. The two works may be studied together with advantage; for the French system, it is well known, provides the public buildings with a bristling array of conductors or points, presenting a large extent of metallic surface—in fact, a concentration of metal in the most elevated position; just where it ought not to be, according to Major Parnell. The information contained in the "pamphlet" comprises the substance of the various reports made to the Academy by experts since 1823, when the first was drawn up by M. Gay-Lussac. It is the orthodox view of the subject, and the systems described are expensive as compared with the cheap method of protection above described.

---

* The Action of Lightning. By ARTHUR PARNELL, Major R.E. London: Crosby Lockwood and Co.

Information about Lightning Conductors issued by the Academy of Science of France, translated by R. ANDERSON. London: E. and F. N. Spon.

THE ORGAN: A COMPREHENSIVE TREATISE ON ITS MANUFACTURE, PROCURAL, AND LODGMENT.[*]

By JOHN WATSON WARMAN,

Associate of the College of Organists, London.

q. THE exception referred to is this. In 2-Manual Instruments that have not a large Pedal Organ it is extremely desirable that the Coupler Swell to Great be of the kind which I have termed a *Clear* one,—that is to say, of such a construction that when both it and the Coupler Great to Pedale are in Action together, yet that the Swell Organ shall *not* be united to the Pedale. This idea of a Clear Coupler occurred to the present writer at about the beginning of 1877: the real value of the device, in all Organs of the kind just mentioned, must be obvious on a moment's consideration, for while such a Pedale, supplemented *only* by the Great, will often furnish a really excellent Bass to the Swell and Great united, the same Pedale supplemented by the Swell as *well* as by the Great will be always very unpleasant, and sometimes actually intolerable (,—though it is only what hundreds of Organists have at the present time to submit to). It is of course, generally desirable (see *r*, next) that there be a distinct Coupler Swell to Pedale also provided,—for special or for extra powerful effects. See, at this point, what is said at *s*, next.

r. It will now be fully apprehended that when the foregoing expedient is adopted, the Participation of Nose with the *Great* Manual Key must be sacrificed; for the Clearance of the Coupling can obviously be secured only by the Pedal Key's being made to drive the Pallet Action of the Great Key *without* depressing the latter itself (because if an actual Key be put down, any Coupling in action with its Section *must* become acted upon also). A more particular description of the Clear Coupler will be found at 90, *r*, together with information as to the influence of such Coupler on the necessity for Key-Participation (see here at *p*, ante; and again at *s*, next). Along with this question of the structure of any Manual to Pedale Coupler there must often be considered that of the admission of or necessity for such Coupler *at all*;—as, for instance, when there are four Manuals present, the Solo to Pedale may occasionally be dispensed with; and where there are three Manuals, the Swell to Pedale may in some cases be sacrificed: on all these points see fully in *Departments* SCHEDULES and SPECIFICATIONS.

rr. It is to be noted that for any Manual that has another Manual *beneath* it, the treatment of causing the Pedal Coupling Sticker to act free of its Key-tail is strongly desirable under any circumstances whatever, in order that such higher Manual may be the more easily Removable for Access to the lower Manual. If the Nose of the Backfall, or Lever, or Square be not in actual contact with such Key-tail (see *o*, ante), but be raised above latter, of course such Pedal Coupling Sticker must be made longer accordingly.

rrr. An *Instance* of the Swell-to-Ped. Stickers' entering the Square-Noses of the regular Key-Action of such Swell occurs in the Hoddesdon Organ (see 60, *v*; and *m*, next).

r, *Bis*. That which has now been said as to the Man.-to-Ped. Sticker's being inserted into the Square or other Action Nose applies, of course, more especially to any Manual which has a second Manual placed under it,—the reason being the facilitation of access to such lower Manual. It thus follows that, for any Manual which is absolutely the *lowermost* one in any Organ, there does not exist so strong a reason for the aforesaid treatment of the Man.-to-Ped. Coupling Contact: and we may, in fact, lay down as a rule, that for such lowermost Manual the Man.-to-Ped. Sticker or other contact may be freely made against the *Key-tail* itself, *unless* a different treatment is required for the provision of the *Clear Coupler* just described, or else the Square or other Action *Nose* is for any other reason set *directly* on such Tails of lowest Keys;—for a moment's reflection will show that the Wiring of a Sticker into the under face of a Manual Key does not of itself furnish any real obstacle to the removal of such Key, while that, on the other hand, such a contact of Action with latter ensures its proper *Participation* (see *n*, ante), and this in a natural and easy manner. A few words must now be given for definite direction as to the precise *point of contact* to be observed for the Action of the Coupler Manual to Pedale when such contact is made against the *Keys* themselves.

rr, *Bis*. Of course, the best point, absolutely, for such contact would be exactly *beneath* the point of contact of the regular Action of the same Key to its Pallett; for then, while on the one hand the length—and consequent obstructiveness—of the Key would not require to be increased, on the other hand there could be no risk of the Coupling Action's causing a lifting of such Key fore-end (see *m*, ante). But such a treatment as this would obviously demand that either the Stickers should be *wireless*—so passing through a Register—or, that if wired, such wires did not extend *through* the Key; and, moreover, that if both sets of Stickers were so wired, the wires of *both* sets should be inserted in *one* single hole in each Key. Concerning these points, see fully hereafter in *Departments* COUPLING-ACTION and KEY-ACTION; it will be sufficient here to observe that neither of such Treatments can be relied on as being desirable or practicable in ordinary cases of Coupling-Actions.

Actually, therefore, the best remaining point of contact for the Coupling to Pedals, when made against the Key, will be the extreme [rear] *end* or tail of the latter this is, remember, speaking exclusively of any *Slope* or Wedge—see *z*, ante—which may exist beyond such point of contact; refer to *Treatment* 5,—at *r*, next, 7th parag.); and the contact of the regular Action to Pallett will then be set at *just inside* the Coupler contact, and as near to latter as is practicable without risk of fouling or of breaking one Wire-hole into the other. By this means there can be no possibility of the fore-lifting of the Key, mentioned a little back. With regard to more exact directions see in the future *PART DETAILED*; it will be sufficient here to define that the lateral distance between such two points of Action contact should not be greater than ⅜in., and that it should preferably be as much less than this as is practicable, but that it probably can never be less than ¼in.

But to the foregoing treatment, which involves a virtual elongation of the Key, there may frequently be objections,—such as that the Key may already be excessively long, or that uniformity in length with another Manual (see *g*, ante) is strongly called for, or that it is extremely desirable to secure a space immediately beyond the regular action point of that Key against which the Ped. Coupler acts directly.

The requirement most likely to have practical weight here is the last mentioned, as existent in the treatment described further on for the *Front Regulation* of the *Swell* Clavier. Turn, therefore, at this point to what is there said (comm. at *h*, next, 9th parag.), from which it will be at once seen, that if the Tail of the Great-Org. Key extends back beyond the Regular Action Sticker of such Key, the Sticker of the Action for Swell-to-Pedals will inevitably also be thrown rearward to a corresponding extent, and, as the Noses of the Squares or Backfalls of the regular Swell-Org. Action are still required to extend as far forward as the Great-Org. regular Stickers (assuming these latter to be present), the ultimate consequence must be an elongation of the said Nose of the Swell Square or Backfall,—itself involving an increase total in the size of the latter.

[Of course the preceeding constitutes a valid though not very forcible *objection* to the provision of Front Regulation for the Swell-Organ under such conditions: see at *h*, next, 10th parag.]

rrr, *Bis*. For these reasons the Builder should here act according to circumstances. Under all conditions the contact of the Coupler Man.-to-Ped., when made actually against the Key, should *preferably* be set either directly beneath, or just rearward beyond, the contact of the regular Action leading from the same Key; and if the coming into and out of coupling action be by means of a *Slope* (see again at *z*, ante), such Sloped portion will extend to the rearward of its own point of contact (see again at *r*, next, 7th parag.). But where the Key is of considerable length — so that there is no real danger of its fore-lifting—, and a Front Regulation of the Manual next above is really necessary or desirable (as when access to the Organ for interior Regulation is not easy), or where space beyond the Tails of the lower Keys is for any other purpose valuable—, then, it will often be the better treatment to set the *regular* Action contact at the extreme end of the Key, and the Pedals Coupler contact just forward of and inside of it; and any existent Sloping should in this case run inwards,—that is, forwards towards Player. Concerning the actual [plan] distance between the two Contacts, see what has been stated a little back (at *rr*, *Bis*, ante,—2nd parag.),—noting, that whenever the said Coupler contact is that which is the nearer one to the Player, the said distance should be as *contracted* as is possible, in order to diminish risk of the fore-lifting of the Key.

It will thus be seen that with the Pedals Coupler contact set beyond the Regular Action contact, the Length Total of the Key will be determined irrespective of the last named; but that with the less preferable treatment of the Coupling contact set inside the Regular contact, the said total length will be determined as entirely independent of the existence of such Coupler.

s. (7) *Coupler between Manuals.*—It is somewhat strange that the benefits of placing the Manual to Manual Coupler actually between the two sets of Keys should have been so little realised. The treatment was common enough some years ago (see *t*, ante and on), but is now looked upon with much disfavour,—quite wrongly, as the following list of only the chief of its advantages will show:—1, Less material is consumed; 2, Less workmanship involved; 3, Total weight or momentum lessened; 4, Greater quietness ensured when in action (if Coupler be properly constructed; see objection *D*); 5, Suitability for the requirements of a *Buffet* (particularly when latter is Reversed, in which case the *Backfall* form of Coupler often becomes impracticable from want of room); 6, Greater facility given for Removal of the Coupling mechanism; 7 (very important), Suitability for the application of a *Clear* Coupler,—on which point go over what has been said with No. 6 previous (comm. at *q*, ante), looking also at *r*, next; 8, Similar suitability, to some extent, for the provision of a *Part* Coupler (see Ex. 1, at *f*, next); 9, The rendering of Key-Participation sometimes less necessary (see *s*, next); 10, Such Participation of the Manual to *Manual* is at once ensured.

The objections that have at various times been brought against the having of a Coupler between two Manuals are:—(*A*) Interference with Slanting one of two sets of [Manual] Keys for the purpose of passing latter through the Stickers of the other such set; (*B*) Prevention of Access to some of the Manual Keys; (*C*) Want of Smoothness in the Coming-on of the Coupler while a Chord is put down on the Manual *to* which the Coupling is made; (*D*) Noise when the Coupler is *not* in Action.

t. A few words will dispose of these. *A* is rendered of no force by reason of a Device to be directly (at *z*, next) mentioned: and even without such expedient the Keys could be sharply [plan] Cranked so as to pass through the Stickers or the Trackers of the other Manual,—though such a Treatment is not to be advocated, because it throws the point of the Coupler-Contact *nearer* to the Key Mid-Pin (see *m*, ante). *B* is of no weight whatever; for, access to the *upper* of the two Manuals is obviously not affected at all by a Coupler beneath it, and as to the *lower* Manual it is equally manifest that under *any* circumstances the upper Keys must be removed to get at it, and that the taking away of the Coupling Mechanism itself will be the work of but a few seconds. *C* can exist only where the Coupling is not of a proper type; thus, the *Drumstick* form, if correctly constructed, comes on smoothly enough, whether any Keys be down or not. *D* can occur only where the Drumsticks are not properly hung; and even in such case rattling can be prevented by the simple expedient of keeping them *clear* of both the sets of Keys when the Coupler is not in Action (see *y*, ante).

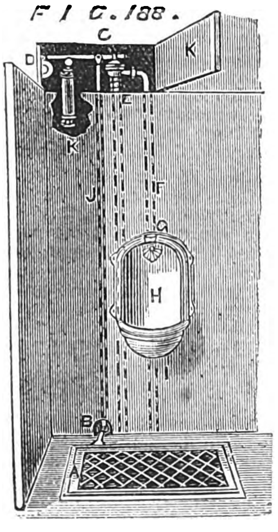
PRACTICAL NOTES ON PLUMBING.—XXXIII.*

By P. J. DAVIES, H.M.A.S.P., &c.

Cradle Urinals.

FIG. 188 represents a front view of the cradle urinal fixed against the wall, and with a valve E, worked with a rod J; the lever of the valve is kept from too suddenly closing by the use of the regulator K. It will be manifest to all practical men that any of the actuating arrangements of the water-valves belonging to either closets or urinals that have hitherto been described and illustrated, may be worked in with each other accordingly as circumstances may require, for instance: the door in Fig. 182 may be made to work the valve V, Fig. 173, or the lever D in Fig. 188, &c.

FIG. 188.



Before closing this chapter on door and seat action closets and urinals, it will be as well to mention that they are, as a rule, only fitted in places, and under circumstances where the users neglect, or cannot be depended upon, to pull the handles for flushing the basins, &c. They also are very useful in preventing waste where persons, mainly through negligence, will leave the handle up, and so leave the water to waste for days together.

It is of the greatest importance that the valves and pipes should be thoroughly washed and cleaned after fixing, to prevent the possibility of any dirt or other extraneous matter being deposited between the face and seating of the valve, so as to avoid any chance of leakage.

As some say that a change is as good as a holiday, for a time let us turn to

Fixing Soil-Pipes and Traps.

(See chapter XX.) This is according to promise when writing that chapter.

Fig. 189 is a plan of a water-closet. A is the trap; B the outlet, branched into the soil-pipe, S. This pipe is shown in this diagram at the left-hand corner of the w.c.; this position, however, is not compulsory, as it may be fixed at any other convenient part, at the discretion of the plumber, &c.

Fig. 190 represents a side elevation of the pipe and ᑌ-trap, as ordinarily fixed. The proper course to pursue in setting out such work as this, is—that having decided the position for the soil-pipe, as in the corner, Fig. 189, place the centre of the trap-dip (if for a valve-closet) 14in. from the back of the brick-work, as from A to H; but, on the other hand, if for a pan-closet, 12½in.: and, again, if the closet is less than 3ft. 6in. wide, place the trap 1in. out of the centre, as shown, the greatest distance being from F to A; or, in other words, keep the centre of the trap 1in. to the right of the centre of the closet, which will allow the dish and pull of the closet to come within the flap, and give a good rail to the closet seat. Next take the distance from the centre of the trap-dip to the back of the brickwork, allowing for the soil-pipe not going quite back (as shown) in the corner behind the soil-pipe; the most advisable plan is to take a short length of the soil-pipe and place it in the angle; then take the distance from the front of the pipe, as at J, to the centre of the trap (say this is 2ft. 6in.). Next is the fall; for this refer to Fig. 190; as a general rule it will be found that there is a 9in. joist to word between, as from the floor-line G to the ceiling-line C, so that there can be at least 4in. fall in the short length between I and J without the outlet-pipe being below the ceiling.

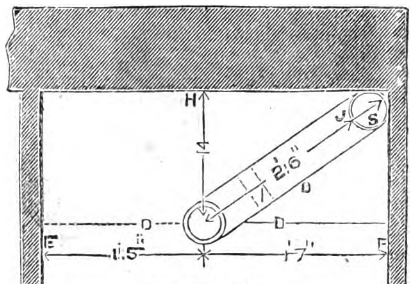


FIG. 189.

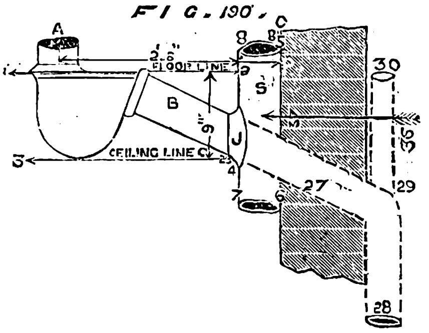
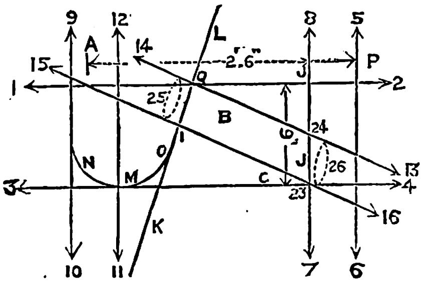
FIG. 190.



These distances being arranged, proceed to mark them on the floor or bench, as at Fig. 191, in the following manner:—Firstly, with the chalk-line snap the floor-line 1, 2, afterwards the ceiling-line 3, 4, 9in. from the floor-line (that is assuming it to be a 9in. joist), but if only a 7in. joist the ceiling-line must be only 7in., and so on in proportion. Now, with the square strike the back-line 5, 6, which must be square to the floor-line, because we are justified in assuming that the walls are thoroughly perpendicular and the floors horizontal; hence, the reason for the back-line being square to the floor-line. Now assume the soil-pipe to be a 4in. pipe, ⅛in. thick; strike the pipe-line, 7, 8, 4¼in. away from the line 5, 6, and parallel to it. This done, you have the floor and ceiling-lines, as also the soil-pipe lines.

FIG. 191.



Next, upon the floor-line, set back the distance from the centre of the dip to the front of the soil-pipe, which I have already said is 2ft. 6in., as from A to J, Figs. 189 and 190; then mark 2¼in. each side of the point A, Fig. 191, as at 9, 12; this will be for the dip lines 9, 10, 11, 12; draw these lines parallel to the wall or soil-pipe lines, and square to the floor-lines. Now take the trap and lay its top edge upon the floor-line, as illustrated at Q Y, Figs. 192 and 193; be assured that the top cheek lies level, which may be adjusted by placing a piece of ½in. or ¾in. board R, Fig. 193, under the trap, sufficient to allow for the flange 18; then, to be quite certain that you have the exact length for the outgo, place the heel of a small square W X, Fig. 192, upon the dip-line, and adjust the dip of the trap to the blade of the square. This done, you may be quite positive that your lengths are accurate. Next, with a blacklead pencil (see V, 19, Fig. 193) held plumb with the band of the trap, mark round the outgo as shown. The outgo of all traps should be straight, as at 20 and 21, Fig. 192. Now take the trap away, and with the straight-edge held to the straight part of the line marked, draw the line K L; this is your cutting line for the short length of pipe B, Figs. 192, 191, 190, 193, and 189; this done, draw the pipe lines, 13, 14, 15, 16, care being taken to get the proper points for the outlet of the trap as at Q I, Fig. 191. Of course, the points 23 and 24 must be taken from the meeting point of the ceiling-line with the pipe-line—that is, in cases where you wish to have all the fall you can get; but this is not always wanted. Now, having these lines 13, 14, 15, 16, lay the pipe as shown by the dotted lines 25 and 26, Fig. 191, and 23 and 24, Fig. 192, upon the lines, using the square as you did with the dip-pipe; or if it is a bend, as at 21, 24, 25, 26, Fig. 193, do likewise; then with a saw (a long panel saw is best) cut the lead pipe through and true to the lines L K and 7, 8. This will be the exact length for the outlet pipe, besides being cut true to suit both trap and pipe. Open the pipe S, Figs. 190, 191, 192; and to come up to a true round hole and face line for the branch pipe to enter, let the lead project ⅜th of an inch past the face, to receive the branch pipe as at 30, and the section 31, Fig. 192. I need not here explain the method of joint-making, nor the preparation of it, but assume that my readers are already efficient in that branch. Having everything soiled, lay the trap down in its place as before, upon the floor-line, and also the

FIG. 192.

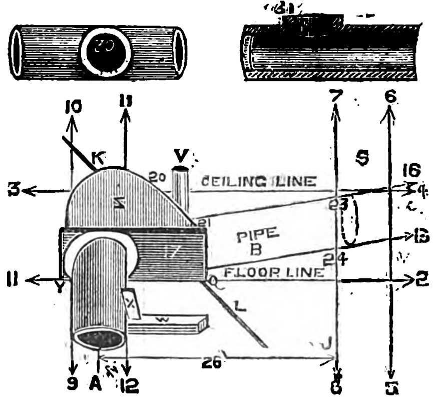


FIG. 193.

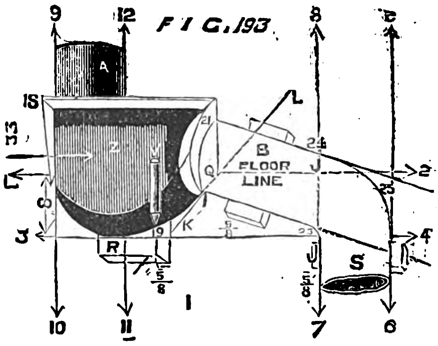

---

* From the *Building News.* All rights reserved.

out-go pipe as fitted; then mark the trap for shaving, shave it, and again lay it down; next, with a ladle half-full of solder, tack the trap to the out-go pipe, so as to fix it together; pick the whole up and fix it on its end in a position something like the illustration, Fig. 194. After the joint is wiped, as at I I, Fig. 190, lay it down again upon your lines and tack the branch joint 23, 24, Fig. 192; but be careful to block the pipes up to a level with the trap outgo, as shown at U T, Fig. 193; then pick up the trap, outgo-pipe, and soil-pipe in such a manner that the soil-pipe S will lie upon its back, as shown at P 6, Fig. 190. This position may be viewed by sighting along the arrow at 36, 37, Fig. 190. When the joint is made, solder on your tacks for supporting the soil-pipe; then fix it in its place.

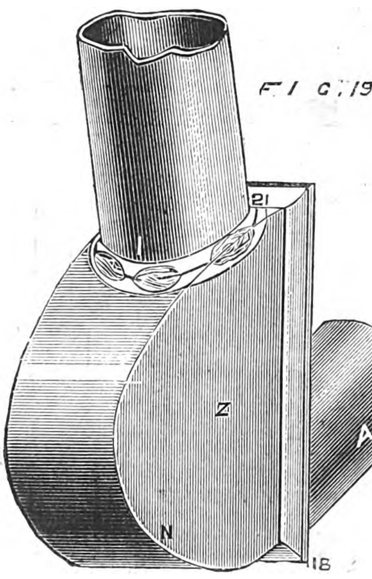

FIG. 194.

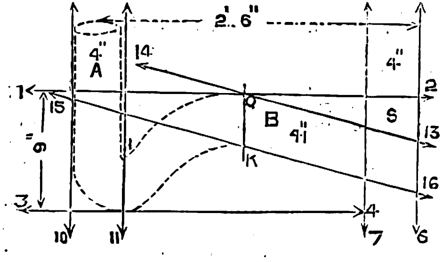
Fig. 195 is an illustration showing the same method for fixing the half ꙅ-trap. The lines are all the same excepting the outgo Q K, which must be struck straight across the outgo and the outlet-pipe, cut to the line Q K, as before; this joint may be made underhanded or upright.

FIG. 195.



After what has been described, the lines suitable for any kind of pipe-work may be easily arrived at, and the main thing is to be careful about your measurements and points.

WATCH-CLEANING AND REPAIRING.

By "A FELLOW-WORKMAN."

(*Continued from page* 188.)

Drawing a Hairspring.

DRAWING a hairspring comes under the heading of what jobbers generally call "doctoring a hairspring." Now, although I do not agree with "doctoring" as a rule, in some instances where the beginner has not the necessary means to keep a stock of hairsprings in hand, he would be glad to know a remedy of how to make the old hairspring do. I will try, therefore, to describe a simple tool by which I draw hairsprings. Fig. 49 is a side view of full size drawing. A is pair of pliers, B hairspring, C the graver (which I have drawn this way on purpose to show its face), D piece of brass plate, E is shaving coming from hairspring, F is a piece of wire for rest. Now look at Fig. 50, and you will see that the rest goes out, then up, then under the graver; the knob of the small drawer, same size as sketch, will do for handle. The graver should be about length shown. Do not press hard on your graver. There should be a little pin where the arrow points (Fig. 50) to keep the graver from slipping. The rest should be a little above the level of plate D. You must raise it gradually until your graver cuts to your satisfaction, and then fasten it.

FIG. 49.

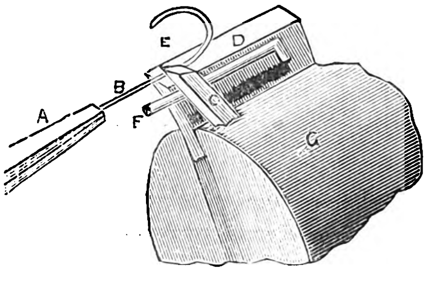


FIG. 50

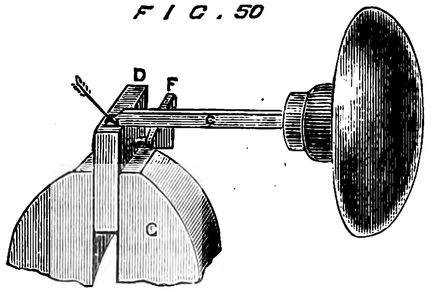

(*To be continued.*)

THE USE OF STAINING FLUIDS IN VEGETABLE MICROSCOPY.[*]

IN bringing this subject before you this evening, it is not my intention to give a formal and original lecture on the use of staining fluids; although, as many of you know, I have, for many years past, made copious use of various reagents in the investigations in which I have been engaged. In the course of my work I have, no doubt, made use of staining fluids which, up to that time, had either not been used or not been referred to in published articles; but I feel very strongly that it is unwise and improper to claim or reclaim priority in any matter of manipulation or methods of research, and I will, therefore ask you to regard this paper as the best *résumé* of the subject I am able, with the time at my disposal, to bring before you.

Staining fluids are used by the microscopist for either of three purposes: 1st, in purely scientific investigation, chiefly to differentiate the living from the non-living, or for the purpose of discriminating between tissues which, unstained, so closely resemble each other as to be undistinguishable; 2nd, to allow of the more ready demonstration of different classes of tissues, as in transverse sections of wood-stems; and 3rd, to make pretty objects for show purposes.

We will take the first of these groups as our starting-point, as not only being more in accordance with the spirit, or what ought to be the spirit, of this society, but also because the use of staining fluids came into microscopy in connection with pure biological research: that their larger use in modern times lies in another direction is possibly a matter to be regretted. The first, or at all events nearly the first, staining fluid used was a solution of iodine for the purpose of demonstrating the presence or absence of starch in a vegetable tissue, and iodine solution is the first reagent with which the scientific phyto-microscopist should make himself familiar. For general purposes, an alkaline solution is preferable, and may be prepared by taking one grain of iodine, three grains of iodide of potassium, and dissolving them in one ounce of distilled water. The method of applying the test is well known to all but the merest beginner in microscopy, but may, perhaps, be mentioned. Suppose you have any thin section of plant-structure on the slide under observation; the section is probably immersed in water under a thin cover-glass, and you wish to apply the test without disturbing the section or even removing the slide from the stage of your microscope. Take a drop of the iodine solution on the end of a glass rod, which must be perfectly clean, place the drop of solution on the slide close to and touching one edge of the cover-glass, touch the opposite edge with a piece of blotting-paper, and as the paper absorbs the water on its side of the cover, the iodine solution will run under to replace it. With practice you can remove the water by the blotting-paper whilst the eye is applied to the microscope, and the reaction watched as it proceeds. It is hardly needful to add that the presence of starch is shown by a blue-violet colouration. The protoplasm matters in vegetable structures are coloured yellowish brown, as are also the woody tissues in a greater or lesser degree. The use of iodine, however, does not end in the yellow and the violet reactions of these three classes of tissues or substances respectively, for, as was known very long ago, it can be used in the detection of cellulose, the substance of which vegetable cell-walls are composed. The application of the test for that purpose is not so simple, but is by no means difficult. The experiment is more easily performed on a section which has not been immersed in water. Take an alcoholic solution of iodine (good sherry-coloured solution) and thoroughly stain the section, remove all surplus iodine solution and apply tolerably strong sulphuric acid (1 part acid to 2 or 3 water), wait a few seconds and if the experiment has been successfully performed you will notice that all the cellulose cell walls assume the blue violet colour characteristic of starch. The principle iodine reactions in vegetable microscopy, then, are—alkaline solution of iodine: starch stains blue violet; cellulose stains yellowish brown; protoplasm, wood, and cellulose stains darker brown. Iodine and sulphuric acid: Cellulose stains blue violet.

A modification of the iodine test, known as Schultz's test, has been recommended as a test for cellulose; but my personal experience of it is very limited. The solution is prepared as follows:—zinc is dissolved in hydrochloric acid, and the solution is allowed to evaporate in contact with metallic zinc, until it attains the consistency of a syrup; this syrup is then saturated with iodide of potassium, and iodine is last added.

Passing over tests, such as Millon's acid nitrate of mercury test, and the sulphuric acid and sugar tests for albuminoids, we will next notice the use of carmine as a staining fluid.

Probably no staining fluid, hardly any method of research, has made so much noise in the world as this. Brought prominently to the front many years ago by Dr. Beale, it has proved in his hands of great value, and may almost be said to form the foundation of his system of biological philosophy. Dr. Beale's method of preparing the fluid is as follows:—Take carmine 10 grains, strong liquid ammonia half a drachm, Price's glycerine two ounces, distilled water two ounces, alcohol ½oz. The carmine is to be placed in a test-tube, and the ammonia added to it. Upon applying the gentle heat of a spirit-lamp the carmine is dissolved. Boil it up for a few seconds, and allow it to cool before adding the other ingredients. Lastly, filter it, or allow it to stand, and decant off the clear solution. The solution should be neither too alkaline nor perfectly neutral. If the former, the colouring becomes too intense, and thus much of the soft or imperfectly-formed tissue is destroyed; if the latter, the uniform staining of formed and germinal matter mars the result. The permeating power of the solution may be increased by the addition of a little more water and alcohol. After the preparation has been properly stained, it should be removed to and washed in a solution of strong glycerine in half its bulk of water, and then transferred to an acid fluid composed of strong glycerine, one ounce; strong acetic acid, five drops; where it must remain three or four days to regain the volume it occupied when fresh. Beale's carmine fluid is not one which commends itself much to the mere preparer of pretty objects; but carefully-cut sections of soft-stem plants, carefully stained by various carmine fluids, are by no means to be despised by such as care only for the æsthetics of microscopy. It is to the micro-biologist, however, that carmine is the most useful; and although, to a certain extent, it has been superseded by aniline dyes, logwood solution, and other fluids, it is, to my mind, for certain purposes by far the most valuable reagent we have, and the permanence of its staining is far beyond that of any aniline dye.

The most important use of carmine staining fluid is in the differentiation of different portions of the protoplasmic matters in a cell or tissue, and upon the differential behaviour of these different portions of protoplasm Dr. Beale bases his theory of bioplasm, of germinal and formed matter. To use his own words:[*] "The matter which I have termed forming, living, or germinal matter, to which I have more recently given the name bioplasm, has been lately spoken of by others as protoplasm. . . . . The word 'protoplasm' would have been used by me, had the term been restricted to the matter of the tissues, which I termed living or germinal matter, and which I showed, in my lectures at the College of Physicians in 1861, underwent conversion into formed matters, and were concerned in forming all tissue. But under the term 'protoplasm' has been included the contractile tissue of muscle, the axis cylinder of the nerve-fibres, processes of nerve-cells, and many other textures which undoubtedly consist of formed material, and are entirely destitute of the properties which belong to my 'germinal matter' or 'bioplasm.' Moreover, the nucleus and nucleolus were by many writers considered to be distinct from the protoplasm. On the other hand, I showed that the nucleus and nucleolus were living. My bioplasm, germinal or living matter, therefore includes both nucleus and nucleolus, as well as some forms of the protoplasmic matter of authors." The proposition thus is, that what we are all in the habit of calling protoplasm really consists of a living and formative substance, which is bioplasm, and a substance which is formed out of (Dr. Beale would probably not say formed *by*) the bioplasm, and the problem is, to demonstrate the existence of these two forms of protoplasm.[*] The answer to the problem arises out of another proposition, "that all bioplasm is coloured red by an ammoniacal solution of carmine, while all formed material, notwithstanding it has been traversed by the alkaline colouring fluid, remains perfectly colourless. In practice certain precautions are necesssary, and the density and composition of the colouring-fluid must be slightly varied in special cases. But it is necessary that I should state distinctly that if the process be properly conducted, every kind of living or germinal matter or bioplasm receives and fixes the colour, while no kind of formed material known is stained under the same circumstances." It is, of course, no part of my duty to-night to express any opinion on the soundness of Dr. Beale's biological opinions, and, under any circumstances, it would be mere presumption on my part were I to attempt to do so. All I have to do is to point out that, for the purpose of clearly demonstrating various shades of difference in the constitution of "protoplasmic" masses in a cell, demonstrating nuclei and nucleoli, Beale's carmine fluid is a most valuable agent. It is a little troublesome to prepare, but will keep for years, and the stained preparations are extremely permanent. Various other preparations of carmine have been introduced into practice. Amongst the more recent ones may be given the following,[†] due to Prof. H. Grenacher, and extracted from the *Journal* of the Microscopical Society for 1879:—

---

[*] A paper read before the Leeds Naturalists' Society, May 2nd, 1882, by HENRY POCKLINGTON, F.R.M.S.

[*] Bioplasm, 1872 ed.

Alum Carmine.—A 1 to 5 per cent. solution of common or ammonia alum in water is boiled for 10 to 20 minutes, with $\frac{1}{2}$ to 1 per cent. of powdered carmine, and the solution filtered when cold. The solution is of a rich red colour, inclining to purple, and when concentrated stains a section in five to ten minutes. Sections, when washed in water for a couple of minutes after staining, have a purple or lilac colour; the staining also is less diffuse, and more confined to the nuclei, than in the case of the ordinary solution of carmine or picro-carmine. It has also the advantage of not over-staining, even if a section be left in it for a whole day; and if it dries up by evaporation (in a watch-glass, for instance), the addition of a little water will render it once more fit for use, no precipitate being produced. It is advisable to add a few drops of some antiseptic to the solution. It will then keep for years.

Borax Carmine.—A one to two per cent. solution (aqueous) of borax is boiled with $\frac{1}{2}$ to $\frac{3}{4}$ per cent. of powdered carmine. To the dark purple solution acetic acid is continuously added, drop by drop, with constant shaking until a bright red colour is attained. It is then filtered, or, as it filters very slowly, allowed to stand and then decanted. This solution stains sections very rapidly, in from one-half to three minutes, but quite uniformly. If, however, they are washed with water, and placed in a watch-glass of from 50 to 70 per cent. of alcohol, containing a drop of hydrochloric acid, the colouring matter is removed from all parts of the tissue except the nuclei, which remain deeply stained.

Alcoholic Carmine.—To 50cc. of strong alcohol (60 to 80 per cent.) three or four drops of hydrocloric acid are added, as much powdered carmine as will lie on the point of a knife (the size of the knife is not stated—presumably a clasp knife or small dessert-knife is meant) is added, and the whole boiled for ten minutes, and filtered when cold. The exact proportion of carmine and acid depend upon the quality of the former. If a section placed in the fluid stains in five to ten minutes uniformly, there is not sufficient acid, and more must be added. If, after standing for some days, the solution assumes a yellowish red colour, too much acid has been added, and the excess must be neutralised by cautious addition of ammonia.

After staining, the sections must be rinsed in alcohol, *not* in water; also, if the solution has been too strong, it must be diluted with alcohol, as water precipitates the carmine.

Purpurin.—About as much purpurin as will lie on the point of a knife is boiled in 50cc. of glycerine. The latter may be concentrated, or have a little water added to it. The resulting orange-red, fluorescent solution is allowed to stand for two or three days and is then filtered. Unlike Ranvier's solution of purpurpin, it may be kept for months without precipitation.

All the above fluids are stated to be quite permanent in the case of balsam preparations; if glycerine be used as the mounting fluid, it should be slightly acidulated.

Logwood.—Another staining fluid of value in the examination of protoplasm is solution of logwood. I have used a preparation made by the formula published some years since by Prof. Arnold, of New York, with success. The solution is made as follows:—The ordinary extract of logwood is finely pulverised in a mortar, and about three times its bulk of powdered alum added; the two ingredients are well rubbed together and mixed with a small quantity of distilled water. The complete admixture of the hæmotoxylin is necessary, and this will require fifteen to twenty minutes' vigorous stirring. More water may now be poured on, and the solution, after filtration, should present a clear, somewhat dark violet colour. If dirty red is obtained, more alum must be incorporated, and the mixture again filtered. By always having an excess of both alum and hæmatoxylin in the mortar, a saturated solution can be obtained, which after filtration may be combined with alcohol, one ounce of the logwood fluid with two drachms of 75 per cent. alcohol. A much better colour is produced by allowing the mixture, after thorough trituration, to stand for several days before filtration and addition of alcohol. This stain colours very rapidly: the nucleus becomes a dark purple, and the remainder of the protoplasm a neutral tint. I have found the fluid extremely useful in the examination of growing points and the structure of ferns.

Aniline Dyes.—My experience of aniline staining fluids only dates back to about 1868, after which I made use of them for several years in the demonstration of the structural elements of plant-stems, and later also in the examination of protoplasmic matters. Aniline staining fluids generally have the merit of being easy to prepare and apply, but have the unfortunate fault of lack of permanency if much exposed to light. Mr. W. H. Jackson some years since[*] published a method by which magenta-stained specimens could, he thought, be made reasonably permanent. The process arose out of the following considerations. "Rosaniline or magenta is a triamine, and, therefore, with monobasic acids forms three salts, in which one, two, or three atoms of hydrogen are replaced by the acid radical. The tri-acid salts are obtained in the presence of an excess of acid, and are all colourless, or nearly so, for the most part having a dull reddish-brown tint (the mon-acid salts are brilliantly coloured). *All* sorts of rosaniline are soluble in alcohol, ether, glycerine, and chloroform, and in fluids containing more than a certain percentage of these substances. Some, *e.g.*, the mon-acetate, or mono-chloride, are soluble also in water or watery solution. Hence a stained tissue, plunged into water, loses a certain amount of colour, and is ultimately left in a most unsatisfactory condition. Moreover, under the influence of light, and in the presence of organic matter, some of the mon-acid salts undergo a decomposition by which a nearly colourless compound is formed, and the preparation thereby spoilt."

It was, therefore necessary to find either a stable mono-basic salt, or to obtain a proper preservative fluid. The latter condition could only be secured by employing a watery solution, as *all* magenta salts will dissolve in all the other media commonly employed. The first condition could be met by employing a mon-acid salt, insoluble and unchangeable, in the preservative fluid. The salt he preferred was the mono-tannate—the preservative a special syrup. A strong solution of tannic acid is prepared in water, a little crystallised magenta is dissolved in water, or Judson's dye, diluted, is placed into a separate vessel and the tannic acid added, drop by drop, shaking the test-tube from side to side after adding each drop, and taking care not to precipitate the magenta *completely*. The precipitate is allowed to settle, the fluid poured off, and the precipitate washed by decantation several times with cold water. It is finally allowed to partially dry, a drop of acetic acid added, and then alcohol drop by drop till it dissolves. The solution is pink, and stains very rapidly and quickly. The stained preparations are mounted in a fluid composed of a strong sugar-syrup, to which is added whilst it is hot, 3 to 4 per cent. of either sodium chloride or calcium chloride. As soon as the preparation is stained, it is washed with water, which sets the stain at once.

When using aniline dyes, chiefly magenta, somewhat extensively some eight or nine years since, in connection with the examination of stem-structure, I was much troubled with the readiness with which the dye was removed from portions of the structure if it was necessary to mount the specimen in in either glycerine or spirit-and-water, or balsam diluted with chloroform, and heated whilst the specimen was immersed in the medium. To some extent I removed the inconvenience by passing the section into oil of cloves or anise, immediately after its removal from the staining liquid. The essential oil, to a great extent, sets the stain, and prevents its being dissolved out with the mounting medium; but I have not found that this process at all lessens the liability of the preparation to fade on exposure to light. As, however, the working biologist preserves a very small proportion of his preparations, the value of magenta as a staining-fluid is only slightly lessened by its liability to fade.

The reaction of magenta on protoplasm is very similar to that of carmine—the nucleus and the nucleoli are stained more deeply than the other portion of the protoplasm; but it does not, within my experience, differentiate different portions of the protoplasm so sharply as carmine.

Magenta is very useful in the examination of stem-structures, as a very short immersion in the dilute dye suffices to deeply stain all the wood wedges and woody fibres; whilst the thinner parenchymatous tissues stain so slightly, that a momentary washing will remove the colour.

Aniline Blue and Violet.—These are useful in much the same way as magenta, and will be found valuable in the examination of bacteria and other low forms of vegetal life, as they are made much more conspicuous by its aid, and are more easily preserved as permanent objects. Magenta and aniline blue, or aniline green, are useful for the purpose of double staining sections of stems and preparations of leaves; but to this I will refer later.

Bismarck Brown.—This reagent, although used by various microscopists for some years, has only recently come into general notice.

L. F. Henneguy[*] having treated Paramecium aurelia with an aqueous solution of aniline brown, was surprised to see them assume a rather intense yellow-brown colour, and move rapidly about in the fluid. The colour first appeared in the vacuoles of the protoplasm, and then it invaded the protoplasm itself. The nucleus generally remains colourless, and thus becomes more visible than in the normal state. Infusoria thus coloured were kept for nearly fifteen days. All infusoria may be stained with aniline brown, but no other aniline colours employed by the author exhibited the same pro-property. They only stained the infusoria after death, and some of them are, in fact, poisonous.

Seeds of cress were sown on cotton soaked with a concentrated solution of the Bismarck brown and they sprouted. The young plants were strongly stained brown, but on crushing the tissues and examining them under the microscope, it was ascertained that the protoplasm of the cells was very feebly coloured. The vessels, on the contrary, showed a very deep brown staining up to the termination in the leaves. The mycelium of a mould which had been developed in a solution of Bismarck brown was clearly stained after having been washed in water, whilst it is known that the mycelium which forms in coloured solutions, such as picro-carmine, hæmatoxylin, &c., remains perfectly colourless. The author concludes that Bismarck brown possesses the property of colouring living protoplasm both in animals and plants.

I have endeavoured to confirm the author's statement on the latter point, but have not been able to come to any other conclusion than that Bismarck brown is not so toxic as other aniline dyes. If used in very strong solution, infusoria rapidly die when immersed in it. When used dilute they live for some time; but the examination of them with high powers has satisfied me that the only portions stained are the formed materials, notably the exterior of the organisms. The author cited above satisfied himself that the protoplasm was stained in Paramecium by crushing the creature, and causing the protoplasm to extrude, when it was seen to be stained. If this operation were performed whilst the creature was swimming in the staining fluid, it is possible that the staining of the extruded protoplasm was purely post-mortem. Experiments performed by myself on Paramecia removed from the staining fluid into clear water gave a purely negative result. I was not able to see any unformed unstained, protoplasm. Cyclosis will proceed in Vallisneria long after its immersion in the staining fluid; but the circulating cell-sap does not become stained so long as its gyration continues. The nucleated mass of protoplasm floating in it does frequently stain, as also do the other contents of the cell, but the purely living—*i.e.*, Beale's germinal matter—does not stain, with the exception of the nucleus (if it *be* unformed protoplasm). Dahlia, and B B B B violet, are said by M. Certes to have a similar selective staining effect on the nucleus, as also cyanin or chunolin blue; the latter, however, not staining the nucleus during life, although the infusorian continues to live in the dye, and is stained by it.

---

[*] Apart from the question of nomenclature and its attendant theory, no biologist would, I think, dissent from this classification.

[†] Specially applicable to nuclei.

[*] *Quarterly Journal Micro. Science*, 1874.

[*] *Micro. Journal*, April, 1882.

Mr. J. M. Macfarlane recommends the use of saffronine for staining latex vessels, good preparations of which are notoriously difficult to procure. As a preliminary step, the preparations are placed in alcohol for a week to coagulate the latex, and after staining are washed in spirit. I have used Judson's blue dye successfully for the same purpose. Heliocin and naphthalin are recommended by the same author for staining cell contents.

Max Niggl uses indol as a reagent for lignified structures as follows:—Pure indol is dissolved in warm water. The section is moistened with this solution and covered with a cover-glass. The indol is then removed with blotting-paper, and a drop of dilute sulphuric acid (one to four) run in. The lignified cell-walls take a beautiful cherry-red, and the sclerenchymatous cells even a purple colour, which is retained by the preparation for some time.

Passing over the use of other aniline dyes than those named, most of which act in a similar manner to either magenta or aniline blue, I will refer a moment to methods of double staining.

The practice of double staining has become very common, and is much more favourably looked upon by microscopists generally than appeared to be the case when, some twelve or fourteen years since, I submitted one of my earliest double stains to some enthusiastic microscopists, and met with the compliment that they were pretty things for children to look at. I tried to set a fashion then, and feel very much disposed now to try and set it the other way, for I very much fear that the very beautiful specimens of double staining turned out by such masters of the art as Mr. Vance Smith and others, will turn many a budding microscopist into the ways of pleasure rather than of work. For class purposes, where it is desirable to demonstrate the several groups of tissues of which a stem is composed as clearly and sharply as possible, these methods of double and treble staining are useful, perhaps; but beyond that I am not prepared to go. I may add that it is at least seven years since I prepared a double stained object, except for temporary purposes, so that I may possibly in this, as in other things, be considered behind the age.

My earliest double stains were made with magenta and Judson's blue. The sections were stained first in the magenta, washed and transferred to the blue, slightly washed and mounted in balsam after passing through oil of cloves or anise. They were fairly successful and reasonably permanent. A better method is that which was published in the *American M. Micro. Journal*, in 1880. It is as follows:—A two-grain neutral solution of eosin is used, and in this the prepared sections are preserved until the operator is ready to use them. They keep perfectly well in this solution, and are always ready to undergo the final process, which requires but a very short time before they can be placed fully finished under the covering-glass. After taking them from the eosin solution, they should be passed through 95 per cent. alcohol, merely to wash off the superfluous colour, and then placed in half-grain solution of Nicholson's blue made neutral. The time required in the blue solution varies with different tissues, and in the nice adjustment of the time lies the whole success of the operation. Three or four sections of each kind are generally spoilt in determining the exact time required. A section is taken from the eosin, holding it lightly in a pair of forceps, rinsed off rapidly in alcohol, and then immersed in the blue still in the forceps, while ten can be counted with moderate haste. Then quickly place in the clean alcohol, and brush lightly with a camel's-hair brush. This immersion in clean alcohol seems to check the action of the blue instantly. It should then be examined under a 1in. objective, to determine whether the exact point where the blue and red remain distinct has been reached. If the blue has not occupied all the softer cells, another section should be taken, and put through the same process, counting twelve, and so on, until the proper point is reached; or, on the other hand, decreasing the count if the blue has impinged upon the red in the more dense tissue. Having thus determined the count for the sections of that particular material, the remainder of the sections are passed through the blue into the alcohol, merely counting off the immersion of each section. Then place the sections for a few moments in absolute alcohol, which seems to fix the colours, then through oil of cloves into benzole, and mount in dammar and benzole. It is sometimes advisable, with very delicate tissues, to merely rinse off the blue in 95 per cent. alcohol, and fix the colours at once in absolute alcohol; but every operator will learn the minor details for himself in the manipulation.

In order to secure fine specimens of double-stained herbaceous stems, or any preparation which contains chlorophyll, or other colouring matter, a preliminary bleaching process is essential. Alcohol will remove chlorophyll, but not very perfectly, and is apt to make the specimens very brittle. Solution of chlorinated lime decolours rapidly, but, unfortunately, also acts upon the tissues, and if they are delicate, rapidly destroys them. Labarragues solution of chlorinated soda, made by decomposing chlorinated lime with sodium carbonate, has been used, but is apt to form a scum, which attaches itself to the object, and is then difficult of removal. I have used free chlorine for bleaching purposes, passing the gas into the water in which the sections are immersed, or preparing an aqueous solution of chlorine beforehand, and placing the sections in small bottles of the solution, shaking them gently to and fro till decoloured; but this operation, unless performed out of doors or in a chimney opening, is apt to lead to premature sore throats and eyes, and in any case must be done with care. Perhaps the safest method of using chlorine for this purpose is to place the sections in a bottle of water, cork with a perforated cork, through which a glass tube leading to the bottom of the water has been passed. The glass tube should be U-shaped, the spare leg passing through the cork of a second bottle an inch or so; in the second bottle place a little chlorinated lime and water, adding a little sulphuric acid. The chlorine, as given off from the lime, will bubble through the water, charging it with the gas and decolouring the sections. When the gas has ceased to be given off, take the bottles containing the sections, cork it tightly, shake gently, and remove the sections. If the water retains much chlorine, cork the bottle and retain it for future use. Place the apparatus out of doors during the entire course of the experiment.

Instead of chlorinated lime, chlorate of potash, and strong sulphuric acid may preferably be used; but in that case place a safety tube through the cork of the vessel containing the chemicals.

I have now brought before you very hurriedly a few rambling notes on staining fluids, and hope such a discussion may follow as shall result in the increase of our knowledge all round, and conduce more to the interest of the meeting than this paper can possibly have done.

COD-LIVER OIL.

Of modern medicaments, there are few which have been so greatly improved, within recent years, as oils in general, and cod-liver oil in particular. Some of these products, as now supplied in druggists' shops, are so different from what were furnished under the same name, say 20 years ago, that one naturally asks whether they contain the same medicinal principles, or to what extent the proportions of these have been altered, if such a change has occurred. The course of this progress in respect to cod-liver oil has been recently traced by M. Carles, in a paper to a Bordeaux medical society, reported in the *Journal de Pharmacie*.

There is a palpable difference between the old cod-liver oil and the new, as regards smell and taste. Formerly the raw material consisted of livers which were always more or less corrupt, and mixed with blood and debris of viscera, and thrown pell mell into an old tun, putrid fermentation being trusted to bring out the fatty matters. This process was found, however, to yield too little, and the production was accordingly stimulated by heating the putrid residue at an open fire. The stronger the fire, the more abundant was the oil, but the darker, too, was its colour, and the greater its acridity, so that it only found favour with stomachs "the most courageous and experienced."

Yet when patients took this "brew," the system was generally benefited, and it required no great prophet to predict for the medicament a rapid success, when it should be properly prepared, and freed from all that made it disagreeable to the senses. Various attempts at this latter object were made. To deceive the smell, recourse was had to aromatic substances, oil of mint, bitter almonds, cinnamon, &c. But patients did not favour these contrivances, and they instinctively reverted to the natural oils, always preferring those that were less odorous and less coloured. The directions for improvement were thus indicated.

At one time the idea was entertained of treating these crude oils with potash for their acridity and acidity, and with bone-black for their smell and colour. But it was soon perceived that the action of these agents was too violent: the oil lost part of its medicinal qualities, the acridity persisted, and the predisposition to rancidity was increased by the chemical treatment.

It was soon understood that instead of seeking to destroy the colour of the brown oils, it would be better to prevent that colour forming, and since the oil only turned brown through putrefaction or fire, the possibility of improvement in this respect was considered.

The livers, deprived of blood and visceral debris, were treated soon after removal from the animal, and if heat was used to facilitate the escape of the oily substances from the liver cells, its action was carefully regulated by means of steam or the water bath. The apparatus was completely transformed; the old wooden tun, whose pores offered an inviolable hiding place to germs of putridity and rancidity, and defied all good cleaning, was replaced by metallic vessels tinned or enamelled, or by glass receivers.

Producers and consumers alike profited; the manufacturer found his deliveries steadily increase, and the patient at length possessed an oil not liable to alteration, pleasing to the eye, and not disagreeable to the taste and smell.

But have these modern oils, M. Carles asks, all the medicinal qualities of the barbarous original oils?

The superiority of the modern oils as regards facility in taking, is important; and of two similar medicaments, it will in general be found that that which causes less apprehension will have the most certain and distinct therapeutic effect.

The superior *digestibility* of these modern oils seems also to be established. Let anyone take every day alternately a spoonful of different kinds of oil, proceeding from the clearest to the brownest or conversely, and he will find that the eructations are more numerous, prolonged and disagreeable, the more coloured the oil; whereas with the clearest oils, these symptoms of difficult digestion are very rare or wholly absent. The laxative action on the intestines is manifested in the same sense.

Lastly, as regards *assimilability*, the following experiment is instructive:—Take 50 grammes of each of those oils, add 5 grammes of a sweet-bread maceration, and agitate; it will appear that the emulsion is more rapid, complete, and persistent, the clearer the oil. A regular series may be thus obtained from the clearest to the most coloured oils.

This phenomenon of coloration is also directly related to another character which is most variable in cod-liver oil—viz., *acidity*, which, perhaps, has hardly received the attention it deserves.

The acidity, in fact, increases proportionally to the intensity of the coloration. This consideration, of itself, is a weighty one in favour of the white oils. Everyone knows that the oils and butters of our tables suit the generality of stomachs when they are neutral, but become indigestible when they are acrid or acid. The same with medicaments; castor oil, *e.g.*, is a purgative always tolerated, if it be neutral, through expression from the seeds in the cold state, whereas it often causes vomiting, if it have acquired acridity and acidity, through pressure combined with heat.

To measure the degree of acidity of cod-liver oils, the author proceeded by two methods, acidimetry and saponification. In the former, 50 grammes of oil were put in a matrass of 200 cubic centimetres capacity; 100cc. of rectified spirit was added, and 20 drops of sensitised tincture of litmus. Through agitation, the fatty acids passed from the oil into the alcohol, and coloured the litmus red. With a dilute solution of caustic soda, the litmus is rendered blue again, and when, after lively agitation, the colour changes no more, one reads on the measuring-glass the quantity of alkaline liquor which is proportional to the acidity of the oil. In this way the acidity of cod-liver oil calculated in acetic acid (the force of which is well known in vinegar), varied from 0·01 to 1·80 per cent.; the lower extreme representing a white oil, and the higher a current type of brown oil.

Saponification gives a similar classification; but, still better, it brings quickly into relief the various general properties of cod-liver oils. Place in a number of parallel porcelain pots 150 grammes of each of the oils to be examined; pour carefully into each 50 grammes of a solution of caustic potash at 30° B, then work the mixture simultaneously in all the pots. If you then compare, you will observe that with the brown oils there is an immediate liberation of heat, accompanied by a strong smell, and that the whole solidifies in less than five minutes: whereas with the pure white oils the mixture remains liquid five hours, notwithstanding frequent agitation, and that it only gives a weak odour. With oils of intermediate hue, the same phenomena occur with variable intensity, and yield a curve which ascends regularly from the pure white oil to the extreme brown.

M. Carles has further a word to say on the chemical proportion of mineral elements in cod-liver oil. There are two of them which are generally brought into prominence—viz., iodine and phosphorus. Iodine has been found by certain chemists in cod-liver oils of all hues, while Delattre and Girardin have not observed a trace of it in oils of cod fished in spring. In many cases, there is little agreement as to the proportions of this metalloid, though it is a tradition that brown oils contain more of it than white. One reason of the disagreement (according to M. Carles) is, that the potash used in saponification of the oils is often not exempt from traces of iodine; secondly, the oils formerly analysed were not always of an absolute limpidity, and iodine is more abundant in the deposits than in the filtered oil.

In all cases, it appears, that when the oil is natural, and well filtered, and the potash used is pure, the proportion of iodine is extremely small (measured by tenths of a milligramme per cent.); hence it is rash to attribute to it a really therapeutic action.

The same uncertainty holds with regard to the presence and proportions of phosphorus; but it appears to the author illogical to attribute any medicinal action to this substance, since it exists in the oil in the state of calcareous phosphate, and its proportions never exceed a few centigrammes per cent.

En résumé :—

Through modifications of old methods of extraction, the barbarous oils of the past have given place to improved ones, of little colour, limpid, having a smell and taste by no means disagreeable, and suiting stomachs which willingly accept sardines, anchovy, &c.

Of these various oils, the modern natural white ones must be every way preferred to the empyreumatic brown.

Even apart from physical and sense-affecting properties, pure golden-green oils must be considered the best, because they are lighter for the stomach, their acidity is hardly sensible, and they are without acridity.

All varieties of the oil contain such infinitesimal quantities of iodine, doubtful traces of bromine, and small quantities of combined phosphorus, that one cannot recognise in any of these elements the cause of the tonic, reconstituting action of cod-liver oil.

The active principle seems to reside almost wholly in the particular fatty substance itself, which is found unaltered in pure oils.

Lastly, these pure modern oils are a product essentially assimilable, and their association with any other medicament can only injure their tolerability and therapeutic action.

MR. MOY'S LECTURE ON FLYING.*

THE lecturer commenced by remarking that it is now 99 years since the invention of balloons, and that there has been scarcely any practical improvement made in balloons during that time. Mr. Coxwell's plan of converting the balloon into a parachute for the purpose of effecting a safe and rapid descent, the invention of the trailing-rope for land, and drag for water, in order to keep the altitude constant, being the only inventions worth mentioning. He suggested that the weight of the net might be utilised and the net dispensed with by slightly adding to the thickness of the material, and providing loops to which to attach the ropes for the car, near the neck of the balloon.

Mr. Moy then spoke upon "dirigible balloons," which he said should be called "dirigible aërostats," and pointed out several important improvements which might be made in this form of vessel, showing that there was nothing to hinder a successful vessel being constructed of not less than 12 tons lifting power, with common coal-gas s. g. 420.

The lecturer then passed on to the subject of mechanical flight, and he said he would begin with facts.

1st. It is a fact that there are no examples in nature of flying by displacement.

2nd. Flying is entirely a mechanical operation.

3rd. The area of the plane is not the index of its sustaining power.

4th. Some birds fly for long intervals, without any exertion of mechanical force.

The two first facts being self-evident, he spoke upon the third and fourth, proving the third fact by means of his pendulum experiment with, first, a fixed plane, and secondly, a rotating plane.

The discussion was opened by Dr. Pole, F.R.S., who expressed himself very much pleased with the able manner in which the subject had been handled, and the sound mechanical views which had been expressed by the lecturer.

THE production of Bessemer steel rails amounted during last year to 1,023,740 tons, being an increase of 283,830 tons, or 38 per cent. on the output of 1880. Of these rails 594,419 tons were exported. Seventy per cent. of the Bessemer ingots made in 1881 were manufactured into rails. This is exactly the proportion which the one bore to the other in 1880.

SCIENTIFIC SOCIETIES.

ROYAL MICROSCOPICAL SOCIETY.

THE PRESIDENT'S ADDRESS.

(*Concluded from p.* 191.)

Penetrating Power of Objectives—Depth of Vision.

THIS again is a subject which has long been obscure; very various opinions being held as to the true nature of what has been generally termed the "penetrating power" of an objective. By some it has been declared to be a defect in the construction of the objective—residual uncorrected spherical aberration, in fact; and by others as necessarily inconsistent with perfect definition, even with the best methods of construction; the approximately correct notion regarding it being that it decreased as the angle of aperture increased.

Professor Abbe, however, in a very valuable paper, placed the question on the scientific basis so long needed, showing that the total depth of vision in the microscope, i.e. the solid space which at one focus of the microscope is visible with sufficient distinctness, depends not merely on the depth of focus of the objective, but is the sum of that and the depth of accommodation by the eye.

The depth of focus (other conditions remaining the same) varies in inverse ratio to the magnifying power and also to the numercial aperture of the objective. Thus with a ¼in. and ⅛in of the same aperture the depth of focus of the former would be twice that of the latter, or if the powers are the same but the apertures are ·50 N.A. and 1·50 N.A., it would be as 2 to ·66.

The depth of accommodation depends upon a point which was entirely new to microscopists until developed by Professor Abbe—viz., the peculiar property of microscopical amplification, by virtue of which the linear amplification of the depth of an object is largely exaggerated, being equal to the square of the linear amplification laterally. Thus an object magnified, according to ordinary parlance, 100 linear diameters (i.e. in breadth) is magnified 10,000 linear diameters in depth. Now the depth of accommodation varies in inverse ratio to this depth-amplification, that is inversely to the square of the magnifying power, so that whilst large with the low powers, it decreases very rapidly and disproportionately as the power is increased.

The joint effect, therefore, of the diminution in the depth of focus and depth of accommodation is that the total depth of microscopical vision diminishes, not in the same ratio as the increase in the magnifying power, but at first in a much greater ratio. With the low powers we have considerable depth of vision, as it is then chiefly influenced by the large accommodation-depth. As we proceed to the medium powers (100-300) the accommodation-depth very rapidly diminishes, and becomes equal to that of the small depth of focus, so that the total depth of vision is necessarily small also. As the power is further increased, the accommodation-depth ceases to have any influence, and the depth of vision becomes principally depth of focus only. If, for instance, an amplification of 30 times is increased to 300, the depth is reduced not to 1-10 but to only 1-50 of its original amount; or taking the depth of vision with a power of 10 times to be 2 mm., with powers of 30, 100, 300, 1000, and 3000, it is only ·254, ·0273, ·0017, ·00091, and ·00026 mm.

The formula

$$\text{depth of vision} = n\left(\frac{L^2}{N^2}\lambda + \frac{L}{N}\frac{\omega}{a}\right)$$

shows at once how much the depth of vision may vary by change in the conditions—represented by the various factors in the formula—which make up the total effect, important among which, as will be seen from the form of the equation, is the refractive index n of the medium in which the object is mounted.

Micro-Stereoscopic Vision.

The determination of the depth of vision (in monocular observation) naturally throws great light also on the conditions for effective micro-stereoscopic vision. It is obviously only when an object can be completely seen in all three dimensions at one adjustment of the focus, that a true stereoscopic image of it can be obtained. So long as only a single layer of inappreciable depth is visible simultaneously with any distinctness, no stereoscopic apparatus, however perfect, can bring into view the form of the whole of the object.

Now with low powers we have large visual depth, so that objects of considerable thickness can be seen as solids. By reason, however, of the rapid decrease of the depth of vision to which I have referred, the thickness of the objects which can be seen in relief rapidly and disproportionately decreases as the power is increased, so that only very thin objects are suitable with even the medium powers, the absolute depth, in the case of an object magnified 300 times, not amounting to a hundredth of a millimetre. With still higher powers the images of solid objects (though the decrease in depth is no longer so irregular) necessarily approach more and more to simple plane sections, the absolute depth with a power of 1,000 times amounting only to a micro-millimetre. For medium and high powers, therefore, the only objects suitable for the stereoscopic binocular are those which present, within a small limit, a sufficiently characteristic structure, that is, which have sufficient salient points for stereoscopic effect. We can, however, increase the depth of vision by using narrow illuminating pencils, and by mounting the objects in some highly refractive substance. The above considerations also show the importance of using the lowest power sufficient to recognise the object.

Whilst the reduction in depth limits effective stereoscopic observation, Professor Abbe properly points out that there is a compensating advantage in ordinary microscopic observation, in that as the depth-perspective becomes more flattened the images of different planes stand out from each other with still greater distinctness, so that "with an increase of amplification the microscope acquires more and more the property of an optical microtome, which presents to the observer's eye, sections of the object of a fineness and sharpness that no instrument could produce by mechanical means."

Another novel point was the demonstration of the very material distinction between ordinary stereoscopic vision and that with the microscope. The perspective shortening of the lines and surfaces by oblique projection, which is an important element of solid vision with the naked eye, is wholly wanting in microscopical vision, in which we have only the other element, a relative displacement of successive layers in the image. That these displacements are seen in the microscope, depends entirely on the peculiar exaggeration in the amplification of the depth of an object which is not found in ordinary vision.

The paper "On the Conditions of Orthoscopic and Pseudoscopic Effects in the Binocular Microscope" is also a most useful contribution to the theory of micro-stereoscopic vision, establishing as it does the true criteria for both classes of effects, and at the same time clearing up a misconception that had arisen as to the supposed necessity for the rays from the two halves of the objective crossing in order to get proper orthoscopic effect. If the delineating pencils have been reflected an even number of times in the same plane, the rays must cross, but otherwise not.

Mounting-Media of High Refractive Indices.

To utilise the full benefit of immersion objectives, it is of course essential that the object should be mounted in a medium, the refractive index of which is not less than that of the immersion fluid; and down to a comparatively recent date Canada balsam was most commonly used for this purpose, particularly for diatoms.

Mr. Stephenson, however, pointed out that although by the use of the balsam we have attained our object so far as the aperture is concerned, yet we have done so at the expense of the visibility of the resultant image, which has become fainter by the nearer approximation to equality of the refractive indices of the diatomaceous silex and the balsam; the visibility of minute structures being proportional to the difference between the refractive indices of the object and the medium in which it is mounted. Instead of balsam, therefore, media of high refractive index should be employed; thus, as the refractive indices of diatomaceous silex and Canada balsam are respectively 1·43 and 1·54, the difference ·11 is the measure of the visibility of a diatom in balsam. Using a solution of phosphorus in bisulphide of carbon, the refractive index of which is 2·10, the difference is ·67, and the visibility of the diatoms is now more than six times as great as it was in the balsam.

Continuing his researches on this subject, and endeavouring to find the best media with high refractive indices, he has quite lately brought before the Society the utility of an aqueous fluid capable of being given the high refractive index of 1·68, viz., a solution of biniodide of mercury and iodide of potassium in distilled water. This more manageable and highly antiseptic medium appears likely to turn out to be of great use in the observation of many objects, as its strength can be diluted till the index of water is obtained. This is of advantage with such objects as muscular fibre, which are themselves of high refractive power, so that fluids of low refractive power must be made use of to obtain the required difference for more perfect visibility. The same communication also contains what was much wanted, detailed practical directions for mounting.

Anyone who has seen the diatoms and scales mounted in phosphorus by Mr. Stephenson's method, and exhibited at our meetings during the past and present sessions, cannot fail to have been struck by the great increase in their visibility as compared with those mounted in balsam, or to have recognised the fact, that the theoretical consideration by which their visibility was pronounced to be much increased was not unfounded.

---

* Given at the meeting of the Balloon Society, on the 28th April, 1882.

[1] By Prof. P. MARTIN DUNCAN, M.B., Lond., F.R.S., &c. (Annual Meeting, 1882.)

In addition to the increase in visibility, there is also the fact that by means of such mounting fluids, the capacity of stereoscopic binoculars with the higher powers is considerably enhanced. True stereoscopic effect, as we have seen, requires a depth of vision not less than the thickness of the object under observation—a depth which, as already shown, increases in direct proportion with the increase in the refractive index (n) of the mounting fluid. If one object is in air when $n = 1{\cdot}0$, whilst another is in a solution of phosphorus, where $n = 2{\cdot}1$, the depth of vision will be more than doubled. Objects, therefore, that by reason of their thickness could only afford an unsatisfactory stereoscopic effect in air may be seen in full relief when mounted in phosphorus.

Here, again, the deductions of theory were remarkably verified by the recent exhibition of Surirella gemma, under the binocular, with a 1-25in. objective.

Relative Value of Objectives with Large and Small Apertures. ("All-Round Vision.")

I now come to a much-vexed question, that of the relative value, practically, of objectives of large and small apertures, in regard to which a great variety of opinions have been promulgated.

The oldest of these views was that which made the preference between the two kinds of objectives depend upon whether they were to be used for the "ordinary purposes of the biologist," or for the examination of diatoms or other lined objects. The objection to this view is, that it assumes the only function of a large aperture to be its resolving power, a much too-restricted notion, and one which deprives the working biologist of a most essential aid to his observations upon structure.

A more modern view errs in the opposite direction, and insists upon the universal superiority of large apertures, so that work done with small apertures will "have to be done over again."

There is again a third view, still more recently put forward, which goes much further than the preceding, and, according to which, it is impossible that wide apertures can give correct images. First on account of the unnatural "all-round vision" which it is extended is obtained with them, and secondly by reason of their supposed inherent defect in defining power, in consequence of the dissimilar images presented by the different parts of the enlarged area of the objective, with a confused image as the general resultant.

The want of exactness in the first two suggestions will sufficiently appear, when we have formulated the grounds upon which large apertures are shown to be indispensable for all observations upon minute structure for which high powers are necessary; but it will be desirable first to point out the erroneous interpretations upon which the third view (as to all-round vision and dissimilar images) has been founded, and for this purpose it will be necessary to refer to the paper by Dr. Royston-Pigott, F.R.S., in which the subject is dealt with.*

After reminding his readers that he had shown that spider-lines, miniatured down to the fourteenth part of the hundred-thousandth of an inch, were distinctly visible to ordinary good eyesight under proper microscopical manipulation (an experiment which, I may remark in passing, has not a satisfactory foundation), Dr. Pigott says:—"Under these circumstances it was interesting to know whether real objects could be detected by the microscope in the surprising degree of attenuation represented by the millionth." Minute particles of mercury were obtained by smashing some with a watch-spring, and they were mounted in petroleum under a thin cover. A vertical illuminator was used to converge rays downwards, through the objective, upon the preparation. In a darkened room minute discs become visible, and upon some of them clusters of minute black points were seen with a power of 1,000 diameters. Comparing them with a micrometer spider-line 1-10,000in. diameter, some of the points were found to be decidedly smaller. Under 1,000 diameters the particle was magnified one hundred times in the micrometric focus, and then appeared less than the spider-line. Its real diameter was therefore less than 1-100th of 1-10,000in., or less than the millionth of an inch, and the writer draws the conclusion that "real objects of unsuspected minuteness may be microscopically displayed as well as minute miniature images." To this part of Dr. Pigott's observations it may be pointed out that it has never been supposed, so far as I am aware, that there is any limit of visibility in the microscope other than that imposed by the sensibility of the observer's retina, the correction of the objective, and the illumination. The question of a limit of visibility is quite distinct from that of a limit of separation, just as in telescopic vision a single star is always visible, however small its visual angle, provided it is sufficiently bright, but a double-star requires a certain minimum aperture of the objective, dependent on the angular distance of both stars.

Discussing the variability of the blackness and thickness of the marginal annulus of refracting molecules, as exemplified in a glass spherule ·1in. diameter, and in the featherlets of the death's-head moth and plumelets of Hipparchus Janira with objectives of 20° Ang. Ap. power 200, and 140° Ang. Ap. power 800, he writes:—"If then the minute fibrillæ of the plume can be clearly distinguished as closely packed black lines at a visual angle of 20 seconds with a low aperture of 20°, this result is fatally opposed to the popular idea that very close lines, or very minute lines or bodies, can only be distinguished with large angular aperture. These lines were most sharply seen, though less than 1-80,000th inch thick." After noting the disappearance of distinctive shadows and consequent obliteration of structural molecules with excessive angular aperture, illustrating his meaning by the structure of Podura scales, with different stops and under very varying conditions, Dr. Pigott states that he has come to the conclusion that residuary aberration was not the only cause of the obstinate obscuration of minute crowded molecules in translucent organic forms, but that

"Excessive angular aperture, he found, attenuated margin . . . There is, it may be said, something unnatural in the mode of vision intrinsic to very high-angled glasses. It is undoubtedly true that such a glass presents an all-round vision. It really conveys visual rays from a given brilliant particle, at every inclination in azimuth and altitude, and this too at one and the same instant. To illustrate this position a minute die may be imagined the 1-100,000th inch broad. The highest angled objective really enables the observer to collect rays emanating from four sides and the top at the same instant. The human eye could at most view three sides at once. Doubtless the effect of this angular vision all round the corners, causes particles to look spherical, when sufficiently minute, even if cubical."

Now it is necessary to say plainly that this view is founded upon a fundamental error, "belonging," to use Professor Abbe's words, "to the venerable relics of the past *naïve* period of microscopical science, which was characterised by an unshaken conviction in the validity of the hypothesis that microscopical vision is in all essential respects the same thing as ordinary vision." The "all-round vision," by virtue of which we are supposed, when looking at a minute cube, to see at the same time the top and all the sides (with the result of rounding off the corners and angles!), does not really exist, as can be shown by the application of the simplest laws of geometrical image formation. The different obliquities of the rays in an objective of wide aperture cannot give rise to any all-round vision, for in the microscope there is no difference of perspective attendant upon oblique vision as with the naked eye. The difference of projection of successive layers which exists is ineffective, except in the case of binocular vision. This absence of perspective may be readily established by examining an object alternately by an axial and an oblique ray; it will be found that there is no shortening of the lines in the latter case, and no capacity in the microscope, therefore, for "all-round vision." Indeed, if this theory were correct, microscopical vision, even of plane objects and with very moderate apertures, would be entirely destroyed.

Equally mistaken is the second branch of the view which I am considering—viz., that a wide aperture must, in the nature of things, impair definition on account of the increase thereby produced in the dissimilar images received through the several parts of the objective. In support of this view, illustrations drawn from stereoscopic vision are adduced, which admittedly does depend upon the dissimilar images formed by the right and left-hand halves of the objective; but, as Professor Abbe has shown, the dissimilarity of images presented by an objective of wide aperture is a dissimilarity in the projection of successive layers only, and this is not effective unless we produce these images by different portions of the aperture separately and conduct them to different eyes, as in binocular microscopes. The sole effect of the wider aperture when the images are not so separated, is a reduction in the depth of vision—to confine us to the vision of thinner objects, not to impair the definition of what is seen when the objects are within the range of penetration.

If we pass to practical experience, we shall find that the principles which theory establishes are amply confirmed. All who have worked with wide-angled objectives cannot fail to have recognised the great fact of modern practical optics, the perfection of definition obtained with such glasses—a fact which has been verified by such authorities as Mr. Dallinger, who, so long ago as 1878, stated of a new ⅛in. homogeneous-immersion objective of the wide aperture of 1·25 that "the sharpness and brilliancy of the definition which this lens yields is absolutely unsurpassed in my experience."

The question of the power of resolution supposed to be possessed by small apertures can also be brought to a very simple practical test by those who believe in that view exhibiting here to the appreciative assemblage which they would have around them, say 75,000 lines to an inch resolved with the low apertures referred to!

We have seen that on the one hand the depth of vision decreases as the aperture is increased, and that on the other as the objects become smaller and smaller the similarity of their images increases with the increase in the aperture—the one representing a disadvantage attendant upon large aperture and the other an advantage—and bearing this in mind we are in a position to arrive at a correct view of the relative value of objectives with large and small apertures, which I take to be this:—

Both kinds of objectives are necessary for investigations into the structure of minute objects, and an observer, to be fully equipped, should provide himself with two objectives, one of moderate and one of wide aperture. The former would be used for the more general survey of the various parts of the object, and the latter for the subsequent examination of its minute structure. In searching, for instance, through a stratum of fluid for bacteria a wide aperture would be unnecessary, but when a particular bacterium is found, it is only that which will give us an accurate view of its flagellum.

But again, in the choice of the objectives, the proper relation between magnifying power and aperture must be maintained. For work with low powers it is useless to have large apertures. The structure of the objects for which such powers would be used is not sufficiently minute to require large apertures for their proper delineation, and we therefore expose ourselves to the disadvantage of very restricted penetration and the trouble of delicate manipulation, without any corresponding benefit.

On the other hand, it is equally useless to work with high powers (that is upon minute objects) with small apertures. We should have only an empty amplification—mere increase in the distance apart of the outlines, without any additional structure being made visible in consequence of the defect in aperture.

Whenever the subjects of our examination are so minute as to require high amplifications in order to be seen, then we must also have large apertures in order to obtain perfect delineation of the objects. Leaving now the theoretical questions, which, after all, have so important a bearing on our practical work, reference only need be made to the descriptions published in our Journal of new inventions in regard to mechanical and optical appliances (most of which have been exhibited at our meetings) to prove that great progress is being made in the designing, manufacture, and application of the microscope. Improved stands and eyepieces, new immersion lenses, stages, and swinging substages, more effective fine movements and elaborate accessory apparatus of all kinds, indicate not only the activity of mind and the abundance of the resources of the microscopical optician, but that these things are really required in a progressive science.

It is to be hoped that the possession of excellent instruments and convenient apparatus will incite many of the Fellows to undertake more careful researches into the minute details of organic nature, or amongst the very fascinating rocks which are being so beautifully cut and mounted by petrologists. It is true that the difficulty of getting upon a path of original research is very deterrent. The activity of Continental and American microscopists is indeed great, and it is always necessary, before committing one's-self to any statement, to search and prove its originality. Much microscopical research is quite beyond the powers of the man who has other avocations, and to whom the instrument is a pleasing, and none the less important, toy. Consider the paraphernalia required to study the microscopy of the details of a minute animal. It has to be put into hardening and water-absorbing solutions, then to be cut with microtomes, perhaps frozen in the first instance, then to be put into other solutions to be cleared and to have its fat got rid of, and then it has to be coloured once, twice, or thrice, and possibly to have some colour discharged. Finally, it has to be mounted in a medium. It is necessarily somewhat deterrent for a modest microscopist to read the excessively pronounced opinions of manipulators about the nature of the structure they discover in such complicated and altered organic matter, and to find that very contradictory opinions are published by different investigators about the nature of identical structures which have been differently prepared. It appears to many an amateur, who happens to investigate structures by disturbing their natural condition as little as possible, that he is, as it were, out of the field. He may find it necessary, even in examining the simplest section, to pay especial care to the illumination and centring, and to the application of particular powers. He is, of course, conscious of inferiority, when he knows that somebody merely puts a chemically-treated specimen under an objective without the least care about optics, and finds out, or thinks he finds out, the truth. But there are numerous opportunities for original research still to be met with in the structure of many of the commonest invertebrates and plants. The study of rocks is in its infancy, and there are many very interesting physical questions yet to be determined, and which can only be settled microscopically. Recondite manipulation is not much required in any of these researches, but rather a good knowledge of how to use the microscope as an instrument.

*Proc. Roy. Soc., xxxi. (1881) pp. 260-78.

SCIENTIFIC NEWS.

COMET *a*, as will be seen elsewhere, has been picked up by several observers. The absence of moonlight now and next week will probably render the comet a more brilliant object. According to Dr. Kreutz, its position for Berlin midnight on May 12 will be R.A. 14m. 24s., N.P.D. 15° 33′; on May 13, R.A. 38m. 56s., N.P.D. 15° 53′. It is in the constellation Cepheus, above the horizon at considerable altitude all night, but it will scarcely be observable without a telescope until the end of the month. The position for Greenwich midnight on May 12 will be R.A. 16m. 22s., N. Dec. 74° 26′. Dr. Kreutz, M. Bigourdan, and Mr. Hind, all assign June 10 as the date of perihelion passage.

The death of Prof. Zöllner, the famous Leipsic physicist, is announced. He was only forty-eight.

The following candidates have been selected by the Council of the Royal Society, and will be elected on June 8th:—Prof. V. Ball, Dr. G. S. Brady, Dr. G. Buchanan, C. B. Clarke, Francis Darwin, Prof. W. Dittmar, Dr. W. H. Gaskell, R. T. Glazebrook, F. Ducane Godman, J. Hutchinson, Prof. A. Liversidge, Prof. J. Malet, W. D. Niven, R. H. Inglis Palgrave, and W. Weldon.

Amongst the papers to be read at the meeting of the Iron and Steel Institute, held on the 10th, 11th, and 12th inst., may be noted that of Mr. E. Richards on "Certain Physical Properties of Iron and Steel," that of Mr. W. Annable on "The Compression of Fluid Steel," that of Mr. Snelus on "The Chemical Composition and Testing of Steel Rails," and that of Mr. Jeans on "The Consumption and Economy of Fuel in Iron and Steel Manufacture."

At the last meeting of the Shorthand Society Mr. J. G. Petrie read a paper on "Reporting and Transcribing Machines." The Danish, Bartholomew, and Michela machines, and their capabilities, were minutely explained. The last-named machine is in use in the Italian Senate, but Mr. Petrie showed, by a careful analysis of the results, that what was attributed to it was mainly due to its work being checked by a large staff of reporters and revisers, while the reports, before appearing in print, are corrected by the speakers themselves. He did not believe that any of the existing machines could do better work than could be done with the old note-book and pen or pencil; at the same time he advocated, from actual experience, the use of the type-writer for the transcription of notes, as it not only got out the "copy" more expeditiously and legibly, but also afforded a salutary change from the drudgery of the pen.

Amongst the most interesting models shown at the Shipwrights' Exhibition is a half-model of a steel twin-screw steamship, designed for the Transatlantic trade by A. McMillan and Son. The length of this vessel is 600ft., breadth 70ft., and the gross tonnage is calculated to be 10,000 tons. The engines will represent an indicated power of 20,000 horses, and the estimated speed is 20 knots, or 23 miles an hour.

The *Stirling Castle* has frequently made 18½ knots on her voyage out to China, and ran from Hong Kong to Shangai in fifty hours, at an average of 17·4 knots. The maximum speed was 19 knots, but the average was reduced by the necessity for slowing and stopping in the river.

The *Alaska* made her last voyage from New York to Queenstown in 7 days 53 minutes, thus eclipsing her own performances, which were the previous quickest passages.

The buildings erected to accommodate the biological students working with Dr. Michael Foster and Mr. F. M. Balfour at Cambridge, are so crowded that a new floor is to be added to the central portion of the new museums. The system now practised is for the students to go through the laboratory work immediately after each lecture.

Prof. H. A. Nicholson has been appointed to the chair of Natural History in Aberdeen, vacant by the removal of Prof. Cossar Ewart to Edinburgh.

The Friday evening discourse during the meeting of the British Association will be delivered by Prof. H. N. Moseley, on "Pelagic Life."

The reports relative to the Exhibition of Gas, Electricity, &c., held under the auspices of the Glasgow Philosophical Society, have been published. They refer, amongst other things, to trials of gas-meters, gas-engines, hot-air engines, &c., which should prove of some value. The engine trials are accompanied by plates of indicator diagrams.

The shareholders in Mr. Keeley's "motor" have obtained judgment in the courts in the shape of an order to Mr. Keeley to disclose the secret of the principle of the machine to them. Keeley refuses to comply with the order, and unless he is frightened by the threat to commit for contempt, the shareholders will probably not even obtain a bit of the "secret" for their money—over a hundred thousand dollars.

On Friday next the Surrey Scientific and Literary Society will hold their last meeting of the session 1881-82 at the Gauden Hotel, Gauden-road (next to Clapham-road Station, L.C. and D R.). The subject for discussion is "The Physical Constitution of the Moon," and will be opened by Mr. H. Sadler, F.R.A.S. Any readers of the English Mechanic who may wish to attend, must apply for admission-cards to Mr. John Weale, hon. sec., 15, The Grove, Clapham-common, S.W.

The question of the vital resistance of trichinæ in salt pork has lately engaged some attention in France. After sundry experiments, M. Colin expressed the opinion that American salt pork, under the present conditions of sending and delays occurred, does not seem apt to transmit trichinosis, though consumed raw or after imperfect cooking. Still, in very recent pieces, or in large pieces badly impregnated, there might remain some live trichinæ; the danger he regarded as slight, but as requiring some care. M. Fourment lately made the following observation: A piece of American pork in Havre, found to contain cysts of trichinæ, was put in fine salt in a vessel which was then kept hermetically closed for a year; add to this the time elapsing from its original preparation, and we have about fifteen months of salting. Now, M. Fourment took small pieces of this lard, and after soaking them some time in water, gave them to mice. The animals fell ill and died, and trichinæ of both sexes were found in their intestines. Thus, in salt meat at least fifteen months old, these parasites may continue alive and capable of development.

The piano manufacturer in Stettin, M. René, who a short time ago improved the durability of pianos for tropical regions, by preparing the wood with ozone, has lately devised a "cell resonance arrangement" for pianos, which is said to be highly appreciated. Inferior pianos acquire thereby the fulness and strength of a grand. In place of the usual sounding-board, M. René uses a sound-chest, over which the strings are stretched, and which, like the resounding body in many-stringed instruments, consists of two arched resonance-plates; the vibration of the upper are communicated to the lower through bell-mouths. The two plates are bordered with hollow walls; the bell-mouths stand on a bridge on the lower plate, and are firmly pressed against the upper plate. The sound-tubes are further connected by a membrane and small resonance rods with the upper plate. We may here note a recent new application of electricity, in the electrical piano of Boudet. An ordinary instrument is provided with two sets of hammers. The upper, electrical series comes into action when certain keys are pressed, and the corresponding hammers go on striking the wire at a quick rate, so long as pressure continues, giving an organ-like effect.

A large development of the wood-carving industry has taken place in New York within the last ten years. Nearly six hundred carvers are now at work for two firms, and as many as a thousand accomplished artists find employment in the city, mostly on interior decoration of houses. A rapid immigration of skilled carvers from Europe has reduced the wages; but the average pay of good carvers is still from four to five dollars a day, and the very finest workmen, especially those possessing some secret processes of doing difficult work, earn as much as eight dollars a day (such a process is that of ebonising cherry-wood). Machinery is now used to cut away the rough parts of a piece of carving; a tool driven by steam-power cuts out the wood wherever it goes, and thus a skilful man blocks out in a rough way as much work a day as twenty men could have done formerly.

A remarkable magnetic storm has been lately experienced. M. Mascart has described to the French Academy its effects as observed at the Collége de France. Indications of its approach began about April 6th, but its beginning may be dated at 11.15 p.m. on the 13th. A great shock occurred in the night of the 16th, affecting all the three magnetic elements, and the needle being much agitated from 11.45 till midnight (an oscillation of 25′ was observed). A similar shock on the 20th; after which the storm gradually abated and disappeared.

It has been proved that caoutchouc is highly absorbent of certain gases, especially the light-yielding constituents of coal-gas. In a recent note to the Berlin Chemical Society, Herr Hempel shows, from experiments, that its absorption of carbonic acid and nitrous oxide, though small, is such as to forbid its use in some very exact gas analyses. The absorbent power may be shown to an audience by connecting a carbonic-acid generator, or nitrous oxide gasometer, by means of a long caoutchouc tube with a glass tube, which is inserted in coloured water. All air having been driven out by a strong current of the gas, and the admission of gas stopped, the coloured liquid gradually rises in the tube, indicating gas absorption. Herr Hempel says that caoutchouc stoppers, tubes, &c., which still retain full elasticity, may be kept long from deterioration if placed in a glass case (hermetically sealed) along with an open vessel of ordinary petroleum. Keeping in wooden boxes is bad; so is exposure to light. Old stoppers that have become hard may be softened very quickly by placing in a vessel with sulphide of carbon vapour. In course of time this action proves too strong, and the caoutchouc should be likewise brought into petroleum vapour.

In a recent lecture in Berlin, Dr. Werner Siemens expressed a wish that in all technical schools in Germany, chairs of "Electrotechnik" might be instituted for instruction of youth in electricity and its applications. This has now been realised in the Technical High School at Stuttgart. One term will be devoted to theoretical principles, the most important measuring instruments and measurement, electrolysis, illumination, and transmission of force, and a second to telegraphy (including railway signalling and telephone matters.) Practical exercises will follow up the lectures. In 1876 a professor of telegraphy was appointed in the Dresden Polytechnikum.

A regular telephone system has been arranged between the Brussels Observatory and the meteorological station at Ostende (about 78 miles), after highly successful experiments with the Rysselberghe improved telephone.

The background of the eye is known to be red; yet no effect of this red colour on sight seems to have been formerly noted. An observation bearing on this has been recently made by Signor Emery. While driving through the streets, and reading a paper, the sun's rays illuminating the sheet directly, he observed the letters to have a fiery red look, the sheet appearing white. When reading the paper under diffuse light, some solar rays came obliquely into one eye, and thereupon the letters appeared red, whereas they looked black each time he shaded his eye against sunlight with his hand or the border of his hat. He supposes that the strongly-illuminated background of the eye affects inductively with its red colour the parts of the retina receiving the image of the dark letters. He records some laboratory experiments in support of this explanation.

The absorption of volatile matters is a problem which is still imperfectly solved; the industrial means employed are often inadequate. According to M. Schlœsing, the main difficulty is with the volatile matters which are in the form of powders (solid or liquid) suspended in a gaseous medium, and are without that proper mobility by virtue of which gases are absorbed by reagents. He therefore recommends the simple plan of bringing them through heat to the gaseous state, which they have lost by cooling; or, better, to prevent the cooling. He gives several instances, one being the case of an air-current charged with liquid dust of sulphuric acid, and sent into a tube filled with fragments of marine salt. So long as the tube is cold, it yields a mixture of fumes of sulphuric and hydrochloric acid; but if heated to 350°, fumes of the latter acid alone are given out. The sulphuric acid is caused to take the gaseous state, and is precipitated on the salt. M. Schlœsing proposes to apply the principle to determination of the nitric acid in the atmosphere, proved to exist there only in combination with ammonia, as a very fine powder, which would be transformed into vapour about 100°. Thus one has only, further, to find a good absorbent.

It has been recently observed by M. de Chardonnet that a plate of rock crystal, silvered so that it is opaque, forms a kind of filter, which is permeable only by the dark rays of the ultra-violet, and may be used for photography without intervention of a single ray of visible light. Very white crown glass, or even the thin glass of St. Gobain, will do instead of the rock salt; some of the most refrangible rays are lost, but this is largely compensated by the extent of the surfaces of admission. The time of exposure is doubled in this mode of impression (it can hardly be called photography), effected in complete darkness.

Like the ports of Havre and Marseilles, that of Bordeaux has been lately provided with elevator-boats (*bateaux-elevateurs*) for discharging grain-laden vessels mechanically. These machines have undergone an important modification. The steam-motor is replaced by an electric one; thus the elevators can be used for discharge of grain by day, but at night they are transformed into electric lighthouses, giving several bright centres, which illuminate the port like daylight. These movable lighthouses will serve in nautical fêtes during the exhibition soon to be held at Bordeaux.

USEFUL AND SCIENTIFIC NOTES.

The Internal Heat of the Earth.—Apropos of some statements as to the heat experienced in the deep workings of the Adalbert silver mine in Bohemia, which has now reached a depth of 1,128 yards, Prof. Höfer, who resides near, says that "at the greatest depth—some 1,000 metres below the surface of the earth—the heat is anything but excessive, the temperature of the rock being 24·4° C.—75·9° Fahr.—and the temperature of the atmosphere 24·6° C.—76·3° Fahr.—so that the natural means of ventilation heretofore employed fully suffice for all purposes."

THE Government have resolved to co-operate with the other nations in establishing a chain of circumpolar magnetical and meteorological observatories. The locality selected for a British station is Fort Rae, in the north of Canada, and the general superintendence of the work will be intrusted to a committee of the Royal Society, the Royal Geographical Society being asked to co-operate as far as regards the promotion of their special studies. The *personnel* of the expedition has not yet been selected. The Swedes have chosen Wyde Bay, in West Spitzbergen, for the site of their station, which will be manned by thirteen attendants, and is established at the cost of Mr. L. O. Smith, a merchant, who has placed £3,333, or 60,000 crowns, at the disposal of the Academy of Science for the purpose.

THE largest increase in the make of steel ingots and rails in 1881 appears in the Cleveland district, where 264,986 tons of ingots were obtained with fourteen converters, being an advance of 120,986 tons on the production of the preceding year. Of these fourteen converters, four were working for only a part of the year, and two for only a few months.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

COMET, 1882, *a* (WELLS).

[20012.]—I HAD an exceedingly fine view of this comet last night, which is getting a brilliant telescopic object.

The tail (which appeared in the finder about 100′ long) was decidedly brighter and better defined on the side preceding the comet's motion, and also looked broader near the head, as if double. The nucleus was very small and stellar with the power used (about 120), and there seemed to be some detail as of a jet of light from it towards the sun, but this was not certainly made out. The telescope used was my new dialyte of 10in. aperture.

Herbert Ingall.

Champion-hill, S.E., May 8.

[20013.]—ON several occasions I have had the satisfaction of viewing this comet by means of my 8½in. silver-on-glass reflector, the first time being on April 20th. It does not seem to me to be increasing in brilliancy so much as I expected, seeing that it is, according to some accounts, to be so bright as to be seen during daylight. Judging from what I have seen of it, I am much afraid we shall be disappointed in this. I last saw it on Saturday evening at about 10.30, and to me it did not appear very much brighter than it did on April 20th. A small bright star could plainly be seen shining through the tail a little behind the nucleus. The field of my eyepiece would cover about 38 minutes; power 100. The comet was between 79 Draco and 16 Cepheus.

Berwick-on-Tweed. **L. J. Fleming.**

[20014.]—I HAD a very good view of the comet on Sunday night at 11 o'clock, through my equatorial; the head is large, tail wide, nucleus not very bright, the whole a nebulous-looking body. It is now just visible to the unassisted eye 14° below the Polar star to the right. R.A. 22·40h., D.N. 76·30°. **C. A. Bowdler.**

South Lambeth-road, May 9.

JUPITER'S RED SPOT.

[20015.]—ON the evening of May 3rd (only 27 days before the conjunction of Jupiter with the sun), I observed the preceding end of the great red spot on the planet's central meridian at 6h. 59m. Clouds came up before I could note the later phases of the transit, and also prevented my observing the white spot, which I had computed would be nearly central at 8h. 15m. Definition was very bad, the planet being low and much in the glare of sunlight.

This is the last observation which it will be possible to make before the reappearance of Jupiter, as a morning star next July.

Bristol, May 5th. **W. F. Denning.**

LEGAL REPLIES.

[20016.]—INHABITED HOUSE DUTY (46810).—I do not think "Landlord" would be liable to pay this duty in the case put, as the value of the house would be below £20 a year; but if he is so charged, he must appeal against the assessment; this being the only way of settling the question.

CLAUSE IN A WILL (46821).—The legacies to the eight children of the brothers became "vested," as we say, at the time of the testator's death, although the payment of them was postponed during the lifetime of the cousins. This being so, the increase in value of the shares in which the £500 was invested would become part of that corpus, and would, therefore, be added to the whole, and thus to each share as it fell in, and could not belong to the residuary legatees.

(46839).—The promise made by D., the father, seems to have been merely verbal, and without consideration, so that I do not see how it could be held binding upon him, and still less upon his son. But there may be some way of proceeding against E. in equity as a trustee who has received property out of which debt should be paid; but for this I must know the case more fully. Of course, A., the original debtor, remains liable, &c., to be sued, even in America.

Fred. Wetherfield, Solicitor.

2, Gresham-buildings, Guildhall.

MEDICAL REPLIES.

[20017.]—SICK CHILD (47762).—Unless this child is suffering from rheumatism in the elbow-joint, it has disease of the bones of the elbow-joint. For this adopt the general regimen described last week under the head "Scrofula." Local treatment needs a splint, on which the arm can be fixed so as to give perfect rest to the joint; and compound mercurial ointment, spread upon lint, should be applied so as to cover up the whole joint, and bound on either by strips of adhesive plaster casing it in, or by a narrow flannel bandage. The dressing should be renewed once a week, and the joint will want care for many months. Cod-liver oil may be given as freely as the child can digest it, and general medical treatment will be required. If the parents can afford it, consult an able medical man in the neighbourhood. **James Edmunds, M.D.**

Grafton-street, Bond-street.

THE BARLOW LENS.

[20018.]—As some difference of opinion evidently exists as to the use, form, and position of the Barlow lens, perhaps the following may be of use to our readers:—The Barlow lens is an achromatised negative or concave lens, placed *within* the converging rays of an o.g., not so far as to cut off any of the cone, but far enough to give due effect to the diverging rays produced by its own form. Four inches from the field-lens of e.p. is a good position for the usual forms supplied by the trade. A simple diagram, however, will show how far towards the o.g. it may be placed. It is important to remember that the nearer the o.g. the greater the increase of power. The Barlow lens, then, is an adjunct to the e.p., producing an increase of magnifying power without necessitating a corresponding increase of tube length. In the forms I have made (some hundreds) I have thought the best position was with the *concave* side to the eye. However, I see that one of our able contributors advises the reverse of this. As this gentleman is a user, possibly, he may correct me, and I shall be glad to alter my mode, for those who *use* are able to give valuable hints to those who *make*. Another able and versatile contributor adopts the same plan as myself; but, and I must confess myself beaten, he makes the crown-lens convex and the flint concave. Now, the old formula for an o.g. *reversed*—viz., 5 flint positive, and 3 crown negative—is the data from which the original lens was computed, the figures for curvature coming out with the rather denser flint used now. Thus: First surface flat; second surface convex; flint = 1. Third surface, concave, 1; fourth surface, concave, 1; crown. So that the combination is a plano-concave with contact curves, and is usually cemented to prevent loss of light by reflection as much as possible.

As many possessors of old-fashioned telescopes are debarred the use of that pain-saving appliance, the zenith e.p., on account of the old tubes being too short for their adaptation, I will suggest to them the addition of a tube to carry a Barlow lens attached to the zenith diagonal. This will, in many instances, lengthen the focus sufficiently to allow of the zenith e.p. being used without the expensive and often destructive cutting away of the eyepiece end of the instrument.

Prismatique.

TO "ORDERIC VITAL."

[20019.]—As I regard the method of figuring mirrors by diaphragms, I have no preference for either of the ratios you name.

G. Calver.

MICROSCOPY.

[20020.]—THERE must be many readers sorry that this subject is so little treated of. My purpose in writing at present is to call the attention of beginners to a very interesting and easy method of examining the circulation of blood in a tadpole's tail, and as the season for these animals is nearly over, those who wish to try it should do so at once. All that is required is to take a hollow slide, or make a little trough by converting four little strips of glass on one of the 3in. by 1in. slips, so as to make a shallow cell of such a size as will contain a tadpole covered with water. After placing the tadpole on its side in the cell, and covering with water, drop a small quantity of chloroform over its head. Let the quantity of chloroform be very small, and rather add to it if after a few seconds the tadpole is not quieted. In this method there is no pain to the tadpole, nor risk of bruising it as when it is put under pressure, and should too much chloroform have been given, it could not die in an easier way.

The tail ought to be examined carefully for the best part, and with a little search a place may be found where both a vein and an artery are in the field at one time, showing in the artery the regular pulsation, and in the vein the steady flow of blood, the pulsation being lost in the capillaries.

Volvox.

WENHAM'S NEW MICROSCOPE.

[20021.]—There is one point in connection with "Wenham's new microscope," which was entirely omitted in the description given of the instrument when exhibited at the Royal Microscopical Society; when recently described and illustrated in the English Mechanic; and now, again, when reviewed and criticised by "F.R.M.S." The point omitted is as to the source of the inspiration from which Mr. Wenham drew his design—a source which is upon record beyond the possibility of cavil or doubt, and is proved as follows:—

On Nov. 10, 1880, at the Royal Microscopical Society, Dr. W. B. Carpenter exhibited and fully described a small rough stand made for students' purposes by Mr. George Wale, and the record of the proceedings of that meeting will be found in the *Journal* of the Royal Microscopical Society for 1880, p. 1087. From that published record I extract the following paragraph:—

"Dr. Edmunds pointed out that this most useful microscope-stand would be vastly improved if only the arc upon which the body turns were so constructed that the centre of the circle of which the arc forms part, were made to coincide in position with the centre of the stage. The object would then undergo no movement of translation, either in rotating the stage or in turning the optical tube from the vertical to the horizontal. In rotating the stage, the object would turn upon the optic axis; in moving the tube into various degrees of obliquity from 0° to 90°, the object would rotate upon its horizontal axis. The result would be that, with a thin stage and a hemispherical lens in immersion contact with the under surface of the slide, all the complicated swinging substages, and other contrivances now upon the table might be swept away, and every angle of illumination could be got by merely inclining the body of the microscope upon its sustaining arc. There would only be needed a lamp on a level with the object, with a condenser at its focal distance standing upon the table in line between the lamp and the object."

If any further explanation of the description here given by Dr. Edmunds be needed, reference to p. 1046 of the same number of the *R. M. Journal* will show a woodcut of Mr. Wale's microscope then under discussion. But Dr. Edmunds' description is so lucid that there can be no question as to his priority of design in regard to the great new principle of microscopic construction, which "F.R.M.S." now tells us, that "Mr. Wenham has grasped," and about which in his last paragraph ("E. M.," page 195) he describes Mr. Wenham as "the inventor of the new microscope." The microscope made by Watson and devised by Mr. Moss, and published a few months since in the English Mechanic, is merely an earlier stand constructed to embody Dr. Edmunds' principle.

Rights of priority are decided by the date of publication, and on that ground only the merit of this important principle of construction is plainly due to Dr. Edmunds, and to him alone. But it can be evidenced that in thus indicating how Mr. Wale's microscope might be so easily transformed in principle, Dr. Edmunds did not contribute to the discussion a mere casual idea suggested by Mr. Wale's microscope. Dr. Edmunds had already thought out and planned a microscope-stand upon the principle of *making the object a central point undergoing no movement of translation, and of arranging the microscope to move about this point as a general centre.* And the drawings of that microscope made in 1878-9 by Dr. Edmunds show a stand far superior in simplicity and efficiency to either of those constructed by Mr. Watson or Mr. Wenham. But the question of priority of title does not turn upon ideas described in a private cabinet or elsewhere than in a scientific journal, and no more need be said on the matter.

The engraving of Watson's stand appeared in the *Journal* of the Royal Microscopical Society for June, 1881, more than six months after its principle had been enunciated by Dr. Edmunds. The engraving of Wenham's stand appeared in the *Journal* of the Royal Microscopical Society for April, 1882, about eighteen months afterwards. On comparing the engravings of the stands of Wale, Watson, and Wenham, their progressive genesis will be understood. Wale's arc had no relation to the object aimed at by Dr. Edmunds, but was transformable, so as to subserve that object roughly and imperfectly for a student's microscope. Watson's stand embodied Dr. Edmunds' principle ambitiously; but by making the horizontal axis of the object turn upon a lateral pivot instead of a meridian arc, Wenham transformed the Wale sliding arc upon the principle suggested by Dr. Edmunds, and baptised the transformed arc as a "sector," so as to shelve Mr. Wale altogether. The beautiful workmanship of Ross and Co., notwithstanding the "sector," proved a rickety and unmanageable contrivance, and, in order to get fairly good results out of "Wenham's new stand," he had to adopt a second cross motion in altitude consisting of Watson's lateral pivot.

Into the criticisms by "F.R.M.S.," upon the fine adjustment and other points I do not now enter, but when "F.R.M.S." says that a thoroughly efficient fine adjustment is a problem still unsolved, he shows that he is not familiar with the beautiful and perfectly efficient and durable fine adjustment upon Powell and Lealand's best stand—a fine adjustment which every critic knows to be first, and the rest nowhere. But the beautiful hand-fitting of Powell and Lealand's work cannot be multiplied indefinitely, and what we want is an equally good fine adjustment that is more generally applicable.

The design by means of which Mr. Wenham has carried out Dr. Edmunds's principle of construction is more fit for a furniture microscope than for scientific work. Its machinery is burdened with useless and rickety complications, and anyone understanding the geometry of the sphere as utilised by Dr. Edmunds for this principle of construction, will at once see that with the object centred upon a revolving stage, and *one* movement in altitude, all possible illuminations are at command. The duplication of the movement in altitude confers upon "Wenham's new microscope" an original feature, and adds, possibly, to its value for exhibition in a chemist's shop-window. But, otherwise, it entails only expense and instability.

Another F.R.M.S.

PROPERTIES OF LENSES, &c.

[20022.]—I am unable to give a definite reply to the queries of your correspondent "Lens," and must, therefore, refer him to "F.R.A.S.," or some other reader, competent to deal with such matters in a satisfactory way. I have endeavoured to answer such of his questions as seemed to fall in my line, and am glad if my two letters have been of service to him. Undoubtedly, the size of the focal image of a fixed star will vary with the quality of the instrument. I remember reading somewhere of Andrew Ross saying: "The more perfect the telescope, the less will be the size of the stellar image"—a remark which drew forth the observation, "Then in the most perfect telescope there will be no star at all." But, putting jokes aside, there is, I presume, a definite formula giving the magnitude of image due to a certain focus and aperture. What this is I shall be glad if "F. R. A. S." or Dr. Edmunds will tell us. Airy's book "On the Undulatory Theory" will, no doubt, go fully into such matters, but I and many others have not had the advantage of reading this masterly treatise.

With regard to the rider extracted by "E. C. A." from the "Cambridge Mathematical Tripos for 1881," there is no difficulty in the proof. It is not likely to interest very many; however, I send it. Let us put the literal rule into an algebraic form: R and F being the radius and focus of the large or "concave" mirror, r and f those of the smaller or "convex," and x their distance apart; then the rule says that $\sqrt{R^2 + 4r^2} + R - 2r = 4x$. To prove this, draw Fig. 1, representing the path of the rays. A ray, AB, parallel to the axis, striking the large mirror at B, is reflected so as to cut the axial ray in E, whose distance, DE, is half the radius DH, or the focal length F (= DE) is the half of R. Now, instead of the ray being allowed to cut the axis, it is intercepted at C by the convex mirror and reflected to the point D. Hence, the points D and E are conjugate foci of the mirror CF. Now, if GF be the radius of the small mirror, the distances DF, FE, and FG are connected by the relation 2 . EF . FD / (FD − FE) = FG. Or, putting the proper algebraical values [$EF = (R/2 - x)$, $FD = x$ and $FG = r$], we have $2x(R - 2x) / 4x - R = r$. Or $4x^2 - 2x(R - 2r) = Rr$. I shall not occupy space with the solution of this quadratic equation; but if any reader works it out, the answer will come out, $4x = (R - 2r) \pm \sqrt{R^2 + 4r^2}$, which is that required.

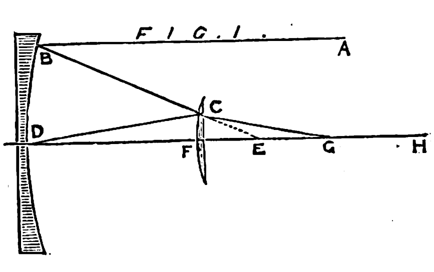

FIG. 1.

I fancy this would be more convenient if put in the following way, and though it is not so accurate, yet it will give the distance approximately, which is all the best rule can do:—Extracting the root of the second quantity to two terms only, it gives $R + 2r^2 / R$. Hence, the whole value is $2R - 2r(1 - r/R)$; or, dividing by 4, we have $x = R/2 - r/2(1 - r/R)$. Now, the semi-radii are the principal focal lengths of each of the mirrors, so that we may put $x = F - f(1 - f/F)$, or $(F - f) + f^2 / F$: or, the distance of the mirrors apart must equal the difference of their foci, increased by a quantity obtained by squaring the lesser focal length and dividing it by the greater.

In the Gregorian form, I find the distance apart should be the sum of the foci, diminished by eight times the square of the shorter focus divided by the longer.

Such rules for both instrruments can only furnish a rough guide for placing the small speculum; for it is assumed that the image is formed at the vertex of the large mirror, which, I need scarcely say, is not the case.

In response to Mr. Brashear's kind notice of my letters, may I be allowed to say that it is a source of much pleasure to me to find that my contributions are of some slight service to "our" Transatlantic friends; and to assure Mr. Brashear that I, and I am sure very many others, eagerly peruse his characteristic and instructive letters, and trust that he will favour us with his account of the practice of the famous American opticians, as soon as convenient. With his well-known success in extending the circulation of the English Mechanic, I hope he will be able to persuade Dr. Hastings to contribute to these columns. **Orderic Vital.**

THE NEW TELEPHONE RECEIVER—SMALL DYNAMO MACHINES.

[20023.]—According to your correspondent in last number, I am singularly unfortunate in my telephonic invention, as it had been previously publicly described. Will he please inform me where it is mentioned that the spiral was surrounded by three bobbins of insulated wire for the purpose of magnetising it, and receiving the inducted or microphone current? I think he is unfortunate, as his first letter does not mention anything about it, and his second letter is almost a repetition of the first, with the exception of the latter paragraph; and all they could do with it was to receive whistling and singing, which any simple receiver would do. The surrounding of the spiral with coils for the purpose as described above, is just as essential as a magnet is to the Bell telephone; and I beg to inform him that I never saw any account where the spiral was used before.

How much more unfortunate must be the patentee of this receiver?

To show how it is possible to make a small dynamo machine, I have made one which only weighs 6lb. 14oz. There is action and reaction; it will charge an electro-magnet, &c., quite as well, in proportion, as a large one. Will send more particulars later on.

George Tolman.

A SIMPLE BAROMETER.

[20024.]—The following is a description of a very simple and inexpensive barometer. Whether anything resembling this has ever been described before I cannot tell; but I have consulted all the books on Physics which I possess, and none of them contain any mention of it.

Take a glass tube about 7in. long, and about ⅜in. internal diameter, and draw out one end before the blowpipe to a point, leaving a very small orifice about 1-100 to 1-60 of an inch diameter. This end of the tube should not be quite sharp, but somewhat rounded, as in Fig. 1. A cork is prepared to fit tightly the wide end of the tube, and if the cork is made of *cork*, its sides and upper end should be greased or coated with paraffin, the lower end being left uncoated. A rubber cork would answer better. The tube should now be filled with distilled water, to the height indicated by the line (although the exact height is of no consequence), and the cork firmly inserted. The tube should be suspended with the point downwards near the window, and it should never be shaken. When the barometric pressure is low, indicating rain, a drop of water will appear at the orifice, and hang to the lower end of the tube. When the barometric pressure rises, the drop will disappear, and a bubble of air may sometimes be seen in the act of entering by the narrow opening. If more than one drop is extruded, of course they will fall, but one drop will always remain suspended. I have had a tube of this description hanging in my laboratory for two years, and I find its indications for rain and dry weather most unerring. The only error arises from extremely sudden rise of temperature, which will sometimes force a drop of water out by expansion, although the barometric pressure is high; but in that case the drop soon dries up: in the other case it hangs persistently, and will in many instances indicate the approach of rain thirty hours before the appearance of the storm. Before rain the drop does not dry up, because then the atmosphere is saturated with moisture. The sensitiveness of this weather-glass depends upon the difference of tension between the surrounding atmosphere and the air within the tube, the latter expanding or contracting according as the barometric pressure is low or high. Fig. 2 is simply a modification in which a glass phial is used with a perforated cork, through which passes a short piece of glass tubing with a narrow orifice at the lower end.

FIG. 1.

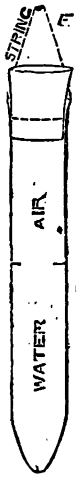

FIG. 2.

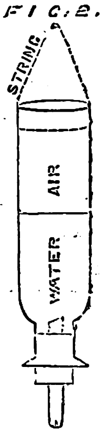
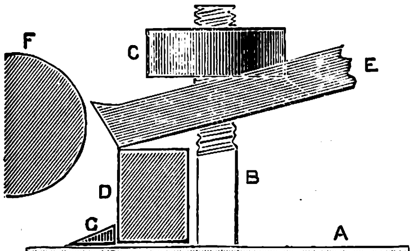


George Hay, M.D. Analytical Chemist.
Analytical Laboratory, 45, South Diamond-street,
Allegheny City, Pa., U.S., April 17th.

A MAKESHIFT.

[20025.]—THE accompanying sketch represents a rough and ready device, which being original (if anything is such under the sun), I venture to describe in the hope that it may prove of some use to beginners in turning, and who do not possess that amateur's delight, a slide-rest. I am myself a veriest tyro, the device being sufficient proof thereof. A is a piece of iron, say 4in. by 1½ by ¼, a hole through centre receives a ⅜ screw bolt 3in. long; B should be a tight fit in hole. This, with the requisite nut C, is the whole affair. Now, for its application as represented—D is cross section of arm of T-rest, E turning-tool, F the work. Now let the handle of tool be firmly pressed *upward* with one hand while the device is held in position with the other, so as to jam the tool as it were between D and C, when I think many a first attempt to turn a piece of metal in a common lathe will result in encouragement instead of despair. Note—the nut C should be a loose fit so as to be easily adjusted, all being in position and without disturbance by a touch of the thumb of the hand holding the device. A stop, as at G, may perhaps give a steadier hold, but I have not found it necessary, more adjustability being possible without it.



C. O.

LATHE MATTERS.

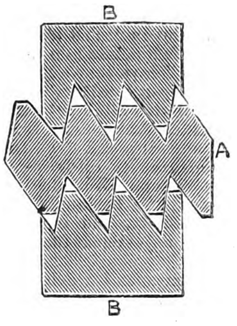
[20026.]—IT would seem, from recent correspondence, that others concur in my opinion respecting the value of a list of dimensions of lathe parts. May I reiterate my request to Mr. Evans to furnish a table of the dimensions of the apparatus he has so ably described. Now that we are to have a series of articles on pattern-making, such a table will be all the more valuable.

I should like to hear more about the lathe with slide-rest in front of the bed. Can Mr. Storey or others furnish further particulars.

Orderic Vital.

ORNAMENTAL SLIDE-REST.

[20027.]—As "M. A.," letter 19980, still does not seem to understand the principle on which the divided nut of my slide-rest acts, I give an exaggerated section of the nut and screw—A is the screw and B B the nut: the small triangular spaces left unshaded give room for tightening, and are formed by first cutting both screw and nut full and sharp, and then taking off the tops of the thread in both. I think anyone can see how the threads wedge into each other on drawing the halves of the nut together. In practice, the top of thread of steel screw should be rounded off so as not to cut a step in the thread of nut, which would prevent the wedge action, and both should be cut deeper and coarser than a Whitworth screw of same diameter. With regard to the query I asked "M.A.," of course I knew perfectly well that practically the dilemma of tapping the holes in the halves of the nut was easily explained and got over; I only asked it to show him how my not having fully gone into the minutiæ of fitting my nut and screw had exposed me to his criticism. "M. A." gives me a very good answer to my insinuation of his quoting Mr. Evans.



F. W. G.

CUTTING-FRAME.

[20028.]—THE cutting-frame illustrated by C. E. Sibley (No. 20005) is very similar to the wheel-cutting frame described by me in the number for April 14th, with the exception of the swivelling arrangement, which is perfectly useless for the purpose of cutting oblique gears, as when using it set obliquely, it would require a special slide to move it, the motion of the slide-rest not being available in that position. But when using it as a fly-cutter, in turning spirals, of course this mode of setting it at an angle is useful, though, for my own part, I prefer another tool. In the illustration there does not appear to be nearly room enough between the circular cutter and the driving-pulley, and in cutting anything of a good-sized wheel, the driving-pulley, if sufficiently large to give power, would touch the top of wheel to be cut. This, of course, is a mere matter of detail in making, and could be easily remedied; but it is against using this as a fly-cutter vertically that the chief objection lies. I made two or three instruments formerly, of different proportions, very much after this pattern, to be used as fly-cutters, and discarded them all in favour of the one I illustrated in the number for April 7th, for one very grave fault, and that is, that when using it vertically, to ornament any work that has a raised moulding or collar at one end, the end screws, and part of head through which they pass, come against the work, or perhaps the chuck, and prevent you commencing your ornamentation close up to the collar. The driving-pulley also must be very small, to allow the tool-point to touch the work. In these respects I have found my pattern much more convenient, and it is just as easily made; and anyone who wishes can make the head swivel round, by substituting a binding-screw for the pin which keeps the head on the square shank.

F. W. G.

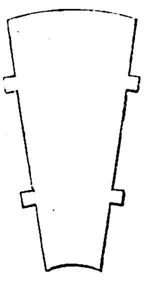
IRON MOULDING.—No. III.

[20029.]—IN my last letter the spindle, loamboard, and guide were ready for the moulder to commence the building of one of the four blades. Suppose the boss to be 3ft. diameter, a base-plate will be required, 7ft. long, 4ft. broad at one end, running to 2ft. at the other. The inner or narrow end of plate will be placed against the bearing or guide that has been built at the bottom of boss, and the centre of broad end of plate will be laid down opposite to the centre line on outside bearing, taking care to have a firm bed underneath, so as it will not sink with the weight of building. (For plan of plate see sketch.) Before any building is done, the boss and bearing at the bottom is coated with parting blackwash, made with clean water and blacking. Some building loam, made from floor sand and clay-water, is now put round the edge of plate, and a 4in. or 9in. wall is built, leaving some of the joints at the back or end wall open, to allow the steam to escape when drying, and the gas when casting. In the inside of the wall bricks are put, but no loam, keeping them a little apart, and filling the space with cinders or small coke, which are rammed tight into the joints so as to keep the bricks firm. The cinders also serve as a channel to carry off the steam and gas; and by so building the mould does not require so much drying as it would if built solid. This kind of building is what is called dry building. The loamboard is now let down the guide to see that the bricks on the face of the building are ½in. clear of the face of the loam board or sweep. Another row of brick is now built along the face, always keeping them ½in. clear of the board: then the wall is carried all round, keeping the end and back wall perpendicular; after that the dry building is repeated same as last course. Each course is now built in the same manner, till the wall is about 9in. broad, when no more dry-building will be necessary; the remainder will be built solid with brick and loam, so as to have it strong. Each course of brick that comes against the boss is rubbed with, and bedded in, red loam, having ¾in. on the face of brick. Where the blade joins the boss, loam bricks are built in so as the sharp edge can be rubbed off and the one rounded into the other.

Loam brick is made of loam in the same manner as common brick is made of clay. Red or facing loam is made of coarse sand and clay-water ground in a mill. The best sand for loam moulding comes from Lough Neagh, Ireland. It is coarse and open, not given to crack when dried, or scab when casting. The North of Ireland contains large quantities of red sand and rotten-rock, which is suitable for any kind of moulding. Large quantities leave several ports as ballast.

Having the brickwork of one blade finished, and looking at the outside end, it will have the appearance of Fig. 2. The angles that are formed by each course of brick being kept further back, so as to be clear of the loamboard coming down the guide, are filled up with loam brick cut the shape, so that when the facing-loam is put on there will be an equal thickness all over the face, which by so doing insures a level and correct surface. Having got the surface of the building made parallel with the travel of the loamboard, a thin coat of soft loam is first put on, so as it will adhere to the face of the building. Afterwards, a second coat is put on more stiff than the first one; then, for the third and finishing coat, soft loam is taken (after having been put through a sieve to extract any pebbles or foreign matter that it may contain) and spread over the surface. The face of the board is now made clean, and brought down the guide as steady as possible. The loamboard is now placed on the guide over the centre line, and along the edge of the board a line is drawn on the face of the blade, which will run to the centre of boss: and for the present the face of the blade is finished. The building of the other three blades is performed in the same manner (as the blades are to be lifted from their bed and baked in the oven); at the bottom of boss, where the bearing is, a joint is required down to the base-plate, and some paper or parting sand put on, so that when the blades are lifted they will part from each other without breaking.

FIG. 1.



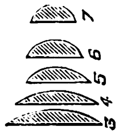


FIG. 2.

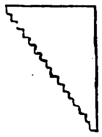

FIG. 8.

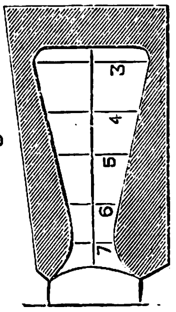
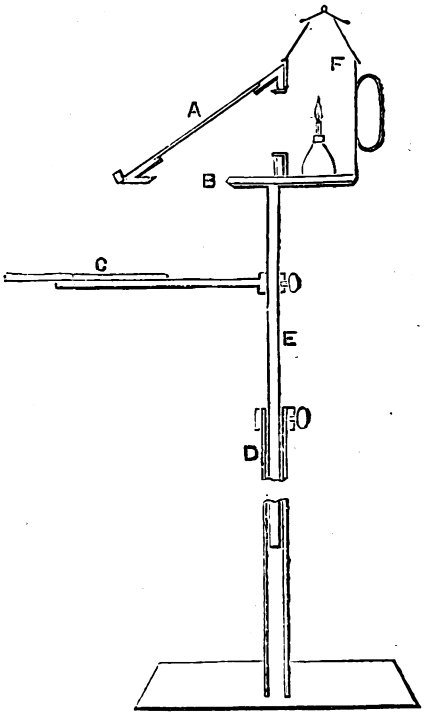


When the fourth blade is built, the first one will be stiff and ready to commence anew. At the top and bottom of the boss there are two portions of the blade that could not be swept; this the moulder makes good with his trowel, so as to have it in harmony with the finished portion. The pattern-maker now supplies three pieces of wood, which are called sections. Figs. 3, 4, 5, 6, 7, and Fig. 8 show sections and their positions on the mould. Where the sections are to be placed, a notch is cut, or the point of a nail is driven into the face of loamboard, so as to form a line on which the sections are placed. When in their place sand is rammed firmly between each, and pared off level with the back and sides. A little care is required so as to have the curve as regular and graceful as possible. When finished it forms a pattern for blade. The sections are then taken out, and the space filled up with sand. The same process is gone through with the remaining blades.

Foundry.

SKETCHING WITH THE TELESCOPE.

[20030.]—I SEND you a drawing of a device I have made for sketching with the telescope. It does not need a detailed description. The principle



is that light from the lamp is transmitted through the sketching paper at A, A being a piece of glass. The opening B is for the passage of reflected light to a book placed on C. B may be closed when desired by a paper or metal slide. The drawing is about ¼ of the size. This stand is cheap, being made of thin wood, and the stem of a piece of wrought-iron pipe, with sliding rod and tightening screw. I do not know that my device is new, but I think it is here. I use a fine 8¼in. reflector by your genial correspondent Mr. Brashear. It is excellent in workmanship and defining power. Of my observatory I hope to be able to write at some future time.

Francis G. du Pont.

TWO-MANUAL AMERICAN ORGAN.

[20031.]—I SEND, according to promise, the details of a scheme for a two-manual reed organ, which I have nearly completed. I may commence by saying I had no knowledge how the larger kind of instruments are constructed by the makers; so I only had my own devices and the ENGLISH MECHANIC to work upon. It was required to place a two-manual action in a case, whose revolving cover is shown at K, Fig. 1, with three or four sets of reeds on the top manual, four or five on the bottom, and whose top manual could be placed as close as possible to the lower one. Fig. 1 shows a section of the action from front to back. It is not drawn exact to scale, as the sizes are so small. The bottom-board B occupies the full play size (Fig. 4)—viz., 51in. by 20in., and carries the tube-boards and bellows in the usual position, and also the stop-action at the sides; and slides on bearers fixed to the case. The bellows are of the usual description, only the ratio between reservoirs and feeder size was increased in favour of the latter, with the idea of getting better expression. Reservoir 50in. by 25in., with a 7½in. fall, and having two 24lb. springs; and feeders 22in. by 24in. with an 8in. fall, and having a 9lb. spring to each. The webbing is attached in such a position that it travels 6in. only. The following stops were decided on, and labelled thus: (the numbers correspond to those on Fig. 1).

LOWER MANUAL.

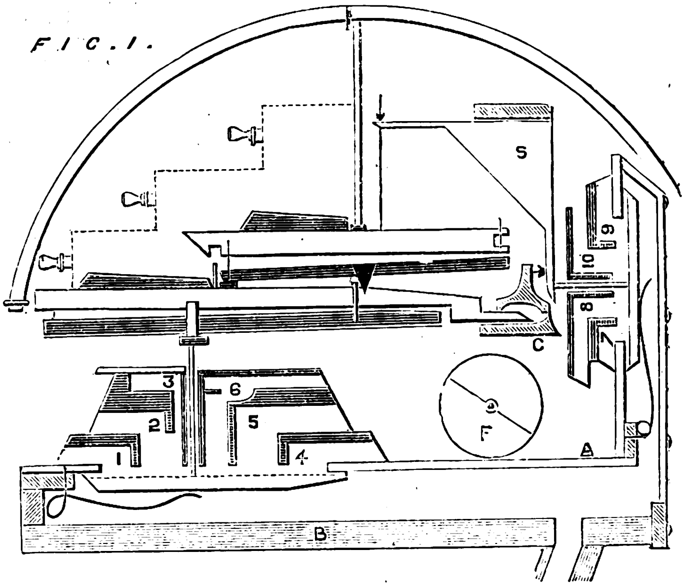
1.	Diapason ..	.. 8ft.	5	octaves
2.	Vox Celeste	.. 8ft.	3	,,
3.	Dulciana ..	.. 4ft.	5	,,
4.	Bourdon ..	.. 16ft.	5	,,
5.	Trumpet ..	.. 16ft.	4	,,
6.	Hautboy ..	.. 8ft.	5	,,

UPPER MANUAL.

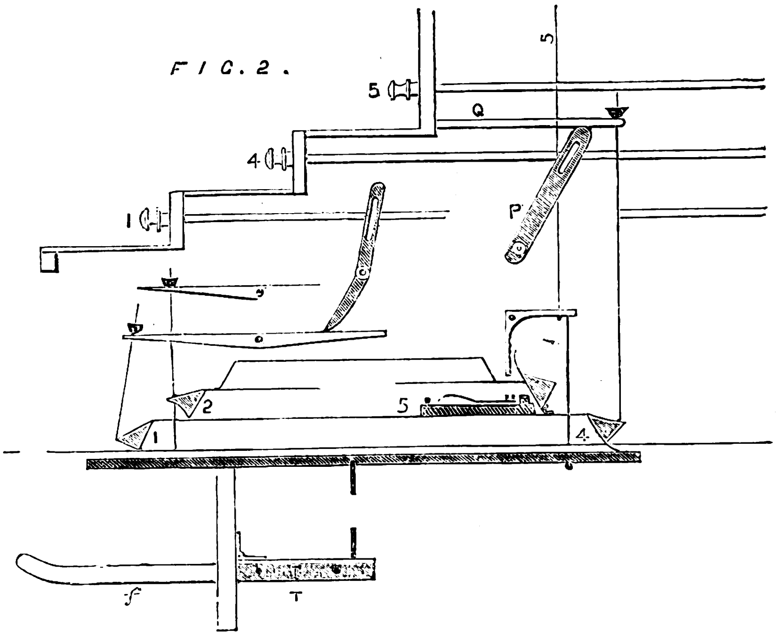
7.	Principal ..	.. 4ft.	5	,,
8.	Vox Humana	.. 16ft.	3	,,
9.	Gamba ..	.. 8ft.	5	,,
10.	Piccolo ..	.. 2ft.	3	,,
11.	Coupler.			
12.	Tremolo.			

Two Knee-swells.
Two footirons for full organ.

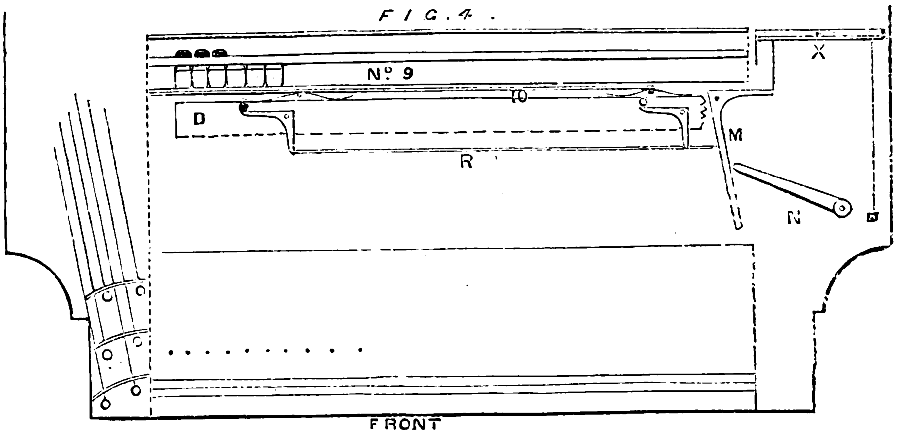
F I C . I .



F I C . 2 .



F I C . 4 .



The soundboard A is cut in two portions, and fixed over the bottom board at right angles to each other as shown; the horizontal portion carrying the lower manual reeds, and the vertical portion the upper.

The reeds used were the Munroe, except Nos. 5 and 10, which are ordinary harmonium reeds. The Munroe reeds are simply excellent in workmanship and disposition; in fact, good-tempered enough to please every one. I should say, as it seems impossible to break them with bending. I have a scratch set which have undergone some curious contortions since being in my possession. They are also of shorter scale than some at the bass end, which is an advantage in a large board. The tube-boards shown had of course to be made (no joke, by the bye, for it is a very tedious job). Having selected the reeds and arranged them, the tubes were cut as follows:—A row of holes was made to form the back-end of the tubes, and the remaining portion was removed with a dovetail saw and a ¼in. firmer chisel. Having served all the registers this fashion, I made a spindle working through a table vertically, and carrying a small circular saw, which would cut the groove to receive the reed, the screw-cap which fastened the saw being the same size as the tube. Great care and good tackle were requisite to glue these tube-boards together, and to the soundboards. The voicing in the reeds was done for me, in the principal sets; the rest I managed myself in making the tubes—for a great difference can be made in the tone by this means. I will try to describe the bending, &c., in the different registers. No. 1, tubes ordinary size, the reed bent and twisted as described in a former volume, by Elève and another correspondent; No. 2, ditto, more bend, consequently softer; No. 3, less bend, tubes vertical and only ⅓ the usual size, and also fastened down in a stuffed box—therefore, very soft; but they seem to waste a lot of wind in this position, and are rather sluggish in speech. No. 4 same as No. 1, but the position in the board alters the tone. No. 5, harmonium reeds, a thin set which required no filing down, but I was devoutly thankful when finished, as they were a lot of trouble. The frames of these reeds had a slot formed at the tip end, and a round-headed screw was placed in the tube-board before glueing up, to receive them; the heel end being fastened down by another screw. The tongue was much bent at the tip, but no twist, and the tone is very strong and rapid. No. 6, tube double the length, and one-half the size of No. 1; the reed is inserted heel first, so that the wind strikes the tip first; no bending, but a little twist; very reedy, quiet tone, and very delicate touch, which latter rather surprised me, as, being so far from the wind, I was afraid they would be sluggish. No. 7 as No. 1. No. 8, tubes one-half the size, the bending and twisting confined to near the tip. No. 9 as No. 1, only less bend, more twist, tone more cutting. No. 10, harmonium reeds screwed on merely, but the tone is a failure, and they will be removed, and replaced by American reeds in tubes, as shown. The two manuals are fastened together at the ends by thin plates, and slide in position from the front on one bearer at each end. Nos. 1 and 9 were tuned with the keys in their place, and the remainder of the tuning was done by means of the plungers.

The lower keys rest on the plungers in the usual manner, only they have a ⅜in. wood pin projecting the thickness of the key-frame, in order to clear the plungers when drawn forward, and the latter are provided with a screw-button.

The upper keys are suspended, by means of a tapped wire, from the set of squares S, which, in turn, rest on the plungers of the upper soundboard. These tapped wires are not fixed in the squares, but fit tightly in a dovetail notch cut in each, so that they can be drawn out and replaced easily.

I suppose, when Mr. Fryer looks at these sketches, he will say it is an utter impossibility to get at the reeds, as he creates such a large mountain out of so small a mole-hill in his letter (46296, p. 157) about the sketch I suggested for "Beta's" alteration. For my own part, I appreciate the advantage of sitting comfortably in front of the instrument during tuning, &c. (and this "&c." is a considerable portion), to performing acrobatic feats in endeavours to get at the reeds. In "Beta's" case, if he can get at his present back row under existing conditions, so will he likewise be able to get at any additional row or rows (if he has the necessary space on his soundboard) with the tubes facing him, by means of a reed-hook bent at right angles on itself; or, supposing he cannot get at them so, he may remove his keyboard and complete his tuning by the plungers. In case of muting through dust the arrangement is not so good as might be; but if this is the only difficulty for the alteration job, "Beta" will be happy. In the present action shown, the keyboards can be removed, and any given reed got at, and all replaced in five minutes. I must, however, except No. 5, as they are screwed in (see Fig. 2), and the mute-valve opens the opposite way to the others. By unscrewing the back board to the upper manual its pallets may be easily got at, and the lower manual pallets partially so. At the tail-end of the lower manual keys is situated the coupler C. It consists of a set of squares hinged to a rail, and provided with a regulating screw-button. The rail D (Fig. 4) travels from front to back by means of its stop, which, when drawn, pulls the lever N forward, and pushes the large square M and the connecting-rod R to the left, and so, by means of the two small squares, presses the coupler in position, as shown in section, Fig. 1. When released, the coupler is forced forward by the springs about ⅜in. so that it does not touch the upper manual squares, but rides idly on the tail-piece of the lower keys. This form of coupler is simple and effective, easily regulated, and so far as I know, new. If Mr. Warman, or any gentleman who knows, should notice this, I should like to hear their opinion of it as it stands on paper.

Fig. 2 shows part of the lower manual stop-action. It is the ordinary bent lever, or a modification of it. When No. 4, say, is drawn, it pulls the lever P upright, which in turn raises lever Q, which lifts the tapped wire running to its stop-valve. Lying across the soundboard, just under the stop-valves, is a wood table H, hinged, and at back, which is raised by the rod W coming from the lower table T, which is hinged to the case on the side of the blow-pedal, and to which is pivotted the foot-iron *f*. This is for full organ to lower manual, and raises any or all the stop-valves by suitable stickers coming from them. At X, Fig. 4, will be, say, another, which opens the upper manual stop-valves, and also couplers. This is worked by a square, not shown, from the other foot-iron, Fig. 3, stop-action to one of the upper manual registers. I do not think these require further explanation.

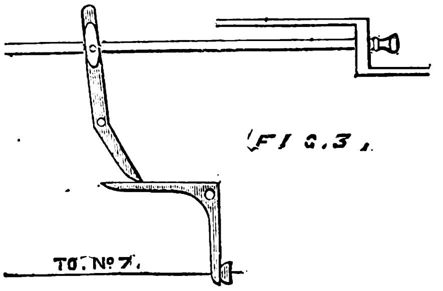


FIG. 3.

The stop-rods are worked in the position shown on the plan, Fig. 4, to the left, which not only clears the manual action, but allows room between the rods for the bent levers, squares, &c., as no given rod falls on a vertical line with any other one. At *f*, Fig. 1, will be seen the position occupied by the fan tremolo. The driving-fan in its box is placed under the right-hand stop-action, and a wire runs from it to hook into the fan-card mounted on a slight frame, which merely rests on the soundboard, and can be removed instantly by unhooking the wire. The swells are not shown, and are not yet made, but the rods to work them from the knee-levers are run lengthways under the bottom-board. If there is any point I could further explain, I should be happy to do so.

Thanks to Mr. W. H. Davies for his kindly help in explaining the method of making the keyboards, as with it and the few special tools he mentions, I made a passable job of them. There is, however, one fault I can mention—viz., matching the ivories, or rather failing to do so. I presume it requires experience or taste, as the colours do not seem to show out until they are polished. Also, commercially, they were a failure, as the time they consumed was rather out of proportion to the prices quoted by makers. But I suppose I should allow a little for experience gained, as it is worth possessing.

If anyone asked my opinion on the utility of placing harmonium reeds on suction, I should side with friend "Organon," and say, Don't, as although a different tone can be got by this means, the extra trouble involved is not compensated by the result. If that gentleman, who has kindly assisted me by his advice on several occasions, or any of "ours" who are interested in the question, would care to come and see this instrument, I shall be pleased to see them. Joiner.

GRINDING AND POLISHING GLASS SPECULA.

[20032.]—Through a mistake of the wood-engraver, the order and numbering of the stops in Fig. 2, p. 129, have been altered from what I drew them, to the creating of a little confusion between Fig. 2 and the tabulated arrangement of the stops, &c., which occurs a little lower down the column, and the letter-press description of Fig. 2 has had to be altered to make it correct with the Fig.; but as we have to begin our testings with the largest zone, it is most natural to call the stop for this zone No. 1, and the others Nos. 2, 3, 4, 5, as they decrease in size of zone. I shall, therefore, adhere in my future descriptions to my original arrangement, and which is preserved in the tabulated arrangement of "No. of stop, Dia. of zone, Aberration," which is about the middle of the first column, p. 129.

In Fig. 4, p. 129, the arrow-head on the metal J is put on the perpendicular side; it would be better on the sloping part where the divisions are, so as to be more easily seen with the divisions through the eyeglass. On the elastic band G there is represented what appears like a capstan-headed pin, with two levers projecting from it. Now, I had intended all this to represent only the knot in the elastic band, with the two ends carelessly projecting. I mention this lest the amateur should think there is something mysterious there that I have forgot to describe. I do not wish to blame the wood-engraver. Perhaps if I had been more careful in my drawing, I might have saved at least all this paragraph.

I must now describe the lamp. It is represented in Fig. 1, which is a little over one-half the size of mine. It is an ordinary ½in. burner, with a brass tube substituted for the glass chimney; it is just large enough to fit in where the glass chimney originally fitted. It is squeezed flat just opposite the flame, something like the glass chimney for the duplex lamp; this allows the broadway of the flame more room, and also the front edge to be flattened, to allow the plate B to lie flat against it; this front edge is filed flat for this purpose also. It is well to squeeze the tube flat a little higher than is actually wanted, and then to file off the bottom till the squeezed-in part fits on or touches the dome though which the flame comes. I may just observe that round the chimney, when in use in testing, a thick cardboard, the thicker the better, is put with a bit of wire round it to keep it together. This is seen well in Fig. 3, p. 129, and here at C, C, C, C, this is to protect the face, especially the forehead and eye, from the great heat of the lamp when testing. This cardboard tube simply rests at the back on the brass wire with the milled head at the end, that raises and lowers the wick. To find out where the hole is to be made, so as to be opposite the brightest part of the flame, the amateur must put the glass chimney on and get a good flame. He must then get a pair of compasses and put one leg on some known point on the lamp 4in. or 5in. below the edgeway of the flame. The other leg he must bring opposite the brightest part of the flame. Now put the light out and put on the flattened and filed brass chimney, and with the one leg of the compasses on the same known point below the flame on the lamp stand and the other against the filed part of the brass chimney, make a mark. This is, of course, opposite where the brightest part of the flame comes. Now make a triangular hole so that the lower angle is on the mark made by the compasses. This hole is shown by dotted lines at B, because it is, as it were, seen through the plate B. Now the inside of the lower angle must be filed with a small smooth three-square file, as seen in section at D. On the front of the chimney over this hole is put a brass plate. It will do less than a 32in. thick. It moves on a rivet which is seen at the right-hand end. The brass plate is filed flat at the back, and the rivet is on a level with the lower angle of the hole in the chimney. Through this brass plate is a hole with the top edge straight, and on a line with the centre of the rivet, and bevelled inwards as seen in section at D, so that this edge becomes a knife-edge as we call it, and like the lower sides and angle of the triangular hole in the chimney; thus when the part F, which is about 3in. long, and which should be made as light as possible, of the plate B is lowered, a small triangular hole is formed of any size required. This is a great convenience, as the amateur simply lowers the end F till he gets the smallest hole that gives the amount of light he can see the shadings with. Thus he easily gets the right size of hole for a partially-polished surface, such as he will have to test upon during the first part of his polishing. The hole he will naturally decrease as the polish increases, and without any trouble he will find the size of hole to test a silvered surface, which hole being of necessity very much smaller than for the plain glass surface is so much more severe as a test. Thus, when he commences his testings, after the first half hour's polishing he requires a much larger hole than when the whole of the emery marks are out; but this need not trouble him, as it would if he used holes in thin metal plates, for then he ought to have several sizes to suit the advancing polish, if he wishes to test to the greatest nicety.

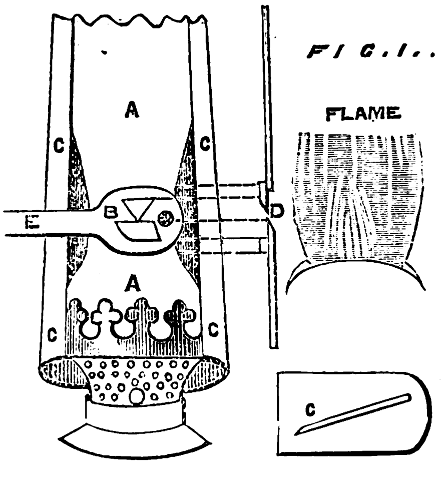

FIG. 1.

I got tired of all this loss of time, and soon devised the above artificial iris, which, although it takes longer to make in the first instance, saves its time over and over again, and then it is always ready for any testings; and another advantage I have found is, that we do not get a long hole, if I may so call it, like we are apt to get by pushing a needle through a thin sheet of metal. Now, this long hole is very detrimental to exact testing, because the focus of the inside edge of the hole would be different to the focus of the outside edge of the hole, and it takes some care to avoid getting a somewhat long hole. This can be easily seen by using a high-power Coddington lens; then we must be very careful not to get a little bit of dirt in the hole of the thin metal; in fact, it wants careful keeping to avoid damaging the hole in one way or another, and altogether is a lot of trouble—all of which is avoided by the artificial iris, which is easily kept clean and ready at any moment; another great convenience is that by opening it to its full extent by raising F, we have a large hole to find the focus with, and fix this focus on the edge of the shutter, and without any further alteration except lowering F, we get our hole in the same place to the exact size we require. I have found the artificial iris a great convenience to me through the immense number of testings I have had to go through for the numerous experiments I have been making to investigate the laws of the whole process. But if anyone thinks the hole through the thin metal plate the best for him, he can get very thin copper—as thin, if not thinner, than notepaper, and by grinding a fine needle on an oilstone to a long point, extending for ½in. from the end, he can make a very fine hole, and, in fact, he will want several sizes if he is to properly test from the commencement; these sizes he can make by pushing the point of the needle further through the metal. Let him examine under a microscope the point of the finest needle, and he will find that only just the point is small, that it suddenly thickens, and that to a size too large for his finest testings; let him hold it nearly flat on the oilstone; and rub it along, turning it round as he grinds, and then examine again under the microscope, and he will see he is getting a longer cone that regularly enlarges from the end to about ½in. up. This is the kind of punch he requires; this is the way I did it till I got tired, and made the artificial iris. If the amateur decides to make one also, he might get the help of a clock or watchmaker for a trifle, just in any part he may feel himself unable to do. I can only tell him that when he once gets it he will not give it up on any account, and return to the old punched holes; but every one has a way, and his way he makes do for himself, and he often likes it best with all its disadvantages. Now, by letting every one be fully persuaded in his own mind as to what is the best way to him in performing any operation, and not pressing on one another what we may think the best way, we may all be pleased, and gradually be brought to see the best in everything.

I will now only briefly describe the way the testing is carried out, as it has been ventilated to some extent in back numbers. In Fig. 1, p. 128, the speculum S is seen in position for testing, the triangles at the back must not be taken off for testing: the amateur must simply rest the studs of the triangles against the board A. Of course, if he works his speculum above the polisher, he will have no triangles at its back, he will simply rest his speculum against the board. The amateur must rest the speculum trough on some firm support, say some strong table, and about twice the focal length of the speculum from the further edge of another table on which the measuring apparatus and lamp are placed; light the lamp, and elevate the lever F of the iris so as to open the hole to its full extent; turn up the flame, and look down the chimney, and see that the hole is nearly opposite the edge, about as shown in section at G. By this means he will get much more light than from the flat side of the flame. Now let him look with one eye from before the front of the speculum at the lamp, and see that the hole is fully illuminated; if not, turn the wick up a little, or turn the lamp on its base to bring the flame to the centre of the hole, especially the lower angle where the small hole will be formed. Now put a sheet of white paper on the measuring apparatus, Fig. 3, p. 129 over F, and extending to the lamp, and as high and low and broad as he likes. Now throw the image of the hole on this paper, by first looking into the speculum and moving the trough about, till he sees the reflection of the hole just on the right, but touching the reflected image of his head. Now he must move his head from the speculum towards the measuring apparatus, keeping his eye on the reflected image of the hole in the lamp; he will by this means see to about where the focus would go to; thus, after two or three trials and alterings of the trough, he will be able to get the image on the paper; he can now easily, while standing by the trough and watching the image on the paper, move it by moving the trough, so that it shall be brought as high as the hole, and about over where the edge of the shutter should be—*i.e.*, about 1½in. from the hole; now he must go to the paper and see if the image of the hole is well-defined when he puts the paper about opposite the middle of the chimney; if it is not, he can either move the lamp and measuring apparatus, or the speculum-trough backwards or forwards till he gets the image well defined, but being careful to finally bring it to its right place beside the chimney. He must now examine the image and see that the lower angle of the hole (the upper in the image) has the brightest part of the flame over it. He may have to turn the lamp on its base to bring this about, or raise the flame, though the flame need be no higher than to show the lower angle the brightest. The amateur can now take away the paper and commence his testings by putting the shutter opposite the middle of the chimney, and so as to just touch the image; now, let him sit on a chair behind the measuring-apparatus, and looking along the edge of the shutter, up and down, till he sees the face of the speculum as one blaze of light, he may have to move the shutter to the left out of the way of the image, by unscrewing the shutter-screw before he thus sees the light from the speculum, the shutter having been too much over the image. He must now lower the lever F of the iris, and cut off the light till it is only just enough to see the shadings when the shutter is passed across the cone of rays from the speculum: the smaller the hole he can do with, the more delicate the testing (he must not lean on the table or touch it in any way while testing). Supposing the amateur has thoroughly mastered what I explained in my two previous letters, he can now commence the testing by putting the index line N, Fig. 4, p. 129, to ·063 (this, of course, supposes a 6in. speculum 60in. focus)—i.e., about 6⅓-100ths further from the speculum than ·0, which is reckoned from the arrowhead on the divided scale. He must put the stop No. 1 against the speculum, and now adjust the shutter by the adjusting-screw till the shadings come on equally and simultaneously on both sides of the zone, as the shutter is passed from left to right by the shutter-screw; now take No. 1 stop off and put on No. 2, and move the index to ·042, and pass the shutter from left to right, and if the shadings come on equally as before this zone is right. In like manner proceed with the other stops, as given on p. 129 middle of 1st col. If all the zones answer well to this test, the speculum cannot be far wrong. Of course I am supposing there are no rings that can be seen when the shutter is passed across the cone of rays without stops, and that the amateur has gained some little experience by experimenting for himself for his own pleasure and information, all which may be done in his workshop, where perhaps he has a fire to keep the air at the proper temperature for the pitch. But we must now proceed to a little more severe testing, and this cannot be done in a place where there is a fire, for the currents of air will interfere fearfully with all exact testings. I always finish my testing, *i.e.*, for the last three or four half-hour's polishings, down the cellar, which is wonderfully free from currents, and will give the same indications over and over again; whereas, when tested in the workshop, or a room where there is a fire, the indications will appear to vary. The fact is, it is the currents of air that are passing, first over one side of the zone and then over the other, while testing, that prevent exact testing. To show this to the amateur, let him try the following experiments in his workshop, or a room where there is a fire:—Let him set the index to ·063, as in the previous testing, set the shutter to No. 1 stop carefully; now put on No. 2 stop, and, by the measuring-screw, put the shutter to cut off both sides, as near as he can judge, alike; now let him examine the index reading, and most likely it will not be ·042. Let him try to set the shutter again, and most likely he will not get the same reading as before; thus let him test his ability to find the exact focus of all the other zones in a room where the air is not perfectly even in temperature, and he will at once feel the evil of currents of air, although he may not be able to see them; but let him now try the same series of experiments down the cellar, or anywhere where the air is perfectly still, and he will be much pleased with the greater constancy of the readings. Of course, as he gets more practice, he will get much more expert. He will find the greatest difficulty with the small zones in getting their exact focus. This I accomplish in the following easy way: I find that with the smallest zone, No. 5 stop, I can always tell a difference of shading if the shutter be more than 2-100in. from its actual focus, but not nearer than this with absolute certainty: so I proceed as follows: I put the index 2-100in. on that side the supposed focus that is nearest to the speculum; I pass the shutter across, and if I cannot detect any difference in the shadings I know the supposed focus is not too long. I then put the index to 2-100in. from the supposed focus on its other side. I pass the shutter across, and if I cannot detect any difference in the shadings, then I know the supposed focus is not too short; therefore it is right, being not too short nor too long. But suppose in the last testing the shading comes on a little more on the right side of the zone than on the left, then the supposed focus is too short, and the real focus is somewhere between the supposed focus and the first testing. I alter in my mind the supposed focus to a little shorter, and commence again to test as before; thus I soon get with great exactness the correct focus. I always test thus the smaller zones, and when in the cellar get wonderfully consistent readings. I may just observe that I do not trouble to have a table in the cellar, but use a low, firm bench, and go on my knees on a cushion. I have a small lantern to take the readings and see my way about. Now, to study the accuracy that this mode of testing the zonal foci produces for celestial observation, let us suppose that A is a spherical speculum, and B is

12345
A ·····
O C O
B 10 9 8 7 6

the amateur's speculum, and that the spherical aberration of A, when tested on a celestial object for the five zones, is represented by 1, 2, 3, 4, 5; 1 being of course the focus of the outside zone, 5 the centre. Now, the aberration of B, if a parabola, when tested at the centre of curvature, would be 4 times the above amount of from 1 to 5, and would be represented by the distance of 10 to 6; 6 being the outside zone focus, 10 the centre. We will suppose the amateur has not quite corrected his speculum, that he has made the mistake of ¼ the whole amount—i.e., the outside ray is not long enough, it is only brought to 7 instead of to 6, and with ordinary care any amateur ought not to be out more than this. Now, when this speculum is tested on a celestial object, it would have its outside ray-focus shorter than its centre by about ¼ the whole spherical aberration—viz., at 4 instead of at 5, all the intermediate rays would be between 4 and 5; in other words, as the whole spherical aberration is about 1-50th in., the undetected aberration would be only about 1-200th in., and this is much nearer than an ordinary amateur would be able to test to on a celestial object. The fact is, a far greater enemy is flexure than aberration, and one that is far more difficult to overcome. I am now trying experiments to overcome flexure, or rather, to avoid it, with the two specula Messrs. Chance Brothers kindly supplied me with, and with a very thin one only ¼in. thick—of course, all 6in. diameter—so that the comparison may be direct, and therefore easy and certain. Now, the ¼in. speculum shows the weak point of every kind of support to a fearful extent. I hope to let all know the results, when I have finished satisfactorily my experiments.

I hope to finish in my next letter the Foucault's testings. If I have omitted any point or written in a way not quite plain to any, I hope I shall receive intimation of the same direct from them, and at once, so that it may be included in my next, which I wish to be my last on this part of the subject; as I know many want now the practical making and working of the machine.

H. A. Wassell.

Addenbrook Villa, Love-lane, Stourbridge.

FRENCH EXPRESS LOCOMOTIVES.

[20033.]—The express locomotives now employed on the "Chemins de Fer de l'Ouest" and "Chemins de Fer du Nord" present some remarkable particularities. These two railway companies are the only ones in France who have adopted the inside-cylinder engine for fast passenger traffic. They are also those upon which most of the French inside-cylinders types are to be found. The inside-cylinders locomotives in France were introduced from England. They do not differ greatly from those employed in England. They were first used there for goods traffic. The prototype was a six-wheeled goods engine of that type made by Sharp many years ago, and in which the dispositions of the "Sphynx" type had been fully embodied. The wheels were all under the barrel. Many locomotives for regular passenger traffic were built after that fashion, keeping the long boiler along with inside machinery of the "Sphynx" type. But the engines we purpose to examine to-day greatly differ from this old type. Those of the Western line have not their equivalent in English practice, whilst the Northern of France's locomotives have a great resemblance with most English locomotives of the modern standard practice.

The types of the Western of France numbered 1, 2, and 3 on the sketches are met with on the lines of Normandy and Brittany. It is, I dare say, over twenty years since the first began to work. The Northern engines are more recent, and their first appearance does not date further back than 1870. Both sorts of engines merit a detailed description.

We shall begin with the Western engines. They have all been turned out from the "Société de Construction des Batignolles," Paris (late Ernest Gouin and Co.). This is to be accounted for by the proximity of the railway to these works. The three types have common features.

Railway Company	Western.			Northern.

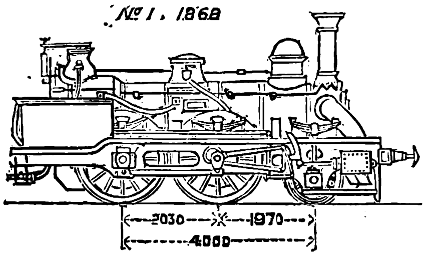
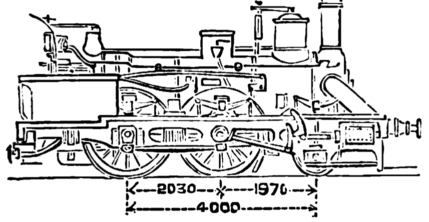
Engineer	M. Mayer.			M. Delebecque.	
Builders	Société Ernest Gouin.			Société Alsacienne.	
First date of construction	1857.			1874.	
Cylinders—					
Diameter	420 (16½in.)			432 (17in.)	
Stroke	560 (22in.)		600 (23·6in.)	610 (24in.)	
Centre to centre	980 (38·58in.)			760 (2ft. 6in.)	
Wheels—					
Leading	1120 (3ft. 8in.)	1000 (39⅜in.)	1280 (4ft. 2·3in.)	1300 (4ft. 3·1in.)	1010 (2 off bogie)
Coupled	1910 (6ft. 2·6in.)	1800 (5ft. 10⅞in.)	1900 (6ft. 2·9in.)	2100	2100 (6ft. 10·6in.)
Total wheel-base	4000 (13ft. 1½in.)		4400 (12ft. 5.2in.)	5500 (18ft.)	6320 (20ft. 8·2in.)
Centre to centre of axles—					
First, leading to second	1970 (6ft. 3·2in.)		2150 (7ft. 1in.)	2910 (9ft. 6·5in.)	1800 (5ft. 10⅞in.)
Second to third	2030 (6ft. 8·1in.)		2250 (7ft. 4½in.)	2590 (8ft. 2·4in.)	1930
Third to fourth	0		0	0	2590 (8ft. 2·4in.)
Diameter of barrel (int.)	1170mm· (3ft. 10·4in.)			1225 (4ft. 0in.)	
Working-pressure	9 atmospheres.			8·5at. (125lb. sq. in.)	10at. (147lb. sq. in.)
Grate—					
Length	1180 (3ft. 9·1in.)	1224 (4ft.)	1624 (5ft. 4in.)	2270 (7ft. 5·3in.)	
Width	1050 (3ft. 4in.)	1074 (3ft. 6in.)	1078 (3ft. 6·4in.)	1023 (3ft. 4in.)	
Heights of firebox	1410 (4ft. 7·2in.)	,,	1150 and 1130	1580 and 810	3ft 3·7in & 5ft 2·1in.
Tubes—					
Number	156			201	
Diameter	50 (2in.)			45 (1⅞in.)	
Length	4000 (13ft. 1½in.)		3850 (12ft. 7·8in.)	3500 (11ft. 5·8in.)	
Heating surface—					
Firebox	6·43m²	7·37	6·98	8·75 m²	94·2 sq. ft.
Tubes	85·33	98·02	94·55	90·60 (ins.)	1069·4 (outs.)
Total	91·76 (986)	105·39 (1130)	101·53 (1086 sq. ft.)	99·35	1163·6
Grate area	1·321m² (11 sq. ft.)	1·24m² (13·5 sq. ft.)	1·78m² (16·5 sq. ft.)	20330 m²	25 sq. ft.
Weight of centre of boiler	1920 (6ft. 3½in.)		,,	2130 (7ft.)	
Weight in working order—					
On first axle	11·1 tons	8 tons	11·15 tons	10·4	14·4 (bogie)
On second axle	11·4 ,,	13 ,,	12·45 ,,	13·5	13·6
On third axle	11·5 ,,	13 ,,	12·45 ,,	13·5	13·6
Total	34·0 ,,	34 ,,	36·05 ,,	37·4	41·6

1st. The employment of outside frames only, save a slab placed in the plane of symmetry of the engine and riveted to the motion-plate, and at the other end to the staying plate in front of firebox.

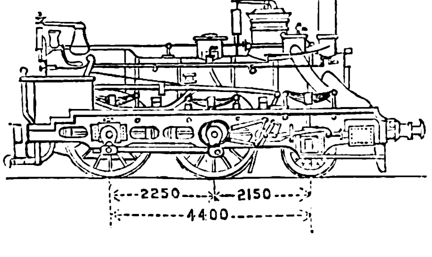
No. 1, 1868.



No. 2. 1874.



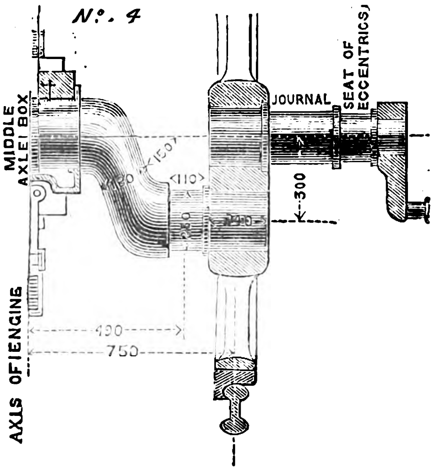
No. 3. 1878.



This slab embraces an axle-box on the crank axle, which is relieved from part of the weight thereon by a spring. This middle axle-box also steadies the said axle.

2nd. The valve-gear is wholly outside, the steam-chest being outside. The valves are easily examined and repaired if necessary. The links in 1 and 2 are of the shifting type, and disposed as in the "Sphynx" engine. In No. 3, however, the link adopted is Allan's with a special modification. The eccentrics sheaves are keyed behind the outside crank of the driving-axle. The whole appearance of the frame and its machinery reminds us of the goods locomotives built in 1855 by the late M. C. Polonceau for the Paris and Orleans Railway, and also of some Austrian engines. The difference between 1 and 2 or 3 lies on the adoption in the two last locomotives of the Martin's crank-axle, which is shown in Fig. 4. It is not unlike the Baldwin crank axle used in Early American engines.

No. 4.

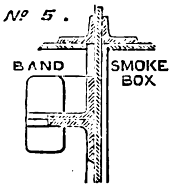


Here there is, so to speak, no proper crank. The axle is simply bent. It allows of bringing the crank-pin nearer the driving-wheel, and is very safe.

The difference between 2 and 3 is easily perceived: in 3 the firebox is enlarged considerably, and extends over the trailing-wheels. In the recent engines of the Western Company, all the stuffing-boxes have Duterne-Dallot's metallic packing, all screwed work in the live steam is adjusted from outside by means of nuts, cleverly contrived. This avoids corrosion of these moving parts.

The boilers of these three types are not very different. The connection between barrel and smokebox is illustrated in Fig. 5. They all have domes against the smokebox, a thing which is no longer the practice of the other railway companies in France. They now prefer the dome on the middle of the barrel. The regulators are of the slide type, but this principle is differently carried out in each engine, though in all the motion is imparted horizontally to the slide by an outside rod. In the first, a bell-crank changes the direction of the motion, and moves the slide as in English engines; in the second, the slide is kept horizontal, the same in the third, but the slide is outside the dome—a dome now favourite with French engineers, as it admits of repairing the regulator without disturbing too many things. We shall find the same arrangement on the Northern engines with a slight difference.

No. 5.



Upon the whole, these engines look very handsome in their appearance: but I object to a want of proper stiffness in the frames. It must be admitted, on the other hand, the dispositions of the cylinders allows of getting them as big as is desired without having to fear a limitation in the size of the steamchests, or to pinch fractions of an inch here and there, in order to get a proper length of journal—a thing which is often detrimental to the strength of the already and inherently weak crank-axle.

The dimensions are found in a special table hereafter. I have said somewhere else that these engines have the cylinder power rather less than it ought to be when the adhesion is considered. The tractive power is = 42² × 600 × 6 / 1,910 = 3,310, and the wheels — driving and trailing — bear 24,900 kilog. available for adhesion, so that 3,310 / 24,900 = 1 / 7·5. Those who know the nature of the traffic will readily admit that the cylinder power is rather small, and that it might have been increased, without exaggeration, to 4,200 kilog., especially when the general disposition afforded means to adopt larger cylinders. The position of the cylinders is not beneath the smokebox, but well forward in advance of it. This favours a good distribution of the weight. The maximum speed is 70 kilometres an hour; or 43 miles.

Turning now to the engines of the Northern of France, we shall find that the present type with a bogie is the result of successive transformations necessitated by the traffic during these last twelve years.

At the time of the Franco-German war the increase of traffic was such that the Crampton locomotive could no longer do for the passenger traffic on main lines. Some four-coupled expresses were then built at Mühlhausen by Kœchlin. These engines constituted a wide departure from the current practice of the Northern Railway. I am sorry I cannot send you sketch of these engines, as I cannot trust my memory to make one. However, I can describe them pretty exactly. They had outside frames just the same as the preceding engines of the Western, only the steamchests were, as in England, between the cylinders. The boiler had a dome over the firebox, but the regulator was in a box against the smokebox, as was usual in French practice. The leading dimensions are as follows:—Cylinders, 432mm. diameter by 610 stroke; heating-surface-firebox, 10 sq. meters; tubes, 81·62—total, 91·62; pressure 9 atmospheres, driving-wheel, 2,100 mm.; weight in working order, 35,610 kilogrammes, with the following repartition: leading, 10,105; driving, 14,000; trailing, 11,505; tubes, 3,170 mm., long.

If you compare these few particulars with those of the most recent engines, you will find the reasons that led to the following transformation. In the subsequent engines, built about 1874, the firebox was longer, and built after Belpaire's design. The grate now enlarged was carried over the trailing axle. The outside frame was kept, but an inside one was added, embracing the two inside axle-boxes of the driving-axle, just as in English practice. The cylinders are cast with a saddle on top, to carry the smokebox, which is cylindrical. The dome was shifted towards the middle of the barrel. The appearance of these engines is very much like some built some years ago for the Great Northern Railway, under the superintendence of Mr. A. Sturrock; all the more, they have also their leading-axle under the cylinders.

The necessity of having express trains on the branches where there are sharp curves led to the adoption of a bogie. This did not alter much the general design of the engine. which is now a little heavier than the preceding. They can pass easily over curves eight chains radius. All engines of this description are fitted with Smith-Hardy vacuum brake.

Upon the whole, these engines form a type which approximates English practice nearer than any other that had been done previously in France. The bogie engines have six-wheeled tenders. Their speed can easily attain fifty miles an hour, and no doubt they have to work the fastest trains from Paris to Calais, such as the English Mail, which has to be forwarded at a speed of not less than 47 miles an hour, stoppages deducted.

4. The bogie is of the old English type, with central pin. It is assisted in its displacements or kept in position by sliding pieces upon which the weight of the fore part of the engine rests transmitted through sockets fitting into hemispherical balls fixed to the cylinders.

The table on previous page gives the dimensions of all the engines described above.

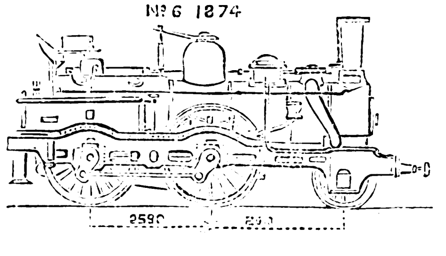
GENERAL REMARKS.

All inside-cylinder engines in France have the smoke-box made cylindrical, and resting upon a saddle cast with the cylinders just as in American practice. The diameter of the smokebox is that of the nearest barrel-plate. In engine 6 the thickness of boiler-plate is 13·5mm., and in No. 7 it is 14·5mm. These two last engines have a box shifting link. All the engines above described are fitted with the Lechatelier counterpressure brake. The latest Northern engine has a compensating arrangement for the springs made, not of a beam, but of two bell-cranks and suitable rods, as shown in sketch. The Northern engines have 2 Friedsmann's injectors.

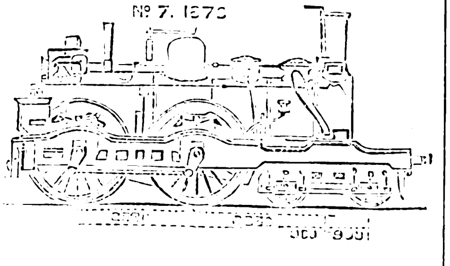
Ed. Gobert, B.Sc.

Heskey-street, Nottingham, 15 April.

Nº 6 1874



Nº 7. 1873



GRADIENTS ON L.B. AND S.C.R.

[20034.]—THE gradients on the L.B. & S.C.R. have often been asked for, as well as those of other lines; but the difficulty in giving them is the inordinate amount of space they take up when engraved. I therefore send these gradients in another way, which avoids encroaching on valuable space, and at the same time gives all needful information. Readers can easily draw the sections for themselves from these figures. The particulars are as follows, and it must be understood that each gradient continues from one point to the next, where a change is noted:—Starting from London-bridge station the line is level to 1¼m., where it begins to rise 1 in 4,744; 2¼m., 1 in 1,820 down; 3m., 1 in 100 up; 5½m., level; 6m., 1 in 2,571 up; 6½m., 1 in 660 up; 7½m., level; 8¼m., 1 in 660 down; 9¼m., 1 in 264 up; 17¼m., level; 18¼m., 1 in 264 down; 25¼m., 1 in 660 up; 26¼m., 1 in 440 up; 26¾m., 1 in 377 up; 27¼m., 1 in 264 up; 31¾m., 1 in 264 down; 37¼m., 1 in 213 down; 37¾m., 1 in 330 down; 38¼m., 1 in 264 down; 39½m., 1 in 528 up; 40m., 1 in 264 up; 41m., 1 in 1,328 up; 42½m., 1 in 264 up; 45¾m., 1 in 264 down; 50m., to Brighton station, level.

I hope some other correspondents will give the gradients of other lines in the same way. We have had the G.W. and G.N., I now give the L.B.S.C. I should be glad to have the L. & N.W., L. & S.W., and Midland, so that we might compare locomotive work, about which so much has been written in these pages. Mr. C. E. Stretton once kindly promised the Midland to Leicester, but was deterred by the space required. Perhaps he will be good enough to give us the information in the manner above illustrated, many readers would greatly appreciate his trouble. **C. R. M.**

Wellington, N.Z., March 25th.

ERRATUM.—Page 195 (Letter 20004).—"Railway Brakes—The Westinghouse Automatic Vacuum."—By a slight printer's error, the word *vacuum* has been omitted in the fourth line of my letter, page 195, 20004. It should read that "the Westinghouse patent, No. 1735 . . ., is the earliest in relation to the Automatic *Vacuum* Brakes."—CLEMENT E. STRETTON.

ERRATUM.—"Telectroscope."—In my letter on this subject I am made to say that selenium has a resistance 10 per cent. that of iron, it should be 10^9, that is 1,000,000,000 that of iron.—L. L. B. A.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[31095.]—**G.N. Locomotives (U.Q.)**—Looking over back volumes, I accidentally came across "Caledonian's" query, previously overlooked, and not yet answered. Old No. 1 on G.N.R. was one of Sharp's passenger engines of the favourite type in use on many English lines—notably, L.B. and S.C., S.E., G.E., L. and N.W., &c. I sent a rough tracing of it, which appears on page 435, Vol. XXX.; but I had then mislaid the dimensions. The driving-wheels were 5ft. 6in. diameter (single), leading and trailing, 3ft. 6in.; cylinders, 15in. by 20in.; heating-surface 748 sq. ft.; double framing. Some of these were rebuilt as tank engines. Old Nos. 223-228 were coupled express engines, with 6ft. 6in. wheels, and cylinders 16½in. by 22in., built by Hawthorn, of Newcastle.—C. R. M., N.Z.

[46378.]—**Bevil Wheels.**—I should advise you to let a 6in. wheel work into a 3in. one. The other arrangement proposed would necessitate (1) a considerable increase of weight, (2) double the circumferential velocity, (3) a great increase of friction, and consequently an increase of power required to work the machine.—KRAUTBRACK.

[46497.]—**Fortified British Cities.**—Carlisle is an old fortified city, and its walls are, I believe, intact to the present day. When the Pretender invaded England in 1745 it was taken by his forces and garrisoned by nearly 500 men. On the retreat of his forces to Scotland, it was besieged by the English army, under the Duke of Cumberland, and for seven or eight days both sides cannonaded each other, ending in the surrender of the place to the Duke, on Dec. 30th, 1745, the garrison, and prisoners. This was the last siege of a town in Great Britain. An old work (dated 1750), says, its walls are so thick that three men can walk abreast, and they are well planted with cannon. It has three gates. Penrith was also a fortified town.—CUMBERLAND.

[46497.]—**Fortified Cities.**—The ancient fortifications or town walls of Leicester were built in the time of the Saxons, and some portions may be traced to this day. A drawing in the Leicester Museum shows a considerable length of the wall, which was removed only a few years ago for the purpose of erecting houses in Bonner's-lane; there were four or more gates in the walls, and circular turrets or towers at each angle. The walls were chiefly built with rough blocks of granite grouted together, and the foundations, which were of a great thickness, are frequently met with in excavating for new works. Throsby, in his "History of Leicester," says Ethelfreda, a Princess of Mercia, has the reputation of extending and repairing the walls of Leicester about the year 901, after it had been desolated by the Danes. Matthew Paris called these walls (which lay in ruins in his time) like forest rocks, indissoluble; indeed, iron crowbars and immense labour are now required to remove portions frequently come across. The almost total destruction of the walls and the castle happened in the reign of Henry II. I shall be pleased to give any further information required.—JAS. FRANK SMITH.

[46500.]—**Cement for Cards.**—If the cards are of cloth, I believe the best makes are cemented with rubber—that is, indiarubber dissolved in bisulphide of carbon, or the soft rubber spread on between, and the layers pressed together. If leather cards, they will, no doubt, be cemented by glue, into which some tannin has been stirred; but leather cards are, I think, used in single thicknesses. A piece of cloth card I had was certainly made by spreading the softened rubber-sheet between the cloths and pressing them well into it.—E. G. M.

[46503.]—**Jamming of Tapered Journals.**—I have to apologise to "Glatton," page 178; but being much occupied, his request escaped notice until this evening. In the first place, I must confess that I don't know what is the meaning of "the angle of repose," as relates to a swiftly revolving mandrel. But were I fitting one up, I should much prefer to make A B D = 8°, than the angle A B C. I don't feel competent to say at what precise angle hardened steel would stick; nor do you state what amount of pressure would be put upon it to make it stick. The pressure of the work in a lathe, acting usually in the reverse direction, I would use a taper of say ⅛in. to 1in. of length in conjunction with a tapered shoulder.—J. J. A., Liverpool.

[46506.]—**French Polish.**—No help for scratched work but to scrape and repolish. Patches may be repolished, but it will need a skilful hand. Consult the papers on "French Polishing" in Nos. 814, 816.—T. P.

[46514.]—**Wood-Turning.**—I don't know how the professional turners do it, but I should mount the vase in the centres, and clear out all but a centre pillar of wood, which could be removed when the hollow was cut out sufficiently.—A NOVICE.

[46524.]—**Air-Pump.**—You might get about 15lb. with a tall column of mercury, but doubtful if you get more. Supposing you mean to work on the principle of the trompe, you won't get so much.—G. M.

[46528.]—**M.R. Locos.**—Seeing that loco. engineers would hesitate before they expressed a definite opinion as to whether the bogie should lead or trail, "F. C. B." will understand that no answer can be given to his question. I think, however, he may take it that where the engine has a tender or is intended for fast traffic the majority of engineers would prefer the bogie to lead.—S. R.

[46532.]—**Confervæ on Portland Cement.**—Coat the Portland with silicate of soda, or else put in some snails to keep the confervæ down.—T. P.

[46544.]—**Glass Rendered Dim.**—If you cannot clean it with strong potash solution, try weak solution of sulphuric acid.—C. K.

[46613.]—**Organ.**—The felt I use is the best table felt about ⅛in. thick, but a *best* plain felt which can be obtained at any carpet warehouse will answer. The advantage of felt over two or three thicknesses of leather is that its keeps it elasticity so much longer. 2. The wind-bar is usually fixed into the ends of the wind-chest, but is not glued to the bars; it is screwed to the thick bars, and a strip of leather is glued to the wind-bar and soundboard. 3. If your Open Diapason is voiced quietly, make the C C in wood 4½ by 3¾, and cut the mouth one-third; but if it is voiced strongly, cut the mouth one-half in height, and give wind to correspond. It should be a difficult matter to tell where the metal ends and the wood begins. 4. None at all; I never use them. Neither are they necessary, and much less useful. I have built many one-manual organs for chambers, and never felt the want of runners, *alias* "castors," and I would not like to build a two-manual organ with independent pedal organ on castors for anyone. In every case they do more harm than good. The use of them implies either bad design or bad workmanship.—J. DRESSER.

[46618].—**Connecting Bourdon Stop with Pedals.**—How long is it since "G. E. S." read

the ENGLISH MECHANIC? "Adept," I am sorry to say, left us more than 10 years since, and "J. D." changed his signature more than eight years ago. If "G. E. S." will give some idea as to the size of his organ, and the height he can allow for his Bourdons, I will help him. Cut the CCC boards 8ft. 2in. long, and the block 3½in.; the CC 4ft. 2in. long, the block 3in.—J. DRESSER.

[46629.] — **Chemical.** — Ammonium chloride could be purified by re-sublimation. The process may easily be conducted by placing the chemical in an earthenware jar, inverting a larger one over it, and applying heat. Any dealer in chemical apparatus will supply you with a book of labels for laboratory.—W. B. A.

[46646.]—**Marking-Ink.**—Some such colouring matter as archil, or an aniline colour, is added to marking ink to give it body. Add to your formula ¼oz. archil. A better ink I prepare by precipitating silver carbonate, dissolving in tartaric acid and ammonia, and adding about 10 per cent. gum and 25 per cent. archil. Requires a warm iron over the marked linen.—W. B. A.

[46670.]—**To Gelatine Paper.**—Have you tried polishing your glass before use with finely-powdered French chalk? I think it will effect your purpose.—W. B. A.

[46672.]—**Binding Screws.**—To. MR. LANCASTER.—I shall be greatly obliged if you will favour me with the instructions for making the above that you offer.—CRUX.

[46680.] — **Horizontal Escapement.** — If "Working Blacksmith" practises the rule, as given on p. 182, of putting horizontal escapement in beat, I have no doubt he will at some time or other find himself at sea. For instance, we will suppose he has got hold of a watch which has had a new cylinder, and the balance not put on in its proper place, then "Working Blacksmith," I am afraid, will find his watch as far out of beat as ever. Now I think I can give a more definite system of putting horizontal watches in beat than that. For instance, in putting the balance, bring the face of cylinder opposite 'scape-wheel jewel; then put your hairspring pin in stud, leaving it slack enough to enable you to draw the spring either way. Then, with a pair of fine-pointed watch tweezers, very gently press forward the fourth wheel (that is the wheel next the 'scape wheel), keeping your eye fixed on one of the balance arms, at the same time noticing where the arm starts from. If you have been fortunate enough to get the watch in beat, which sometimes happens, you will see the balance-arm move an equal distance on each side from where it started from. In case it should not do so, and you have more draw on the right than the left, let out the spring a little; work in this manner until you have the lift or draw equal. Then put your pin in tight, and you will find your watch in perfect beat. The same rule applies to verge and lever work, with the exception of what is called fourth wheel in lever and Geneve watches, is the contrate or crown wheel in verge watches.—THIRDS' PRACTICAL WATCHMAKER.

[46686.]—**Organ Reeds.**—"Wits' End" had better get some one who knows his work to put the oboe back into the swell. If he came into my shop and put a reed pipe to his mouth, he would soon find the 5s. fine laid on for so doing. No one but a person totally ignorant of reed work would attempt to do such a trick as poor "Wits' End" has done, and many a good organ is spoiled by such clever performances.—J. DRESSER.

[46690.] — **Waterproofing Fabrics.** — On several occasions lately queries have been sent to the "E.M." asking how to render clothing material waterproof, and in replies directions have been given either to use linseed-oil and size, or to soak the articles in solution of alum and lead acetate. As the whole subject of waterproofing ordinary cloth or linen fabrics seems to me of great importance, I would venture to call the attention of our readers to that small portion of the subject which has come within the scope of my own knowledge, to give suggestions, and to ask information. I think that, to get a waterproof garment few would like to spoil their coats with linseed-oil, to stiffen them with size into the similitude of a "sou'-wester" cape, or to subject themselves to the chance of poisoning by the use of lead. The great desideratum is a process by which ordinary cloth may be made waterproof, or even unwettable without damaging its appearance, rendering its use unpleasant or harmful, or hindering the free passage of air through its pores. The objection to indiarubber is, of course, that it is heavy, stops perspiration, and is not adapted to be worn in both wet and dry weather. A patent was taken out in 1875 by a Frenchman for waterproofing fabrics by passing them from a roller through a bath of paraffin dissolved in carbon bisulphide or naphtha, and then, after pressing between rollers to remove excess of liquid, driving off the solvent in a hot chamber, and so leaving paraffin in the fibres of the cloth. I should imagine that there are several objections to this process; but I suggest that something similar might be done by way of trial by the querists, and I shall be glad to learn the result. It seems to me that it is by no means impossible to get a practical process of waterproofing goods so that water shall roll off them without wetting, and also air pass freely through the pores. In the animal creation many aquatic birds have oily feathers and can dive under water without a wetting; and in the vegetable creation many plants have leaves covered with delicate hairs which throw off the rain. And even water itself supports small globules, owing to what is called "surface-tension." How would it be to manufacture a fabric of a hairy nature, and partially saturate the pores with some unobjectionable oil. —KERUX.

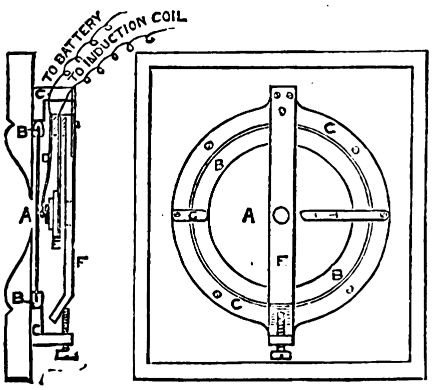
[46699.]—**Shellac Cement.**—I consider shellac useless for this purpose. The following answers well: Place some isinglass in a wide-mouthed bottle. Put the bottle in boiling water, and add sufficient acetic acid drop by drop until the whole forms a stiff paste. Stir well, and, when required for use, place bottle in hot water until contents are softened. Apply to glass with a camel-hair pencil. —W. B. A.

[46700.]—**Intensity Coil.**—When making my first intensity coil I obtained similar results. The sticking of the break's hammer to the core was caused through imperfect insulation of the two sets of tinfoil forming the condenser. Examine your condenser in this direction. The reason why the "breaker" does not vibrate when the condenser is detached may be—too great a stiffness of the hammer-spring, too great a distance between the core and hammer, or imperfect metallic contact between "breaker" and regulating-screw when the hammer is at rest. The points of contact should be amalgamated, or, still better, consist of small platinum wire and disc soldered to regulating-screw and "breaker."—KRAUTBRACK.

[46702.]—**Drills.**—Drills for iron and brass are different from each other, as the latter has its bevelled edge at a sharper angle than the former. They may be set by grinding the flat side on a grindstone and then finishing on an oilstone. To harden them it is necessary to first heat them in a clear fire. When of an even red cherry tint they should be taken out and plunged into a vessel for about ½in. down; then count ten, and immerse the rest of the drill, then rub them on an oilstone.—BEETLE CRUSHERS.

[46704.]—**Blake Transmitter.**—The carbon is not fixed to the diaphragm in the Blake transmitter. This instrument was fully described and illustrated in Vol. XXXI., No. 781, page 14, ENGLISH MECHANIC. If "Practical Amateur" finds any difficulty in getting the copy of "E.M." to which I refer, I shall be happy to lend him one I have, if he will give his name and address. I have recently made a pair of the above form of transmitters, which give splendid results, but they are rather difficult for an amateur to construct.—J. P. M.

[46704.]—**Blake Transmitter.**—There is no electrical connection between the microphone and the diaphragm; the latter simply vibrates from the action of soundwaves. Any other substance but iron may be used; but experiment proves iron the best for this kind of transmitter. I send back and sectional views, which I hope will be useful.



A, diaphragm; B B, indiarubber band surrounding diaphragm; C C, cast-iron ring, screwed on to case; D, fine spring, tipped with a bead of platinum; E, microphone, sunk in brass cap and suspended by piece of watch-spring; F, micrometer adjustment; G, small stiff piece bent brass, pressing upon indiarubber band to keep diaphragm in position; H, stiff spring, the end covered with indiarubber, pressing firmly upon diaphragm, near centre, to control vibrations. The springs, D and E, and adjustment-bar, F, are insulated from each other by pieces of vulcanite. The current flows thus: from C of battery to spring D, thence by contact through microphone E, through primary-wire of induction-coil to Z of battery, and thence to C of battery, completing the circuit. The secondary-wire goes, of course, one end to line, the other to earth or return wire. If this is not found sufficiently clear, shall be glad to assist you further.—YOSHI.

[46713.]—**Bleaching Clothes.**—The following recipe, which I saw the other day, may prove useful:—Take 4 pounds washing-soda, and put it into 1 gallon boiling water. Boil the whole half an hour. Then add 1 pound chloride of lime free from lumps. Strain when cold, and keep in corked bottles. A teacupful is sufficient for a large wash. —W. B. A.

[46715.]—**Photographic.**—(1) I should advise "Semper Fidelis" to purchase a handbook on the production of opals. (2) A cloth bellows may be easily made at a trifling cost, by any amateur; cut some thin cardboard to the length required, and mitered at the ends; glue on with thin glue on to Italian cloth or black twill. For a bellows for camera 7¼in. by 4½in., ⅝in. will be about the right width; if larger, wider in proportion. Let each piece be about ⅛in. apart, leave about 3in. of cloth longer than required, and arrange the cardboard so that the inner joint will be at the top of bellows, and the outer one at the bottom, or you will have a thick and ugly joint. Now glue together, leaving the cardboard outside; then cut another piece of cloth and glue the bellows with very thin glue and put the cloth on, working well into the blank spaces with the fingers; put on one side till nearly set, then fold and place under a weight. A much nicer appearance will be obtained if the outside is thin leather instead of cloth.—JAMES PARKINSON.

[46715.] — **Photographic.** — I have made a camera bellows, which works well, as below. Cut some cardboard into strips (1) the size, when placed together, of the bellows required. Take the pieces required (2) for, say, the bottom of bellows. Lay them on a table (3), paste together by sticking brown paper over the whole. Proceed the same for the other sides. Place them in position. Glue brown paper over the whole, and upon that one thickness of black twilled calico. The apparatus will last a long time and work well.—W. B. A.

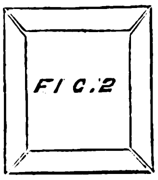


FIG. 2

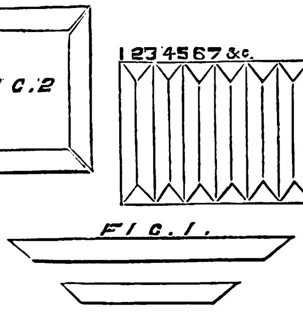

FIG. 1.

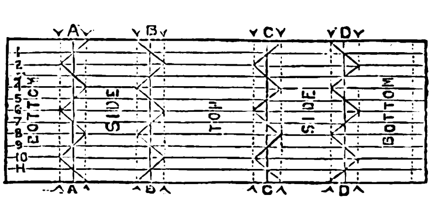
[46715.]—**Photographic.**—1. Opal plates are prepared in the same manner as any other dry plate; the difference is in the glass opal being used instead of plain glass. 2. To make a camera bellows, obtain a piece of black twill of the required size, and glue thereto a piece of brown paper, dry, and rule lines as per sketch. The lines numbered 1, 2, 3, &c., should be an inch apart. The others, *a a*, *b b*, *c c*, and *d d*, must, of course, be at a distance corresponding to the lengths of the sides, top, and bottom of camera. The dotted lines *v v v v* are an inch distant from the last. Now fold as follows:—1. towards you; 2. back; 3. towards you, and so on till all are folded; rub the creases well down, and again spread your bellows out flat. Now fold *a a*, *b b*, *c c*, *d d* (the brown paper being uppermost) all towards you, crease well and again spread out flat; now fold the diagonal lines all inwards, and pinch them with a pair of nippers, blacken the brown paper with some dead black varnish, glue the two ends *x* and *x* together, and I fancy you will have but little difficulty in finding the way to coax the bellows into shutting up. If "Semper Fidelis" finds any difficulty about this



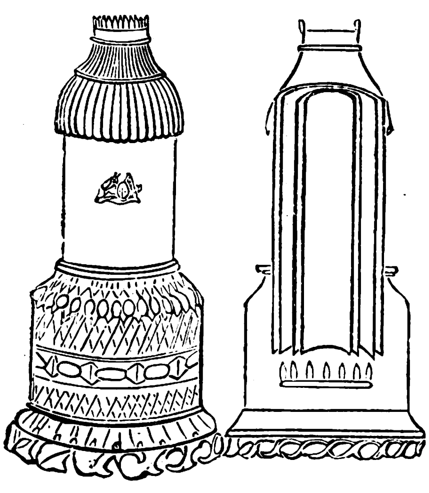
job, and will advertise his address, I will send him a piece already folded as a pattern for him to work by.—GLOWWORM.

[46732.]—**Microscopic Fungi.**—"L. L." will find in No. 836, Vol. XXXIII., page 84, directions for mounting leaf fungi as opaque objects; he must, however, take care that before putting them into the cells they are thoroughly dry. I keep mine between blotting-paper for two or three months before mounting.—T. W. W.

[46741.]—**Landscape Photography and Dry Plates.**—If "Holiday Work" will make an emulsion after the following formula, I think he will have just what he requires:—Ammonium bromide, 36gr.; idodide potass, 4gr.; chloride ammonium, 2gr.; gelatine, 70gr.; water, 1oz.; nit. silver, 65gr.; water, 1oz. Emulsify at about 90° F., and keep at same temperature for one hour, wash, filter, and coat plates. I find this very little quicker than wet collodion, and a splendid quality of plate.—GLOWWORM.

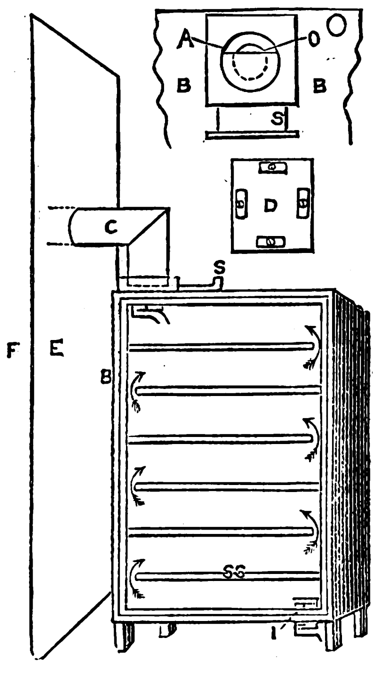
[46745.]—**Stopping Teeth.**—"Murano" has evidently overdone his stopping. The correct thing is to place a tiny crystal of pure carbolic acid on cotton wool, introduce it into the offending tooth, then (if you like), a little collodionised wool, and over all a small piece of cotton wool saturated with a solution of gum-mastic in ether. This is the treatment practised in one of our largest provincial hospitals.—W. B. A.

[46746.]—**Balmer's and Phillip's Gas-Stoves.**—It was recommended as the best means of altering an old stove. A description was then given. I now send a drawing of one I have in use. A round ring of jets are made to burn between two sheet air space cylinders, as shown. It will be seen that there is a large amount of heated surface by this arrangement. The cylinders are screwed together at bottom, and a row of holes punched round opposite to the burner-jets.—THE GAS-MAN.



[46765.]—**Periosteal Rheumatism.**—That means an affection of the bones; there is also nervous and muscular rheumatism. I think I have fifty remedies for my complaint, and I have tried most of them without effect. I have had the best professional advice, have even tried to form a diagnosis of my case to help them; they without exception say it is either a sprain or rheumatism. As the complaint did not kill me I left them, and get on as well as I can. But now I'll say what I think is the matter with both of us: it is the liver that causes all this pain. Professor Huxley says: "The liver is the largest glandular organ in the body, weighing 50oz., which lies in the right side of the body, immediately below the diaphragm, &c.; it lies edgeways and fits into the diaphragm, while its lower surface touches the intestines and right kidney." I find it impossible to lie on my right side; it causes immense pain in back and right arm. I was told to forsake malt or alcoholic liquors, and try milk diet; it made me worse, and brought on a fit of piles, which I got rid of with much trouble. What people call a stitch in the side proceeds from inflammation of the liver; it adheres to the diaphragm and affects the breathing. Our case is enlargement of the liver. What's the remedy? Purgatives? Alas! no: they will only serve to increase the production of secretions, and excite the organ when it should be less active. I only say what I know. The less we eat and drink the better, and take plenty of exercise. I cannot advise further at present. The Turks have great respect for the liver. A cadi addressed Layard as "Friend of my heart and joy of my liver."—FIDDLER.

[46747.]—**Rapid Drying-Box.**—I send desired sketch with pleasure. The letters correspond. A, opening for tin chimney; B, box; C, chimney, which should be forced into opening in strawboard screen, entirely covering a fireplace; D, light-tight door, omitted in sketch; E, screen; F, fireplace; I, air inlet; O, air outlet; S, sliding shutter; S S, shelves. The edges of the shelves, and inside of door, must be covered with felt or flannel, to insure proper current of air, the direction of which is shown by arrows. The box should be used after the fire is out, in a fireplace with a good draught. In summer a Bunsen should be burnt in the grate, to create draught.—GELATINO-BROMIDE.



[46753.]—**A Water-Closet Nuisance.**—If "Silence" will get a short piece of indiarubber hose-pipe and force it on to nose of ball-tap and leave it so long that it may reach to within an inch of bottom of cistern, it will stop all sound as soon as the water rises to above end of hose-pipe. I have proved it often.—A. RICKABBY, Newcastle-on-Tyne.

[46773.]—**Prince of Wales Harp.**—If Mr. Worley will observe the following instructions he will be able to make a Prince of Wales harp that will be far superior to those sold in the shops. Presuming that Mr. Worley is acquainted with the shape of these instruments, I propose that he should make a strong frame of the shape required of good dry beech ¾in. thick. The longest side of this frame should be 18in. and the shortest 15in. The width of the frame should be 12in. The width of the pieces forming the two sides of the frame should be 1½in., and the end pieces 2in. wide. The bottom of the soundboard should be of dry beech ⅜in. thick, planed smooth on both sides, and firmly secured to the frame with hot glue and a few good screws. The upper part of the soundboard may be made of dry beech not more than ¼in. thick before planed. This also should be firmly secured to the frame with good hot glue, but before securing, drill six holes of 1in. diameter, three in a row about 1in. apart in the centre. When this is firmly secured to the frame, place two bridges about 1in. from the ends of the frame, one at each end; cut a small groove in each of the bridges, which should be made of hard wood ¼in. thick and ½in. wide, and glued firmly to the upper portion of the soundboard. In each groove place a piece of thick iron wire, which should be perfectly straight. Secure 18 steel pins a little beyond the bridge towards the edge of the straight portion, or bottom of the soundboard. This will serve to fasten the ends of the wires to. At the other end, which is slanting, fix eighteen good pianoforte pegs ½in. from the bridge. The instrument is now ready for wiring. The wire used should be fine steel wire, such as is employed for the higher treble notes in a pianoforte. In the instrument described there will be eighteen wires, and consequently eighteen notes. The lowest note should be tuned in unison with the 4th or G string on the violin. These eighteen notes will make a compass of a little more than two octaves, excluding the semitones. If any semitones are required, it will be necessary either to reduce the compass or otherwise to increase the width over 12in. The pegs and pins should be placed ½in. apart, in order to allow room for the fingers in playing. Should Mr. Worley require further explanation or information, I will gladly comply with his request, and do my best to help him.—G. FRYER.

[46818.]—**Putting Chain in Watch.**—If you look at the bottom or large part of the fusee, you see a slot cut in the groove where the chain runs, and in this groove there should be a pin, and on this pin you must hook your chain. If you look at the outside of barrel you will see a small hole, this is for the other end of the chain. Take the movements in your left hand, with the pin in fusee and hold barrel upwards, so that they may be easily got at; now hook the V hook (it generally has tail or spike) in the barrel. Place the thumb of your left hand lightly on the hook to keep it from dropping out; let the chain hang straight between the two plates; now take your pliers or a key, turn the arbor backwards, keep your thumb on the barrel to guide the chain and steady it. When you have got chain on barrel, with the exception of about half an inch, take your tweezers and put U-hook under the pillar and hook it on to the fusee; now turn the arbor and allow watch to run down: now put on ratchet, and set up about half a turn; now put on regulator, next balance, get it in beat, &c. I did not give this in my article—I did not think of it. If there is anything else I forgot, I will explain if asked.—A FELLOW-WORKMAN.

[46819.]—**Telescope.**—"Aqua Fortis" is very strong. He asks, "Why are not telescopes made with concave eye-lenses, and the definition would be improved." As to the object being seen erect, that is of no importance in astronomical telescopes. Now, telescopes are made with convex eye-lenses, because the definition is better than with concave. The field is larger, &c. In fact, I would advise "A. F.," as Sterne advised the possible questioners as to the pedigree of "Uncle Tickletoby's mare," to "Read, read, read." I will suggest to "A. F." "Herschel, on the Telescope" (Adam and Chas. Black, Endinburgh, publishers) for a start. It would take up a lot of space, more than our Editor could spare, to go right back to "A. F."; it is a long story.—PRISMATIQUE.

[46823.]—**Watch.**—To "FELLOW-WORKMAN." If you cannot fit a crystal to your bezel in its present form, you will not (in my opinion), be able to fit it at all, as any alteration in the height of the bezel (which would, of course, be necessary), would spoil the look of the watch. You might possibly get a crystal sufficiently concave to clear the hands, &c. Try Stockall, 6 and 8, Clerkenwell-road, or, M. Cohen, Kirkgate, Leeds. —A FELLOW-WORKMAN.

[46823.]—**To "A Fellow-Workman."**—I have sent full instructions for weakening hair-springs, which is in hands of Editor. "Ted Arthur," I think, will succeed with the said instructions.—A FELLOW-WORKMAN.

[46832.]—**Value of Lease.**—Not having seen the property, I should say the present value of "Farmer's" 18 years' lease, to pay 7 per cent. (which it should do), would be £2,600; but if only calculated on the 6 per cent. rate, the present value would be £2,790.—THOMAS WISE, 83, North-street, Clapham-common, S.W.

[46833.]—**Bumping Noise in Engine.**—Most likely your flywheel is not keyed on tight. Cure for this is to cut a key-groove in the shaft, and make a key that will fit both that and the key-way in the boss of the wheel itself.—J. K. P.

[46833.]—**Bumping Noise in Engine.**—I would recommend you to take off the cover of the valve-chest, and ascertain if she does not commence to "open her ports" when the crank is on, or after it has passed the "dead centres." In order to work smoothly, the cylinder should begin to take steam before reaching the dead centres.—J. J. A., Liverpool.

[46840.]—**Organ Reeds.**—I had written another reply to "Wit's End" before I saw this query. As the pipes were in good order when in the swell, it is evident that the wind supply is now insufficient. I should say put them back into the swell, and leave well alone.—J. DRESSER.

[46843.]—**Gas-Inspectors.**—You must first get the Justices of the Peace in general or quarter sessions assembled to adopt the Sales of Gas Acts, 22 and 23 Vic., cap. 66, and order the standard holders, &c., necessary. A 5½ft. holder costs £30 or £35. They can, if the Act is adopted, determine where and when the inspector shall attend to test meters. You should read the book by the late chief inspector of Edinburgh (Mr. Ferrier), which may be had from McKenzie and Suthren, Leith, for 6½d. —A. M. T.

THE New South Wales South-West Railway is now open as far as Carrathpool, or 320 miles in a continuous line from Sydney.

THE electric conductivity of phosphor bronze is given as two and a half times that of iron and steel, and one-third that of copper.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Since our last, "C. R. M.," N.Z., has replied to 31095.

QUERIES.

[46846.]—**Engineering.**—Would any reader of the "E. M." kindly inform me if an examination has to be passed before a person can become an engineer, either mechanical or civil, and if so, what are the subjects?—SEAWEED.

[46847.]—**Equation.**—The following equation appeared in your journal some time ago for solution as an adfected quadratic; but in my opinion the attempts then made to solve the problem as a *quadratic* were all unsatisfactory, while some of them were decidedly illegitimate. Moreover, the equation having hitherto (as far as I am aware) been considered insolvable as a quadratic by the usual means of completing the square, and the only solution I have ever yet been able to obtain from a large circle of mathematical friends has been that of a factor struck out from an expression involving higher powers than a quadratic. I beg, therefore, to submit the following solution as satisfying the conditions of the equation as an adfected quadratic:—

$$x + y + z = 11. \quad (1)$$
$$x^2 + y^2 + z^2 = 49. \quad (2)$$
$$zy = 3x(z - y). \quad (3)$$

Subtracting (2) from the square of (1) and reducing, we obtain—

$$xy + xz + zy = 36. \quad (a)$$

Subtracting (3) from this, we get—

$$2zx - xy = 18. \quad \therefore zx = 9 + \frac{xy}{2}. \quad (b)$$

$$\text{From (3) } zx - xy = \frac{zy}{3}. \quad (c)$$

$$\text{From } (a) \; zx + xy = 36 - zy. \quad (d)$$

Substituting the value of zx from (b) in (c) and (d), we get—

$$9 - \frac{xy}{2} = \frac{zy}{3} \quad (E)$$

$$9 + \frac{3}{2}xy = 36 - zy.$$

Multiplying these together—

$$81 + 9xy - \frac{3}{4}x^2y^2 = 12zy - \frac{z^2y^2}{3}.$$

$$\text{Then } \frac{x^2y^2}{4} - 3xy = \frac{z^2y^2}{9} - 4zy + 27.$$

Completing the squares of both sides—

$$\frac{x^2y^2}{4} - 3xy + 9 = \frac{z^2y^2}{9} - 4zy + 36.$$

$$\therefore \frac{xy}{2} - 3 = \frac{zy}{3} - 6$$

$$\frac{xy}{2} = \frac{zy}{3} - 3.$$

Substituting this value of $\frac{xy}{2}$ in (E), we get—

$$9 - \left(\frac{zy}{3} - 3\right) = \frac{zy}{3}, \; \frac{2}{3}zy = 12, \; zy = 18.$$

From which the values of x, y, and z are readily found.—J. LANE DAVIES.

[46848.]—**Watch Repairing.**—Will "Fellow Workman," or any other correspondent, kindly inform me how to get the fusee chain on barrel? The watch is one of the old style, having a worm instead of a ratchet-wheel. I have tried putting the chain on whilst top-plate was off, but it always slipped off the barrel when putting the plate on. Also, how to lacquer brass dial for clock-face?—A. RIGG.

[46849.]—**Bent Timber Trade.**—I have a small wheelwright's business which I am desirous of further extending, but as it is situated in a small provincial town, there is very little chance of doing this locally. I should, therefore, be glad if some kind reader would suggest something which could easily be manufactured, and for which there is a good market in London, or any other large city. I have steam-power, and labour and materials are cheap; distance from town 100 miles. My own idea was to go into the bent timber trade, shafts, felloes, &c., for the London market; but I have been told this is already overdone. Can anyone say is this so? Any information or advice will be appreciated by one—ANXIOUS TO GET ON.

[46850.]—**Electro-Magnet.**—Will some fellow-reader kindly answer the following?—Last week I purchased an electro-magnet about 2½in. long, with core ½in. in diam. I found that it would not work even with three pint bichromate cells, newly charged, so I took it to pieces and found that upon one limb there were seven coils (about 125ft.) of silk-covered wire, while upon the other there were only three coils. Was this the cause of the magnet not working? If not, what power would be necessary to work such a magnet? Also, what power would be necessary to work it if each limb were wound with an equal number of coils?—PERPLEXED.

[46851.]—**Queensland.**—Would any of your kind correspondents give a few hints on this colony? What prospects are there for a mechanic with a fair knowledge of marine and land engines and general work, with second-class engineer's certificate? Would he be likely to find employment?—FARQUHAR.

[46852.]—**Swollen Glands.**—To DR. EDMUNDS.—Having, for about a year past, been annoyed with swollen glands on the right side of the neck, I should feel much obliged for any information which would lead to their permanent removal. I am 18 years of age, of fair complexion, and enjoying good health.—INQUIRER.

[46853.]—**Bunions or Enlarged Toe-joints.**—Will "Homeo, Nyborg, Denmark," kindly advise me as to the best means to apply to a bunion or enlarged toe-joint. I have them on both large toes. Curiously the one on the left foot I never felt, whilst the one on the right foot of late years has taken to grow a hard skin on the top with a dark centre. This, I found on carefully paring down, was coagulated blood. In doing it, I made it bleed very slightly, and it was perfectly easy for a week or so. Now it is again growing the hard skin, and is most painful when touched. Any suggestion for relief will be gratefully received by—S. J. M.

[46854.]—**Mechanical Action.**—I have two bottle batteries, usual construction, in left-hand back corner of a large case, and I want an arrangement that will prevent the lid of case being closed until the rods of cells are drawn up, to work automatically by the pushing down of the rods. It should also be so constructed that the lid accidentally falling down will not injure the cells.—S. J. M.

[46855.]—**Cayenne Feeding of Canaries.**—Will some reader give a few hints on the above?—AN OLD SUBSCRIBER.

[46856.]—**Electrotypy.**—I have some plaster casts about 6in. diam., nearly flat, which I have been trying to reproduce in copper by electro-deposition; to do which, I made up a couple of Daniell cells, thus—I fitted into two half-gallon pickle jars, copper cylinders filling the inner circumference, porous pots 7×2½, zinc cylinders 1in. dia., unamalgamated in porous pots, exciting liquid, rain-water, and provision is made to keep the copper solution saturated. The plaster casts I coated to saturation with boiled oil, and when dry, carefully covered with black lead, Nixey's, and put into the depositing bath, composed of four parts saturated copper solution, and one part water, to which one-tenth (by measure) of sulphuric acid had been added (Sprague). I coupled up the cells intensity form, and left them—expecting to find a nice deposit of copper on the casts in the morning; but, to my disgust, found only a slight sandy deposit near the supporting-wire, and my porous pots nearly empty. I filled them up again, and in a few hours they were again in the same condition. Now, I can account for the non-deposition on the casts in a measure, owing to the blacklead being bad, or using too much battery-power, or perhaps both combined; but I can't account for the exosmose. I also tried dispensing with the battery by placing the porous pot into the depositing bath (after saturation), and connecting the cast up with the zinc, but could get no further deposit. I have been pretty successful in depositing gold, silver, and alkaline copper; but this is my first attempt at the black lead business in a sulphate solution, and I never have had exosmose occur before.—DISPART.

[46857.]—**Cheap Form of Battery.**—Will your correspondent, H. E. Hawkins, kindly supply the following particulars concerning his battery? viz.:—How he conducts his connection-wire from the iron borings, and how many hours each day, and for how many days the lamp would burn to give a good light? as I presume he has given it a fair trial. My Swan lamp is about 2½in. in diam., and I had an opportunity lately of trying how many ordinary quart cells of bichromate it would take to get a good light, and found it would take 50, and they soon exhausted themselves. So I had to abandon the idea on account of the cost. If Mr. Hawkins will give me the required information, or any other that may be of service to me in lighting my lamp for, say, two hours each evening, I shall be exceedingly obliged to him.—H. M.

[46858.]—**Organ Playing.**—I am a good hymn-tune player, having a fair knowledge of music and time; but being almost entirely self-taught, I am not able to execute pieces upon the organ as quickly as is requisite. I shall, therefore, be glad to know what would be best course for me to follow in practising, what music I should practise, and study? Am not afraid of working, but want some kind fellow-reader to put me in right groove. I have a small Estey organ, no pedals.—POOR QUILL DRIVER.

[46859.]—**Indigo Blue Dyeing—Read, Holliday, and Son's Process.**—Would some of "ours" kindly inform me as to the above process, and in what manner it differs from woad vats?—BLACKWATER.

[46860.]—**Wills and Trustees.**—To MR. WETHERFIELD.—Querist has a small family of girls, in whose favour he wishes to make his will. Unfortunately, what he has to leave them is but small—consisting of furniture and a few hundreds—saved by means of life-insurance. Querist would wish the money kept intact, the interest to be devoted to their support, and the principal divided share and share alike when all are married, but has no one whom he could ask to act as trustee—a generally thankless and troublesome office. Would Mr. Wetherfield kindly say if the Court of Chancery would act in such a case? If so, what officer should be named, with any other information likely to be useful in carrying out the object in view? Querist has been told by some friends that it would be a very expensive mode of protecting their interest, counsel having to be employed at every hand's turn. But to set against that there would be the perfect safety of their small property.—H. NOLAN.

[46861.]—**Cockroaches.**—To what tribe do these belong? I know their names, Blatta orientalis, but I want further information as to their classification. Do they belong to the locust tribe, Gryllus, and to the Neuroptera? In what respect do they differ from the Coleoptera? A friend of mine examined the wings with the microscope, and found them folded back. Why cannot they, and other insects which have wings, fly?—BRICKWALL.

[46862.]—**Telegraph.**—I have an electric telegraph; it runs a distance of about sixty yards. They work pretty fair at a distance of about half-a-dozen yards, but, at the full distance, the needles only move slightly. I have used No. 26 cotton-covered copper wire for inside the telegraphs. I also used the same varnished for the conducting-wires. Does this offer too much resistance? What size should I use for the telegraphs, and what size for the conducting-wires? Why should a fine wire offer more resistance when in a line than it should when wound in an induction-coil where there is a stronger current?—A. H. B., Olney.

[46863.]—**Painting on Silk.**—I have to paint a banner of red silk. The subject is simply a scroll and lettering in gold and silver. Will some of our able correspondents kindly give me full information as to preparing the silk, the kinds of paints to use, and the method of silvering and gilding the letters, and very much oblige—ARTIST.

[46864.]—**Canvas Canoe.**—I have made a light canvas canoe, 9ft. long, 2ft. beam, and 1ft. deep, but I find that I cannot sit in it without about half a cwt. of ballast, as it is too high out of the water. I should be much obliged if some kind friend would tell me where the fault lies. Is it because the canoe is too large? I weigh about nine stone, and I think it would hold two persons of my weight; but I only want it to hold one. I should like to make it smaller if someone would be so kind as to give me the dimensions of a canoe which would carry me without any ballast. Every time I have used it I have had to fill two bags with gravel and put them in the bottom of the canoe; but that was rather too much trouble, as I have to carry it some distance to the water.—ROB ROY.

[46865.]—**Cod-Liver Oil.**—A child aged eighteen months suddenly refuses to take the above, after having taken it about two months with good results. We know of no means of getting it into him now but during the time that he is crying, as he closes his teeth firmly as soon as it is within smelling distance. I would like to know if we may expect it to do him the same amount of good when forced into him in this way. Or I would be glad of any hints as to mixing it or otherwise, so as to induce him to take it as before.—LEEDS.

[46866.]—**Photographic.**—I shall be greatly obliged if some reader of the "E. M." will kindly answer the following questions:—(1) What is the principal cause of want of density when using dry plates? Is it possibly want of sufficient emulsion on the plates? (2) What is the least quantity of emulsion required to coat a quarter-plate? (3) In most formulæ for emulsions in which heat is employed to increase sensitiveness, the washing has to be done after heating. Will washing before heating in any way change the nature of the emulsion? Is one thickness of deep ruby glass sufficient for a dark-room lantern when using rapid dry-plates? If not, what further protection should be used? (5) Is there any means of removing light fog from an emulsion, or from fogged plates? (6) Can anyone supply me with a good formula for dry plates, suitable for landscape? I gather from what I have read that rapid plates are by no means suitable.—L. C. N.

[46867.]—**Bichromate Battery and Intensity Coil.**—Many thanks to J. M. Stocks and G. Tolman for their answers to my query. By intensity coil I meant, could I make one to increase my battery-power equal to sixty bichromate cells? Also, does the solution lose its strength by exposure to the air, as I made a fresh solution on Saturday, and on the Tuesday following (May 2nd), when I tried it, the current was only about half as strong; or, if that form of battery is unfit for lighting, would G. Tolman, or any other kind reader suggest a better? Would the battery described by H. E. Hawkins in No. 891 of the "E. M." be better, and also, would H. E. Hawkins, or any kind reader, give me the length of platinised silver strips, and how to connect the currents.—JACK IN A FIX.

[46868.]—**Auctioneers' Responsibilities.**—To MR. F. WETHERFIELD.—I shall feel obliged if a correspondent will kindly give me legal advice as follows:—I placed an article in the hands of an auctioneer for sale, which was not sold; but while in his possession, on or before day of sale, a part of the article was broken and rendered incomplete. I refused to take it away, and sent him a claim for full value of the article. Should I sue him for the whole, or only part of the article broken, providing I can have the part replaced? Can he charge for warehouse-room under the circumstances.—J. CURTIS?

[46869.]—**Carbon, Resistance of.**—Wishing to construct a set of resistances less cumbersome than the Post-office coils, out of powdered carbon, I should be glad of suggestions. Can any one say the best diameter and lengths for the ebonite tubes for the purpose, and give their opinions as to how they think they will answer? I should feel much obliged for references in the "E. M.," or other works, to articles on carbon, particularly to the one written, I think, by "Sigma," where he says, "carbon possesses the little-known quality of diminishing its resistance with pressure."—M.M.I.Sc.S.

[46870.]—**Triple Star in Monoceros**.—On the 15th March, with my 2¼in Bateman, I picked up a beautiful triplet in Monoceros, in about R.A. 6h. 15m., and 7° 0′ S. The components are probably of the 6, 8, and 9 mags., and their position angles [illegible], 305°, and 2′5′, 7′. As I have only seen this star on two occasions, and as I fail to recognise it by either Webb's "Celestial Objects," or Proctor's "Smaller Atlas," will any of "ours" give the name and particulars of it? I don't think it is 11 Mono., as the angles do not agree. I may say, for the guidance of beginners, who, like myself, have these cheap telescopes, they can, when the weather will admit, easily see the companions to Rigel and Polaris, and divide such stars as λ Orionis, γ Leonis, &c., with power 70, and ϵ^1 and ϵ^2 Lyræ with 115 dia.—T. TINDALE, Gateshead.

[46871.]—**Platinised Silver Plates for Smee's Battery**.—Will Mr. Lancaster or Mr. Tolman inform me how the plates are platinised? I have some silver plates, 13 by 9, that have become useless on account of the platinum wearing off, and they have, up to the present, defied all attempts on my part to give them the dead black colour they had on them when they first came into my possession. I have been told it is done with heat and a brush, and that, when done by heat, they give better results than when platinised by the battery process. The plates are very thick, one weighing about 7oz. A cheap and good method will be of great service to—OLD SUB.

[46872.]—**Staining(?) Walnut**.—On sandpapering a walnut worktable I found that the lid was made up of several pieces, which were of different colours. The difference in colour was not noticeable until I took off the polish with the sandpaper. Will someone tell me how to treat the lid so that when repolished it may appear as one piece, as it originally did? Should the lighter pieces be stained? And if so, what stain is used?—POLISHER.

[46873.]—**Tempering Wagon Springs**.—What is the best and safest way of tempering railway wagon springs?—ANXIOUS ENQUIRER.

[46874.]—**Australian Railway Prospects**.—Would some reader give a few hints as to the best part to go, and what are the prospects in the loco department? RAILWAY FIREMAN.

[46875.]—**Model Electric Engine**.—To "SUNLIGHT."—Kindly give more minute details of the engine described by "R. W.," ENG. MEC., March 17th, 1882 (46217). I am in the dark on some points, especially with the working of connecting-rod, G, and beam, B (Fig. 1). What is meant by "Mercury cups M.M.M. connected by N to E"? Please explain construction of keeper, E, and contact-breaker, &c., Fig. 3. Any general information on the subject, and description of good constant battery will be esteemed by—DARKNESS.

[46876.]—**Circular Saw**.—Will some brother-reader of the "E. M." inform me what speed a circular saw should run?—the saw about 18in. and turned by hand from a wheel 5ft. high, and about 2½ cwt. And what sort of teeth would be best for cutting ash and oak? The wheel is what turns my lathe, and I want to work the saw from the counter-shaft. The strap runs off the 5ft. wheel on to 1ft. pulley on the counter-shaft. And a few hints on making saw-bench, and what size spindle and bearings would be best.—A YOUNG WHEELWRIGHT.

[46877.]—**Wheel Skates**.—Will any reader of the "E. M." kindly explain the construction of a pair of pedomotors?—BEETLE CRUSHERS.

[46878.]—**Respiration and Ventilation**.—Will some of your readers kindly say where I have gone wrong in the following conclusion?—In Prof. McKendrick's "Outlines of Physiology," page 309, it is stated in reference to breathing air in a confined space that "when the proportion of oxygen does not fall below 15 per cent., respiration is normal; from 15 to 7 per cent., respiration becomes deep and prolonged; from 7 to 4 per cent., respiration is carried on with great difficulty, and below that amount, there is risk of immediate asphyxia." Now taking the composition of the air at N 79 and O 21, when the O is reduced to 4½ per cent., its place has been taken by CO_2 to the extent of 16½ per cent. But surely asphyxia will take place when there is much less CO_2 than that. Huxley, in "Elementary Lessons in Physiology," page 100, says that asphyxia takes place whenever the proportion of CO_2 reaches 10 per cent. McKendrick, in his small handbook, published by Chambers, under head "Ventilation," page 99, says, "If CO_2 be present to the extent of 1½ to 3 parts in 1,000, headache and giddiness are felt; and if it be increased to 20 parts in 1,000, death will, in all likelihood, be the result." This does not seem to agree with what is quoted above.—VOLVOX.

[46879.]—**Telephone Transmitter**.—Will Mr. Frank and Mr. Tolman accept my best thanks for kind replies to query, and would the latter please send sketch of transmitter, as offered? I am just completing a pair of circuits and calls (as per 46836), and should be glad if he would kindly answer the following:—1. Amount of primary and secondary with gauge? 2. Would Bell's pattern be a good receiver? 3. Over what length of ordinary line wire should they be serviceable if well-fitted? —ON GUARD.

[46880.]—**Analysis of Water**.—Can any of "ours" inform me which is the most suitable battery to accomplish the analysis of water, and which will also give a spark sufficient to explode a mixture of H and O synthetically? I have been pressed by some of my friends to give a lecture during the forthcoming winter to fill up a series, as this is a subject in which I am much interested. If I comply, I should like to make it as practicable as possible. But what I desire most is to make all necessary apparatus myself, even if not of an elaborate kind.—CLAYTON.

[46881.]—**Boring Working Barrel**.— Would "Sunlight" or "Jack of All Trades" favour me with a sketch of a boring bar suitable for boring a 12in. working barrel out with a 10in. centre lathe? The barrel is 9ft. long, and the bed of lathe 14ft. long.—A COLLIERY MECHANIC.

[46882.]—**Dynamite**.—Will some kind reader inform me what gases are produced and disengaged in the combustion of dynamite? And why the force exerted by the evolution of the gases at the instant of explosion is downward, whilst that of blasting powder is upward?—ZULU.

[46883.]—**Bleaching Straw Hats**.—Can any of "ours" tell me the best and cheapest way to bleach straw hats that have been discoloured by the sun?—STRAW.

[46884.]—**Varnishing**.—Could any reader of the "E. M." instruct me what polish or varnish should be used for Windsor chairs that have been newly painted? I have tried French polish (which I bought ready mixed), which does not give satisfaction, and if French polish should be used, how?—7 4 M.

[46885.]—"**Austral**" **and** "**Sahara**."—I shall be glad if any kind reader will tell me the dimensions of the engines and boilers in the above two named vessels owned by the Orient and Cunard lines, respectively?—ALDIBORON.

[46886.]—**Model Marine Screw Engine**.—I have a pair of double-action oscillating cylinders inverted 1¼in. stroke by ⅝in. bore. The boiler is of copper, 6in. long by 4in. wide, 3½in. deep, copper riveted, with one flue, pressure 20lb. per sq. in. Will any kind reader inform me what size of boat these engines would drive? The propeller I propose is 2½in. diam., three blades. Would it drive a boat 3ft. by 4½in. wide, 5½in. deep, at 10 miles per hour? And will the boiler stand any higher pressure than above? It is made of 20 gauge copper. The boiler ends are flanged and lamp underneath.—ALDIBORON.

[46887.]—**Composition for Tablets**.—How is the cream-coloured material made with which portable writing-cases are often fitted? Pencil marks are easily erased from it, either by water or indiarubber.—GLATTON.

[46888.]—**Astronomical**.—Will some correspondent kindly tell me at what point in the heavens the sun is first seen on the longest and also on the shortest day?—*i.e.*, how many degrees to the north or south of east? I have been examining a reputed British cromlech—a circle of large stones, now buried and planted with trees. About 120 yards distant lies a huge boulder, which evidently at one time has been placed upright as monolith. A line drawn from centre of circle to base of this stone, and continued, would strike, I think, the point of latest sun rising. This circle, I believe, will prove to have been connected with the worship of the sun by our ancestors. But please answer above questions.—NEO.

[46889.]—**Microscopy**.—To DR. SCHRÖDER, of Frankfort.—Vague rumours have been circulated, within the last year or more, of the existence of a microtome devised and constructed by Dr. Schröder, of Frankfort (formerly of Hamburg), which is capable of cutting horizontal sections of P. angulatum, scales of Podura, or sections of the brain of minute insects, &c. Will Dr. Schröder oblige by a statement of facts regarding the practical success of his microtome? One would think such an apparatus would go far towards clearing up the much-vexed question as to the "hemispherical bosses," "depressions," or "hexagonal apertures," in P. angulatum, &c., and possibly introduce precise data for at any rate disproving *some* of the multitudinous guesses regarding the composition of the scales of Podura. It is also rumoured that Dr. Schröder constructed (wholly, or in part) the ruling machine used by the late F. Nobert for the production of his famous test-plates, and that he supplied the diamond points used in the ruling. It is well-known that Nobert was extremely reticent about communicating information on his method of ruling. Now, however, by his death—leaving no working successor—there can surely be no further need of secrecy, and Dr. Schröder might render a service to science by figuring and describing the instrument, and the method of using it, the preparation of the plates, &c.? By making such information public property, possible simplifications might be suggested in the construction, and the test-plates thus rendered accessible to a large body of microscopists to whom the present cost of them is entirely prohibitive.—AKAKIA.

[46890.]—**Microscopy**.— To PROF. E. ABBE, of Jena.—Prof. Abbe would confer a boon upon microscopists if he would explain, by means of diagrams, the best method of determining (1) the focal length (= power, as generally understood in England) of microscope objectives, dry and immersion? (2) The focal length of eyepieces, Huyghenian, Ramsden, "Orthoscopic," and "Holosteric"? (3) The combined magnifying power of objective and eyepiece? The third will, I presume, include the answer to the often-asked query, What is to be regarded as the strict 10in. tube—*i.e.*, between what points should the 10in. distance be reckoned? I need hardly inform Prof. Abbe that English text-books of the microscope, whatever other merits they possess, do not overflow with information on technical questions relating to the testing of the instrument, but very much the reverse. Therefore, a short exposition of the subject from the pen of so eminent an authority as himself will, I am sure, be highly appreciated in England, where his name has come to be synonymous with all that concerns the development of microscopy, both in theory and practice.—AKAKIA.

[46891.]—**To Mr. Lancaster**.—I am sorry to give you so much trouble. I have a Siemens' armature (6½in. by 4½in.) wrapped with No. 18, and wish to construct an electromotor on either Griscom's or Trouvé's principle. The resistance of the armature is ·625ohms. What must be the thickness and resistance of the wire on the field-magnets? Could you also advise me as to which principle I ought to adopt, and oblige?—CLOTURE.

[46892.]—**Japanning**.—Among my other duties at an hotel in France, I have to paint about 100 copper hot-water cans. I have tried various kinds of paint, but it all blisters. The cans were originally made and japanned outside in England, and I cannot get them re-japanned here. I should be very thankful if any of "ours" would tell me how to paint or japan them so that they will stand hot water.—BOOTS.

[46893.]—**Speaking-Tubes**.—Will any reader kindly say the greatest distance that a speaking-tube is available for, the diameter of pipe, and any particulars? I have a stable about 150 yards from the house, and am uncertain whether to erect telephone or speaking-tubes.—DIAMONDS.

[46894.]—**Covering Silk Balloons**.—I have made a small silk balloon which I thought I could make air-tight by soaking in oil, but I find it is not perfectly air-tight now. I believe there is some kind of varnish I could use, but could I varnish it without taking out the oil from the silk first. I do not think it would be worth while to take out the oil, as it is not a very large one. I only made it for an experiment. Please oblige—CREDENTIBUS NIL DIFICILE.

[46895.]—**Manganate of Calcium**.—Will any of our chemical friends tell me how to make this, or the permanganate for experimental purposes? And, if either of them are produced commercially? I know how to get the potash and soda compounds.—ANGLO-SCOT.

[46896.]—**Manganese**.—How can I regenerate manganese compounds decomposed by contact with organic matter?—ANGLO-SCOT.

[46897.]—**Powerful Bichromate Battery**.—Would some kind reader give description of above, composed of several separate cells, each cell having several carbons, with means of raising and lowering zincs? If drawing could be sent showing plan of lowering zincs, and of joining all the cells together, so as to give a very strong current for electric light purposes, it would be most useful.—A CONSTANT READER.

[46898.]—**Musical Box**.—Would any reader kindly inform me how to fasten the small springs (or quilling, as it is generally called) on the teeth in the comb of a musical box when they become loose and cause the instrument to scratch when playing? and also if a small musical box can be repaired when it begins to scratch in the same way.—W. J. E.

[46899.]—**Heating-Room for Turkish Bath**.—Will some one kindly inform me of an economical, and, at same time, healthy method for heating a room by hot-air, for use as Turkish bath on a small scale for private use? I want something that will not give much trouble. —DELTA.

[46900.]—**Mounting Micro. Lens**.—Thanks to Mr. Lancaster for his notice of my query. My difficulty is this: In mounting a plano-convex lens with plane side inwards, I can turn a square shoulder on which to rest the lens, and can depend upon its being truly centred; but when it is required to mount the plane side outwards, and have the convex side for a bearance, I fail to see how I can secure its being truly centred in the cell. Will Mr. L. kindly help me?—MICRO.

[46901.]—**Watt's Parallel Motion**.—Can any reader favour me with a solution of the following problem? If the beam and the radius-bar be of equal length, and the distance between their centres of motion be given, what proportion should the length of the link bear to the length of the beam, in order that the middle point of the link shall most nearly describe a straight line?—A. J. SMITH.

[46902.]—**Construction of Maps**.—Can any reader refer me to a book now in print dealing fully with the different methods of projection employed in the construction of maps?—A. J. SMITH.

[46903.]—**Electric Bell**.—Will Mr. Lancaster, or other correspondent, kindly put me right? I have made an electric bell (a small one), but it does not answer to my satisfaction. On completing circuit, instead of getting a clear ringing sound, the blows of the hammer are heard quite as plainly as the sound of the bell. The hammer, when at rest, is ⅛ of an inch from the bell, and, if I move back the contact-screw, the magnet is not powerful enough to draw up the keeper. It appears to me I have got the magnet and armature too near the hammer, and, consequently, cannot get sufficient stroke. Also please say if four layers of 26 wire on ⅜ core is about right for magnet, and much oblige—OLD SUBSCRIBER.

[46904.]—**Secondary Battery**.—Would J. Hezmalhalch, jun., kindly give the dimensions of his parallel plate Sutton's secondary battery, how he connected the wires, what battery power he used to charge it—in short, a full description how to make it.—SEAWEED.

[46905.]—**Incandescent Lighting**.—I have made one of Mr. Bennett's cells, by way of trial. The tin pot measures 5½in. high by 3in. in diameter. It rings a bell fairly well, and I have calculated that three of them would equal two small Leclanchés. Now, I should like to know how many of these it would take to light one incandescent lamp equal to four or five candles.—SEAWEED.

[46906.]—**Swiss Watch**.—Will "Alfojoe," or any other watchmaking subscriber, inform me what is the cause of a clinking noise in a Swiss watch when it is held dial upwards? Also, how to rectify? Also, how can I form an idea of the strength of a pendulum spring to a new watch—viz., by pulling out spring from balance by aid of the tweezers?—HARRIS.

[46907.]—**Benzoline**.—To MR. FRED FISHER.—Would you please tell me if you can use benzoline with your generator with as much safety as ether?—W. H. PITT.

[46908.]—**To Hy. E. Hawkins**.—Would you be kind enough to tell me if a quart cell of your form of cheap battery would be anywhere near the power of a Bunsen cell of same size? Also, object of wooden plug, and length and size of platinum wire in Swan's lamp—if not troubling you too much?—W. H. PITT.

[46909.]—**To "H. S. B."**—Would you kindly give us a description of the electric lamp you used with your Bunsen's battery, as I intend making a battery like yours? W. H. PITT.

[46910.]—**Watch Mainspring**.—Will some horological friend tell me how to calculate the length for new mainspring? I trust "A Fellow Workman" will continue his articles on "Watch Cleaning and Repairing." —BAZIL BEE.

[46911.]—**Lathe**.—Would some reader kindly inform me the capabilities of a 5in. lathe without back-gear, compared with a 4in. with back-gear?—BRASS.

[46912.]—**Medical Coil**.—I have a bobbin 6in. long, with hole of 1in. in diameter. What length (or weight) and size of primary and secondary coils? Can the current be properly controlled by adjusting-screw over contact-breaker? Or, would it be advisable to make use of the iron wire core for that purpose? What kind of battery and size is the best to make the whole a portable and useful apparatus; also, what would be the probable cost to complete it? I might add I have a small lathe, and plenty of small tools.—G. D. G.

[46913.]—**Stopping for Decayed Teeth.**—To "ALFOJOE."—Some time ago I tried in vain to make a metallic stopping, as described by you, that would set hard. What is the reason I could not succeed? Coarse and fine pure silver filings were used, and an amalgam formed, but it would not set in the least. Excess of mercury was squeezed out. Silver, 60 parts; tin, 20 parts; and zinc, 6—but with same result. I have teeth stopped by dentists, and it is quite solid. What is it they use?—J. S. R.

[46914.]—**Drop - Shutter.**—Would some reader kindly describe how I can make a simple but efficient drop shutter to fit a lens, diam. of which is 3¼in.? Full instructions, with the measures, would oblige—F.

[46915.]—**Die-Sinking.**—Could anyone recommend me a good book on die-sinking? Also, inform me what tools, &c., are necessary?—JACQUES.

[46916.]—**Carpenter's Bench.**—Will someone send me instructions for making a cheap, strong, and useful carpenter's bench?—W.

[46917.]—**Raising Water.**—Would any kind contributor give me instructions how to raise water a height of 40ft. from a distance of 70ft. up hill? I am living in Burgoyne Bay, Salt Spring Island, British Columbia, so the materials for making the above are very limited.—W.

[46918.]—**Deeds.**—To MR. WETHERFIELD.—A. buys household property of B, a mortgage being left on the said property of which B. holds the deeds. A. pays the mortgage off. B. will only give the last deed up, refuseing to give up the old deeds, under the plea that A. has all he requires for his safety in the property. Can A. claim the old deeds, or what course should he pursue?—R. J.

[46919.]—**American Organ.**—Will some reader be so good as to tell me how I can get at the vibrators of an American organ? One note of mine (an ordinary four-stop organ, with knee swell) has gone dumb. I wrote to the person from whom I purchased it, and he cannot tell me how to get at the vibrator. I took out the front and upper part, and then the key-board. Under this there is a row of pegs on which the keys act. Behind and in front of these there are two thin boards screwed in. These I took out; but I cannot see any more screws, or any means of getting further towards the vibrators.—B. M.

[46920.]—**Skin Disease.**—Will Dr. Edmunds kindly say what agent to apply after the hair-drawing and poulticing, which he advised "Sufferer," in the case of sycosis, a few weeks back? I have had sycosis 23 years. It began, apparently, with a pimple from a cut in shaving; spreading over the lower part of my face and now going up behind the ears into my head.—ARC.

[46921.]—**Organ or Harmonium.**—If "Joiner" will advise me as to following, it will prevent another query, and complete the information needed. Decided that half rows only be used, as I have sub-bass in way. Can I use strips across under side of soundboard for sub-bass? so making one pallet do the work, and dispensing with the existing double pallet action, which is hard, and wastes wind. Of course I know such channels would have to be radiated, but would the sub-bass be as effective? 2. Adopting this, what length should bass-end pallets be? 3. Shall I glue parchment on under side of strips, and finish with wood where pallet rests? 4. My instrument at present has two rows reeds—sub-bass, and octave coupler. The bellows is 2ft. 11in. by 2ft. 8½in., and opens out 6in. With the two extra half-rows added, is bellows large enough, or can it be enlarged, and how? The case won't admit wider.—BETA.

[46922.]—**Patent Wrought Sharp-Pointed Nails.**—Will any reader please inform me how the above are made?—W. H.

[46923.]—**Hollow Back Vellum Binding.**—I have just made six foolscap folio account books with hollow spring backs, but although fairly satisfactory in the result, the means employed by me were, I am sure, not the correct ones, they being so awkward. A few plain directions in vellum binding, a hint or two on case-making would be welcomed.—PRINTER-BOOKBINDER.

[46924.]—**Anemometer for Use in Mines.**—Could any of the correspondents of this valuable paper give me any particulars of the above instrument as used in coal mines, &c., to ascertain the velocity of air passing in a given time? Any information on the subject will oblige—A NEW SUBSCRIBER.

[46925.]—**Water in Gravel-Pit.**—I have a gravel pit of about two acres, in which I am troubled with a considerable amount of water. I have had serious thoughts about getting rid of this water; could I overcome this difficulty by sinking a deep well down to the mainspring, and so draining same way? I should very much like the advice of some of our practical men. Also, if the above would answer? Which is my best way to sink a well for this purpose, and about what would be the cost of same? Any advice on the above would be gratefully received.—H. BOOKER.

[46926.]—**Regilding Candlesticks.**—I have a couple of candlesticks which I want to regild, and I wish to know whether they are done in gold-leaf or bronze. Would Mr. Soward, or some other correspondent, please give the desired information and oblige. I can do plain gilding.—E. RILEY.

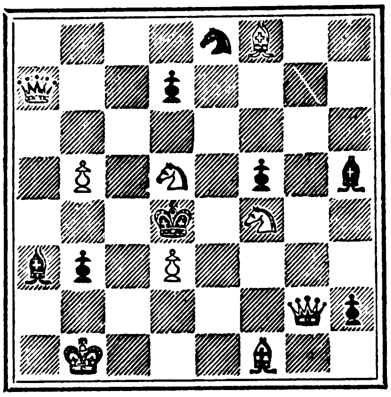
[46927.]—**Gas Bath.**—I have a patent gas-bath by Phillips and Son, Barbican, London, in which the water is heated by circulating through a copper boiler attached to the bath. When first used it gave every satisfaction; but, latterly, the heating has become a very slow process, taking more than two hours instead of the original half-hour. This, I presume, arises from the lime deposited by the water in the tubes having narrowed the passage, and so prevented the rapid circulation necessary. Perhaps some of the many obliging correspondents of "ours" would say what is required that would be within the reach of an amateur, the workmanship being so solid as to be quite beyond his ability to open up. Would it answer to bring up the lower opening into the bath, and pour paraffin into the upper one until the coil be filled, with a view to dissolve the lime? and, if so, how long should it be left in?—H. NOLAN, Clifton Villas, W.

CHESS.

ALL Communications for this department must be addressed to the Chess Editor, at the office of the ENGLISH MECHANIC, 31, Tavistock-street, Covent-garden, W.C.

PROBLEM DCCXLV.—By SERGT.-MAJOR MCARTHUR.

Black.

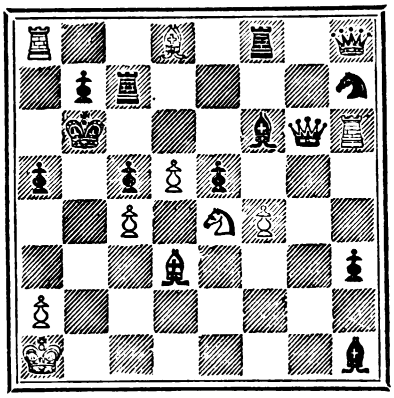


White.

White to play and mate in three moves.

PROBLEM DCCXLVI.—By R. B. WORMALD.
From *Chess Openings.*

Black.



White.

White to play and mate in three moves.

SOLUTION TO 741.

White.	*Black.*
1. Q to K B 4.	1. Anything.
2. P to K B 8 (Kt) mate or Q or R mates accordingly.	

SOLUTION TO 742.

White.	*Black.*
2. Kt to K Kt 6.	1. Anything.
3. Q or Kt mates.	

NOTICES TO CORRESPONDENTS.

CORRECT solution to 741 and 742 by Schmucke.

GAME played recently by correspondence between Messrs. W. T. Pierce and J. Pierce:—

(Steinitz Gambit.)

White. Mr. W. T. Pierce.	*Black.* Mr. J. Pierce.

Black here inadvertently played Q to Q sq., and thus White secured a draw.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or requies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, May 10, and unacknowledged elsewhere:—

GRIMSHAW AND BAXTER.—E. P. Alexander.—Rev. H. L. James.—G. Marecroft.—J. and H. Grace.—S. Lancaster.—C. R. Hibbert.—H. Milnes.—Crossley Bros.—F. A. Cobbold.—A. Broatch.—T. C. Molesworth.—J. Tripplin.—Pragmatical.—Glatton.—H. A. Wassell.—Stereo.—F. Roberts.—Svenska.—J. L. M.—C.—J. C. A.—Odine.—Chemist.—Jas. Parkinson.—H. J. J.—E. R. Trotman.—F. C.—A. Parker.—Aria.—T. W. W.—Moonlight.—E. ANXIOUS INQUIRER. (1st query inserted. 2. Yes, under our present land laws your landlord will take without recompense every improvement you have effected.)—W. J., North Wales. (Such employment *would* tend to deteriorate your sight. Dr. Edmunds intended as such, plainly and rightly.)—J. W. HISCOX. (Your liability *is* limited to the amount of the shares you hold.)—J. F. (Yes, but not to the extent it is used in England.)—H. B. (1. Yes, speaking generally. 2. The exact meaning of the word is "without knowledge," and a modern agnostic is one who holds his belief, as it were, in suspension about matters which others either have or profess to have a clearer idea or belief. 3. We do not know where you are likely to obtain the instrument made by the optician you mention. Possibly an advertisement in the "Wanted" column might procure one, though it is questionable if many were ever made. 4. We know nothing of the maker named. It is, we believe, a common trick on the part of unscrupulous vendors to offer "fire-proof" safes for sale marked with a name closely resembling that of some well-known maker.)—E. HOLMES. (Thanks for the sketches, but we can scarcely find space for drawings which serve only to show that sunspots appear slightly different to different observers.)—W. ROBINSON. (In the first case, apply to the Board of Trade, in the second to the secretary of Lloyd's. For the third, look out for advertisements of the steamship companies wanting a superintendent. If you have any "influence," that would be a great help.)—W. WILD. (If pure rubber, you can join with rubber cement alone, but if vulcanised you will, perhaps, succeed by scarfing the ends and binding them well, using the cement and a piece of thin linen, with fine string or thread. 2. The cement you mean is made by melting together half pound of guttapercha, 2oz. indiarubber, 1oz. pitch, ½oz. shellac, and 1oz. linseed oil. Applied by melting. Not suited for china. For that, shellac alone dissolved in alcohol to a paste is used, or isinglass dissolved in acetic acid. See No. 729 for a variety of cements.)—H. FIELD. (A similar request is made in the last number.)—G. C. FOX. (If the maker advised the glycerine developer, write to him for further instructions. Read the paper on p. 189.)—A. H. METZ. (Besides the number mentioned last week, full directions for making single-needle telegraphs were given in Nos. 549 and 555. Those numbers are out of print, but you might be able to pick them up at some of the second-hand booksellers, or obtain them through the "Sale" column.)—C. THORP. (Prof. Dolbear's description will be found on p. 396, No. 849, and on p. 81 *ante* a correspondent gave an account of the paper Prof. Dolbear read recently at the Society of Telegraph Engineers.)—H. WORTH. (Connect one wire or pole of the condenser to the pillar and the other to the hammer.)—AS I KNOW NOT. (Gold size, marine glue, or asphaltum varnish, but roughen the cell and the slide where it is to be fixed. Gold size is easiest to work. It does for both mediums, provided there is no spirit or turpentine in the preservative. You can add a little whiting to it, or, which will perhaps suit best, use plaster of Paris beaten up with white of egg thin.)—ONE IN A FIX. (You will find a number of recipes for making gold plating solution in Vols. XXVIII. and XXIX. Also in recent volumes many practical directions.)—VOLTAMETRE. (No, we do not. Such matters are of interest only to manufacturers, but there are many machinists who would be glad to make a stamping apparatus of the kind.)—

AND

WORLD OF SCIENCE AND ART.

FRIDAY, MAY 19, 1882.

THE IRON AND STEEL INSTITUTE.

THE meeting of the Iron and Steel Institute was held last week. The first paper read was that by Mr. E. Richards, on "Certain Physical Tests and Properties of 'Mild' Steel," a material which has recently become of great importance to mechanical engineers and steel-makers. The paper was of purely technical interest, being chiefly devoted to giving an account of a number of experiments made by the author. Mild steel, he said, is a metal possessing the excellent qualities of ductility and strength in so high a degree that it is worked with the greatest satisfaction by practical men. Its use is rapidly increasing, and it is therefore important to ascertain what is its real strength. The author in his paper gives his results for tension after tension, tension after compression, and tension after torsion, and his experiments show that the elastic limit of a steel bar varies according to the treatment undergone by the bar before testing. In one sense, his experiments support the view held by Dr. Siemens that any mechanical treatment to which mild steel is subjected invariably increases its strength, but Mr. Richards points out that this dictum holds good only when "strength" is taken as increased resistance to statical pressure. If by strength is meant the power to resist impact, then mechanical treatment has the effect of diminishing the strength. The paper contained some interesting notes on the permanent magnetic properties acquired by bars tested in a machine placed in a line north and south. Steel under compression he finds also becomes permanently magnetic, the polarity being determined by that of the magnetic field in which the bar is placed during compression. Besides this point the paper is of special interest to makers and users of mild steel, and as the president said, it will bear careful study when published in the *Journal*.

Probably the most interesting paper read at the meeting, from the popular point of view, was that in which Mr. Mosley, of London, described a new method of mining coal, which avoids all the risks that are inherent in the usual system of blasting. The method has been patented by Messrs. Smith and Moore, and has been in use for several months at the Shipley collieries, Derbyshire. The new method consists in the use of a cartridge of lime instead of gunpowder or dynamite,—the expansion of the lime when slaking being utilised for forcing down the coal, thus avoiding the dangerous flame from the explosion of gunpowder. The lime is in a highly caustic state, and after being ground to a fine powder is consolidated under a pressure of 40 tons to the square inch into cartridges of 2½in. diameter, with a groove on one side for the admission of the water-pipe. The shot holes are drilled by means of a light boring machine at Shipley, and an iron tube about ½in. in diameter is inserted first. This tube is perforated, and is inclosed in a calico bag, which covers the perforations and one end, the other being closed by means of a tap. This pipe, it will be understood, fills the groove in the lime-cartridge, which is inserted after the pipe and lightly rammed. The hole is then tamped in the usual way, and a small force-pump is connected by means of a flexible tube. Water equal in bulk to the lime is then forced in, which, escaping at the inner end of the tube and from the perforations, flows along the groove towards the tamping, driving the air before it. The tap is then closed and the flexible pipe disconnected, the steam generated by the action of the lime on the water cracking the coal away from the roof by the high pressure it reaches. After introducing the water, the operator has ample time to get away to a safe distance, though, as a matter of fact, we believe there is no danger of the steam blowing out, and no risk from too early fall of the coal. After the steam has exerted its effect, the expansion of the lime comes into play, and the force can be judged by the bulk occupied by a slaked cartridge as compared with one of the compressed specimens. At any rate, the force exerted is sufficient to bring down the coal in large masses clean from the roof, with the minimum of "small," and in greater quantities than is possible with "wedging." The coal is underholed by the hewer, who places sprags underneath, and it is found as a rule that the coal is cracked away for a distance of several inches beyond the inner end of the bore hole. In places with bad roofs, the collier would remove only a few sprags at a time, so as to let down enough coal to load, and giving him an opportunity of supporting the roof before clearing a large space. The time occupied in drilling is averaged at twelve minutes, charging and tamping consumes four, and "firing," which in this case is pumping, one minute—thus effecting a saving of time as compared with blasting. This saving, however, appears to be lost subsequently, as the lime cartridge acts slowly; but in from ten to fifteen minutes after pumping the coal has been cracked away, and is ready to fall when the sprags are removed. As, however, there is no loss of time in preparing to fire a shot, and no risk of igniting the explosive gases, this method of coal-getting will probably prove to be, as Mr. Cowper said, one of the most important inventions for getting coal we have had. Besides the advantages above noted, it should be remembered that the action of the lime, powerful as it is, is free from shock or concussion, which has much to do with roof-falls, and with disturbing bodies of gas that would otherwise be harmless. No wave is imparted to the air of the workings, and the coal comes down with the minimum of dust, both of which are occasionally elements in an explosion. To give an idea of the power exerted by the lime cartridge, two iron pipes were shown, which had been broken by the expansive force of the lime and steam, though one had been previously tested to a pressure of 953lb. on the square inch. The author of the paper gave a comparative statement of the quantity of coal got in adjoining stalls by means of wedging and lime-cartridges respectively, the comparison being greatly in favour of the latter; but its chief merits are unquestionably the avoidance of risk of explosion and the lessened danger from falls of roof—two evils inherent in the system of shot firing.

The next paper was by Mr. W. Gill, of Luchana, Spain, on the iron ore district of Bilbao. The information given will be of interest to many ironmasters, but possibly the details of the wire-ropeways will be regarded as of most value by miners. There are several miles of them belonging to different companies in the district, and Mr. Gill's paper contains full particulars of their arrangement and working.

Prof. Von Tünner, of Leoben, Austria, sent a paper "On the Use of Lignite in the Blast Furnace," a subject which is not of much interest to English ironmasters, though what the author has to say may be of use to them in other countries.

A paper by Mr. Geo. E. Woodcock, of Sheffield, was read on Friday, in which the author endeavoured to show (1) that the carbon of steel is, primarily, in a state of simple absorption in the iron; (2) that the hardening of steel is due to a metamorphic change in the condition of the carbon, which then assumes a crystalline form, closely analogous to that of the diamond; (3) that the varied tempering of steel results from the dissociation of this crystallised carbon at varying but low temperatures; and (4) that the real strength of steel does not vary to any material degree with a varying content of carbon—that is, *cæteris paribus*, steel is not increased in tensile strength by an increased percentage of carbon. Mr. Woodcock inclines to the theories of Jullien and Prof. Akermann, and he holds that Jullien's hypothesis, slightly modified, is correct. The hardening of steel on this view is due to the crystallisation of the "combined," or, as Mr. Woodcock prefers to put it, "absorbed," carbon in a form resembling the diamond—an hypothesis which was reported on by a committee of the Institution of Mechanical Engineers, who found that, while it accounted for hardening, it left tempering unexplained. Unless some change occurs in the carbon, no hardening takes place: raw cemented steel, as it comes from the furnace, says Mr. Woodcock, is as soft and easy to work with the file as the wrought iron from which it is made; but on being heated and quenched, it becomes as hard as any other description, and if fractured, shows a crystalline structure which can be due to nothing else than carbon. The crystals are not found in wrought iron; they are more numerous in proportion as the original amount of carbon in the steel increases; and in a large bar they may be found more numerous in the outer layers than in the inner, whilst the centre may have none at all. In such a case the hardness of the metal will be found to decrease inwards until when the centre is reached, where no crystals are seen, the steel is found to be as soft as it was in the original unhardened state. The diamond is the only known form of crystalline carbon, and it would seem to follow that the hardening of steel is due to the carbon being metamorphosed into a number of small particles analogous in constitution to diamonds. This "diamond" question naturally formed the chief feature in the discussion, Mr. Stead suggesting that it might be settled by dissolving the steel in acid, for if powdered diamond were mixed with powdered iron, and the mixture digested with acid, the diamond would be found undissolved; but if hardened steel were dissolved in the same, no residuum of "diamond" dust would be left. The general result of the discussion was that more experiments were needed before a conclusion could be arrived at—one at least of the speakers contending that if carbon is combined with the iron it is only by the loosest ties. A paper by Mr. Jeans, the secretary, on the consumption and economy of fuel in iron and steel manufacture, was a statistical account of the development of the manufacture from the point of view of fuel.

LAWSON'S BOILER EXPLOSION EXPERIMENTS.

ON p. 461 of the last volume, we gave an account of the experiments carried out by Mr. Lawson at Pittsburg, with the view of solving some of the mysteries of boiler explosions. His contention is that if steam in a boiler is suddenly allowed to move, and is as suddenly checked, it produces a concussive effect; and, further, that every particle of the water contained in the boiler tends to fly into steam as soon as any portion is released. On the occasion to which we referred at the place mentioned, a boiler, the bursting pressure of which, according to our formula, was 329lb., exploded with a loud report when a pressure of 380lb. was reached, the explosion taking place immediately after, and being consequent on, the sudden opening of a valve which admitted the steam into a closed vessel. As we pointed out at the time, the explosion of a boiler strained beyond its bursting pressure proves nothing; but Mr. Lawson has lately succeeded in bursting a similar boiler at a pressure much below what it is calculated to withstand, and it follows either that there is some substratum of fact in his theory, or that the boiler was not so strong as by the formula it should be. We can only speak from the published statements, and those show that the boiler lately exploded was identical in construction with that referred to on p. 461 of our last volume. It was 6ft. long, 30in. in diameter, the shell being formed of two plates of best iron three-sixteenths thick, the heads being of three-eighths iron, stayed by a one-inch iron rod passing through the centres of the heads. By the well-known formula—$P = T \times c / D$ the bursting-pressure of such a shell is 329lb., single riveting being assumed, for T equal thickness of metal in sixteenths, c equal a constant (1097) for single riveting, and D equal the diameter of the shell in quarter feet. We have thus $3 \times 1097 / 40 = 329$. Two shells of these dimensions constructed from the same batch of plates were prepared for the experiments, but one of them was fitted with Mr. Lawson's patent "diaphragm," an arched perforated plate of three-sixteenths iron, fitted near the water-line inside the boiler and riveted all round—forming, we need scarcely say, a very strong "stay," and enormously increasing the strength of the boiler. The scene of the experiments was the Munhall Valley, about eight miles from Pittsburg, a place which, so to speak, has been fitted up for such trials, and was selected by the Government commission in 1873. Through loopholes left in the bomb-proof, visitors can witness in safety the actual explosion of a boiler. The conditions of the recent experiments were much the same as those detailed in our previous article, the boiler being connected to an old engine cylinder 8in. in diameter and 36in. long, by 15ft. of horizontal, and 3ft. of vertical iron pipe $3\frac{1}{2}$in. in diameter. Near the elbow of this pipe—that is, about 15ft. from the boiler—was placed a quick-opening gate-valve $3\frac{1}{2}$in. in diameter, and the furnace was fed by injecting petroleum on the incandescent coals. Inside the bomb-proof were two gauges connected respectively with the front head of the boiler, one above, the other below the Lawson diaphragm, that is, one to indicate the pressure and disturbance in the steam space—the other to show the disturbance in the water-pressure when the valve was suddenly opened. These pressure-gauges seem to have been very untrustworthy, being some 50lb. or 100lb. "too fast"; but allowance being made for that, no result followed the experiments on the patent boiler with pressures estimated at 225lb. On attempting to experiment with the plain boiler, one of the heads cracked, and it was found impossible to get a higher pressure than 220lb., owing to leakage. Accordingly the patent boiler was reset and trials made at gradually increasing pressures up to 300lb., without creating an explosion. The patent diaphragm was then cut out, with the exception of a margin all round about 3in. wide, so that the boiler was really stronger or weaker than that experimented upon last year by just the difference due to these 3in. strips, less the weakening effect of the rivet-holes by which they were held to the shell and heads. With 20in. of water in this boiler (leaving 10in. at the crown for steam space), experiments were made by opening the valve at every rise of 25lb. up to 225lb., without result. After reaching 235lb. the valve was again opened, and the boiler immediately exploded, the water disappearing in what are termed "practically ultimate atoms," and the shell being "torn into shreds." Seeing that the water in a steam boiler under a pressure of 235lb. has a temperature of 400° Fahr., it is not a matter for surprise that it vanished as a cloud of steam when the boiler was rent into shreds; but the curious part of this experiment is that a boiler, the bursting pressure of which is by calculation 329lb., should have exploded at a pressure of 235lb., when another of similar dimensions and practically identical did not explode until a pressure of 380lb. had been indicated (see p. 461, Vol. XXXIV.). As the facts stand, the result of the experiment would seem to prove that Mr. Lawson's hypothesis is correct, and that boilers may be exploded by the sudden opening of a valve, provided the rush of steam is also suddenly stopped, thus producing a sort of concussive effect; but we suspect that those who remember that steam is an elastic fluid, will scarcely regard these experiments as conclusive, either of the "blow" theory or of the merits of Mr. Lawson's diaphragm, which is supposed to prevent explosions in some occult way by compelling the suddenly created steam to pass through its perforations before it can impinge upon the boiler shell. At the close of our previous article we said that for such experiments to support Mr. Lawson's view it will be necessary for him to show that a boiler which could stand the hydraulic test up to, say, 500lb., can be exploded by merely opening the valve leading to a closed cylinder when the gauge shows a pressure of only 380lb. The figures are not of much moment, and as it is expensive work exploding new boilers, it may be worth while pointing out that old ones will serve just as well. If the "blow" theory is correct, there should be no difficulty in demonstrating it in a satisfactory manner, which can be done only by exploding a boiler at a pressure less than it has previously sustained when tested by the hydraulic method.

SECONDARY BATTERIES.

THE important part that secondary batteries will eventually play in electric lighting, renders any items in connection with their construction of great interest. As will have been expected, several patents have been recently taken out, and many others are awaiting publication. Of some of the devices we are enabled to give a brief description, which may be of interest, though there is reason to believe that later forms have superseded them. As we mentioned some time ago, Mr. Sellon has taken out several patents for secondary batteries, and as the development of that invention will form a feature in the electrical history of the nineteenth century, we give a short account of some of his devices, supplemented by those of other inventors. In his specification of September 10th last, he describes the use of perforated plates, or sheets roughened, serrated, or indented, composed of lead, platinum, or carbon, upon, in, or against which are held films of spongy lead, or salts of lead, or other suitable substances. In the drawings accompanying this specification, Mr. Sellon shows lead plates bent so as to form a series of dovetails over the surface, or serrated like the teeth of a saw, both being perforated with numerous holes, in which and in the folds of the serrations or the dovetails, the active material can be packed, the object being to get as much as possible of that into the smallest compass. Five days after that specification was deposited, Mr. Sellon appears to have left another, the main feature in which is the use of an alloy of lead with antimony as the material of which the plates are to be composed. It is clear that the ingenuity of the inventor has tolerably wide scope in determining what shall be the actual form of the elements or supporting plates of the secondary battery, and it is obvious that if perforated lead plates are an advantage, they can be made up of a number of short pieces of lead tube, arranged with their axes parallel. We have reason to believe that experience has declared in favour of an alloy of lead and antimony in preference to the simple metal, and for convenience in working or for remedying any accidental effects of local action, plain plates, with many perforations, are preferred to the corrugated and other devices suggested for the purpose of gaining surface. It will be understood that one object of these inventions is to dispense with the canvas or felt supports for the coating of oxide, because in practice it is found that nothing yet tried will long withstand the effect of the acid liquors used to excite the action. Corrugating the plates possesses an advantage in presenting greater surface in an equal space; but when felt or canvas is dispensed with, there is some liability of "lead-trees" forming a cross and connecting the two elements of a cell. Hence, it is found advisable to so arrange the plates that any points of contact of that kind can be readily removed. M. de Kabath, of Paris, has also taken out patents for secondary batteries, the feature of his invention being the method adopted to prevent the coating of lead-oxide from falling off. He forms a composite electrode of thin sheets of lead, folded around a thicker sheet, which acts as a support, the whole being enveloped in a sheet of parchment-paper, a substance which, having been already acted upon by sulphuric acid, is only slowly destroyed in the battery. In M. de Kabath's design the sheets are either plain or corrugated; but in all cases a thin coat of sulphate of lead is formed upon them, and the form consists of alternate plain and corrugated lead plates, packed between stout lead covers held together by indiarubber bands, the whole being inclosed in a case pierced with holes. M. de Kabath has also taken out a patent for a method of regulating the discharge of secondary batteries (September 20th, 1881). That is accomplished by increasing or diminishing the depth of solution in the battery-cell by means of a tap moved by magnets actuated by a relay. Thus when the current in the main circuit decreases, the spring of the relay moves the index and puts into action the magnet controlling the inlet of solution, so that a greater surface of the plates is immersed, and the current is increased in proportion. Similarly, if the current is too great, the tap is so turned as to run out some of the solution from the battery, so leaving a smaller surface of plates under action. MM. Deprez and Carpentier have also obtained a patent (September 24th, 1881) for distributing and regulating the transmission of electrical power, in which they use two secondary batteries, so connected by means of a commutator that while one is being charged the other is giving out current; but as they do not specify any form of battery, the claim is only for the details of the arrangement.

Secondary batteries having some really novel features, have been patented by Mr. A. Watt, of Liverpool (October 1st, 1881). He uses the lead-plates, but coats them with a mixture of calcium hydrate, manganese dioxide, and sodium chloride, or preferably with what is known as "Weldon mud," mixed in equal parts with powdered coke. Plates of carbon may be used instead of lead, and in a solution of sulphate of manganese can be employed in one cell, as the sulphate decomposes and covers the carbon with peroxide of manganese. Another form of battery consists of alternate layers of carbon and granulated manganese dioxide mixed with granulated carbon, preferably in equal volumes, or of lead and manganese dioxide or layers arranged as follows: — $MnO_2Pb \| C, MnO^2C \| C, MnO_2 \| C, PbMnO_2C \| C$ and so on, or $Pb, MnO_2C \| C, Pb, Mn\,O_2\,C \| C$, the vertical bars representing porous diaphragms. The exciting liquid is sal-ammoniac, common salt, or dilute sulphuric acid. A convenient form of cell consists of an ordinary battery tank divided down the centre by a porous diaphragm. The charged porous pots, fresh or exhausted, of Leclanché cells, may even be used without further preparation than immersing them in one of the solutions. If one pot be fresh and the other exhausted, the couple is charged and ready to work. Another modification consists of a porous pot containing a plate of carbon charged with a mixture of manganese dioxide and carbon or coke, in a state of coarse powder, and placed in a leaden vessel containing dilute sulphuric acid, the space between the pot and the leaden vessel being filled with a mixture of manganese dioxide and carbon or coke, or simply with granulated lead.

Another secondary battery, which is based on the action of chlorine on copper, has been patented by Mr. A. P. Laurie, of Edinburgh (October 4, 1881). The cell is made up of a thin plate of copper, coated with a paste of cuprous chloride, and wrapped in parchment-paper; that, together with a plate of zinc, is placed in a solution of chloride of zinc, and the two being connected a current is set up, which continues until the cuprous chloride is reduced to a mass of spongy copper. The zinc plate is then withdrawn, and a copper plate put into the cell, which is then ready for charging. The action of the chlorine on the spongy copper can be regulated by means of copper gauze placed over the spongy coat, and connected to the copper plate. These notes, together with those given in p. 413, and elsewhere in the last volume, will serve to convey some idea of the different methods of making up secondary batteries. It is tolerably obvious that, but for its weight, lead would be the only metal experimented upon, its advantages being so considerable, especially in the shape of cost; where, however, portability is desired, it is probable that Sutton's or some modification of the copper-lead cell will be utilised. Possibly, the researches of Dr. Gladstone and Mr. Tribe may lead to the discovery of something more valuable than is yet available.

REID'S PATENT SELF-ACTING CLOCK SYSTEM.

THE above is in action at the Crystal Palace Electrical Exhibition. Fig. 1 shows the principal parts connected with the regulator or motor clock.

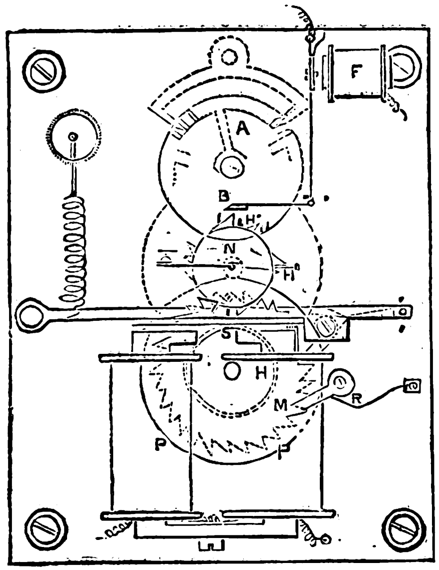

FIG. 1.

By the power of the mainspring contained in the going-barrel H, motion is imparted to the train-wheels and the dead-beat escapement A; the ivory or contact-wheel being outside the clock-plate and attached to the 3rd wheel-pivot of clock-train; the ivory wheel making but one revolution in four minutes; whilst revolving, it lifts in turn the contact platinum-plate B, by the insulating ratchet tooth I on ivory wheel, and allows it to fall on the platinum-point H, by which means it completes an electric circuit, the current passing around the coils of electro-magnet PP, Fig. 1, and A in Fig. 2, the armature S being attracted, and by the click arrangement attached thereto to the mainspring that is contained in the going-barrel H, one tooth of the ratchet-wheels M, and at the same time setting on a relay battery by the electro-magnet A (Fig. 2), its armature being attracted around; and by the contacts D, an electric circuit is completed, which passes through the electro-magnet F (Fig. 1), allowing of its armature's attraction, and throwing the platinum contact-plate into the further insulated ratchet-tooth J, therefore freeing all contacts for expiration of one minute, when a repetition of the same takes place.

The relay (Fig. 2) is provided with a clockwork arrangement, in order to regulate the exact length of time the current should be complete, for which purpose the further end of arm G carries a ratchet-hook, E, which acts in the ratchet-teeth of the wheel C. The current being broken, the arm would instantly rise by the elasticity of the spring K, but is retarded in action by the spring having to force round the wheel C, and with it the train-wheels and fly L, which is capable of any adjustment; the advantage of this arrangement is that, it allows sufficient time for the relays to be properly worked, and time for the attraction of the different armatures, as well as neutralising any error or vibration that might be made by the contacts H and B. If 20 or more contacts be made almost simultaneously, all the dials would only register but one minute or one stroke of current only.

FIG. 2.

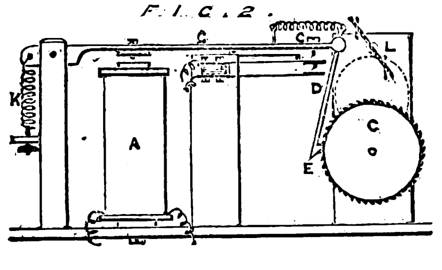

FIG. 3

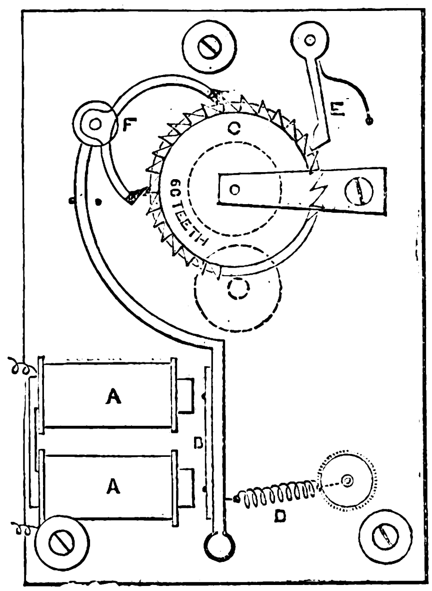

The dial parts are on an improved principle: the electro-magnets, A A, may be in the same circuit as the coils F (Fig. 1), or may be set on by a relay in the same circuit as latter, the current passing instantaneously one stroke per minute. The magnet attracts its armature B, lifting the pallet-hook into a further tooth of the ratchet-wheel C, allowing (when current is broken), by the elasticity of spring D, to pull back the pallet-hook, and drive the wheel one tooth forward, or 1-60th of a revolution, keeping it in position by the connter-ratchet E, and awaiting a further action for next minute, the pallet-hook F being always firm against the ratchet-wheel C when no current is passing; therefore the hands are always firm, and cannot be easily moved, except by the friction of minute-wheel or arbor, &c., &c., the dial-wheels being under the plate, as shown by dotted lines.

MICROSCOPES AND MICROSCOPY.

By DR. ROYSTON-PIGOTT, M.A., F.R.S.

THE following is the substance of a lecture recently delivered by Dr. Royston-Pigott, F.R.S., to the Eastbourne Young Men's Christian Association. The subject was Microscopes and Microscopy, and some remarks on light formed the introduction. Why, said the lecturer, should its hottest rays be absolutely dark? Why should electric light kill vegetation in some cases unless it first passes through glass? Why should a bar-magnet which lifted 6lb. be able to lift nearly double the weight by two days' exposure to an Italian sun? The solar rays are always pouring magnetism into the earth. The sun attracts the earth with as much force as though the whole of its surface were pulled to the sun with the strength of steel rods, thick as the blades of grass. Again, why should magnetism be poured out from the sun principally by the violet rays? Magnetic storms also exhibited on the earth correspond to changes on the solar disc. Again, why should electricity be always present with magnetism as truly as a shadow follows the light? Let us examine what light is by its known phenomena. It is resolvable and may be recomposed. It is radiant and can be turned from its course.—*Deviation by refraction.*—On this principle the action of the microscope entirely depends. This very principle of deviation, however difficult for man to deal with, is the means of displaying the beauties of the rainbow, the glories of the heavenly hosts, the dazzling flashes of oriental gems, the gorgeous colouring of the dew drops sparkling in the rising sun, the flashing loveliness of the hovering moth, the splendours of the golden west and the awful sublimities of the Arctic Aurora—itself a magnificent phenomenon. The inconceivable powers of sight conferred on a minute insect, every one of whose thousand eyes is a hundredfold more powerful in magnification than the strongest human microscope, result from the same property—*Deviation.* Again, water-sight is wonderful—a fish sees a horizontal bank elevated on high with great precision by the refraction of light passing through through water. And on the same principle the modern microscope, by means of a drop of water covering the object, is immensely improved by what are now called immersion lenses, which crowd a much greater number of rays from the object along the line of sight. The microscope entirely depends on the qualities of a prism for decomposing light and bending the rays towards its thicker side. The pictures on the wall give us all these details. A lens is really a series of minute prisms. It enables the observer to see an object like an insect settled upon it. But by using compound lenses in exact imitation of the formation of the human eye, the colours at first developed by refraction are reunited into white light. An enveloped image is again re-magnified by another set of lenses and thus the total magnification may amount to several thousand times. Armed with this great microscopic eye, the naturalist plunges into a new world of structural wonders. The chemist studies the dissolution and re-combination of the elements; the geologist recognises the minute remains of organisms myriads of ages old, chiefly used by Nature to build up mountains, continents, and islands. The physician detects sure signs of organic disorder and even minute living organisms pervading the very blood of man. The expert reproduces the old blood stains of the murdered or the entombed poison used by the assassin—the adulteration of food and the distinctive marks and signs of different bodies—and distinguishes the paste from the diamond at a glance. Impossible is it to enumerate the innumerable uses of this noble instrument. In magnifying power it far exceeds the telescope—and unlike it, can be applied at all times and seasons. It is essentially a home instrument, and it delights hundreds of thousands of its votaries with an interest ever new and inexhaustible. It was the microscope that first demonstrated the circulation of the blood—a discovery stubbornly scouted by the whole of the doctors of the day. It revealed the nations on a leaf and the swarms of animal life in a speck, whose minuteness is so great as to baffle human conception. Malpighi first saw what Harvey had sagaciously asserted—the streams of blood globules traversing a frog's foot. Sea mosses and sea ferns were found to be forms of animal life. The ancient fable of the Hydra was revived and reinstated. Corallines now were seen to be animals. To the microscope we owe the disproval of spontaneous generation. The various parasites which infest the bodies of animals, causing infinite trouble, and those which attack cultivated plants as blight or fungi, the spread of disease germs, the movements of minute cells in the sap of vegetables, the various and beautiful forms of minute eggs—each true to its own type; these, and a thousand other things, show how vastly our knowledge and power of research has been extended by the microscope, by presenting us with a deeper insight into the mysteries of life. Not only every human tissue has been explored, but I might say those of the whole animal kingdom. "What," says a well-known writer, "can be a more worthy occupation than the attempt to gain an insight, however limited, into the operations of creative wisdom?" These are as wonderful in the smallest as in the largest animal. No insignificant part of the globe's crust is made up of myriads of microscopic skeletons, principally formed of flint, equally indestructible by fire and aquafortis. No instrument more promotes the faculty of philosophic reasonings. Microscopic pursuits at once engage our highest faculties, whether merely as an absorbing recreation, or as a profound research embodying a system of ascertained facts of high value. The microscope brings man face to face with nature in her most minute details. A whole evening may be delightfully spent over the head of a single spider. The eye is not satisfied with seeing, and this instrument, more than any other, at once both gratifies and stimulates the thirst for knowledge and advancement in the works of Nature. "A walk without an object," says Mr. Kingsley, "is a poor exercise, unless in the most lovely and novel scenery, and as a recreation is utterly *nil*. If we wish rural walks to do our children any good we must give them a love for rural sights, an object in every walk. We must teach them—and we can teach them—to find wonder in every insect, sublimity in every hedgerow, the records of past worlds in every pebble, and boundless fertility in the barren shore; and so, by teaching them to make full use of that limited sphere in which they now are, make them faithful in a few things, that they may be fit hereafter to be rulers over much." To teach by rote by book and board, is too often to disgust the tender wonder of budding youth, whilst real Nature presented excites a most lively and abiding interest. A school boy's holiday consists in the liberty of the fields like the flight of a caged bird. Human curiosity and delight is inexhaustible among the microscopic riches of infinite forms and functions. To quench this spirit of inquiry by birch and lesson is one of the saddest outcomes of a bygone pedagogueism. Some strong spirits, it is true, survive long years of literary slavery to the desk and slate; but alas, in too many cases, this system has driven its nauseated victims inte the full enjoyment of coarser pursuits. If the microscope engages youthful curiosity, elevates the taste, raises the mind from a love of sordid to ennobling pursuits, it must be a great boon to rising manhood. Innumerable microscopic societies have thus sprung up all over the world, and their doings fill thousands of "Transactions." But I must have done with these eulogies, though I might add such societies unite in singing the charms of Nature's minutest works. I cannot better illustrate the action of the microscope than pointing to the oxygen lamp illustrating the subject. If you suppose a microscope forty feet long, furnished with an object-glass of a few inches focus, the object is so magnified by distance of the screen as to require no eye-glass for further amplification. These glasses before the lamp are constructed with the highest art. As no single glass can form a distinct image at a distance by its own refraction, on account of the unequal deviation of the various coloured rays, means are taken to unite as many as to produce white light, leaving, however, generally a little outstanding colour at the margin. If only white light could be used, containing no violet or other coloured rays, this margin would disappear: then, however, the difficulty of bringing all the rays to one precise focus for every point of the picture—a difficulty described by the term aberration—is so great as to tax the highest skill of either mathematician or artist. Photographic lenses are simply the same in which the picture is taken in the reverse course from the object, and a very perfect miniature formed on collodion. Some of the most interesting sights the microscope can display is metamorphosis. The larva of the straw-coloured plumed gnat (*Tipula crystallina* of De Geers), emerges from the egg in May and June (it inhabits almost invisibly the water). It rapidly changes into the pupa, about three-quarters of a ninch long and a tenth thick. Keeping it in clear spring water retards the change. Its transformation commences under the eye of the observer—a most interesting spectacle. So complete is the change that its former organisation can no longer be recognised in its new state of existence. The tail had consisted of 22 beautiful plumes. It converts itself into two fine membranes, permeated with numerous vessels. Not the slightest resemblance remains, nor are any vestiges of tail to be seen in the water. Two small horns appear folded up in the head, destined to form the white plumed antennæ. The food canal appears nearly to vanish in the pupa, as it takes no food in that state. During the latter part of the day the rudiments of perfect legs may be traced. It now floats in a vertical position, the head being only just submerged. It had formerly swum in a horizontal position. The circuitous mode of these transformations is truly wonderful. The mere bursting forth of the perfect creature from its envelope is but a small part of the complicated transformations it has gradually undergone. The circulation of the blood in these insects is quite visible, though it is transparent, by the onward movement of little oat-shaped blood corpuscles in vessels furnished with closing valves, as perfectly constructed as those of the human veins. The breathing apparatus of insects, shown by the microscope, evidences beautiful design. As they have no lungs or gills, air is conveyed through trachea or tubes, around which a network of blood vessels are employed to aerate the blood by diffused circulation. The dorsal vessel pulsates, the oat cells are seen to pass rapidly forward. The action of the valves is a most beautiful sight. The air vessels pass down each side of the body, along the legs, the horns or antennæ and the three-forked tail, whilst the blood corpuscles circulate to each (the larva of the day fly). I cannot resist relating an observation on young tadpoles. I observed one of these lively captives did not produce his legs, whilst his fellows were leaping out of the basin. The microscope showed he was suffering from a real poverty of the blood—few particles only could be seen, like solitary sentinels, slowly pacing along their routes. Nutrition had nearly ceased. But the study of formation gives marvellous insights into design—means devised for special ends. An indiarubber tube is guarded and strengthened with spiral wire. The breathing tubes of insects are wound round and round with elastic fibre in two different directions, producing a very beautiful wavy appearance. Again, the human eye lens is exceedingly complex, though in health transparent. It has a curvature different on each face, so as to produce the most distinct image on the retina, which is a receiver of the images formed there. A black ball is visible about two miles off if about ten inches in diameter and elevated on a pole against a dull sky. Now, what do you suppose is about the size of this black ball as pictured on the retina? It is readily shown by optics that its size is about the one hundred and twenty thousandth part of an inch, and yet the optical vision of a really good eye is equal to a result which severely tasks the powers of a very fine microscope. I have frequently seen a black object of this kind. What must be the microscopic arrangement of the tissues of the eye to enable it to convey the impression of such a minute black dot as this to the brain? But much smaller points of this are distinguished if brilliant. The eye is, in fact, a microscope in itself, but used to from miniatures, photographs, as some think. The eyes of insects, however, apparently greatly exceed ours in complexity and contrivance. They have no eye-lids; they must see all round at once to escape their enemies. Accordingly, we find great variety in the quantity of actual eyes studding the head; 4,000 in the house fly, 17,000 in the common cabbage or yellow butterfly, 24,000 in the dragon fly, 25,000 in the mordella beetle. Each eye is made up of two lenses and an intervening cylinder, and tapering pyramids prolong the whole to the nerve fibres. The light is regulated in each by a layer of black matter (pigment) perforated by a minute aperture (just as we are obliged to use in the microscope or telephone to shut off extraneous light). What complicated design and execution, arrangement, order, precision, and baffling minuteness are here in the head of the smallest insect!

THE APPLICATIONS OF ELECTRICITY.[*]

(*Continued from page* 168.)

THE electric arc was first studied by Davy, who investigated the phenomenon with a very powerful battery. Its practical application is, however, but of very recent date, and the different kinds of electrical regulators and lamps which you have seen at the Exposition are mostly of very recent invention. First were invented the costly and complicated regulators of Serrin and Foucault. The electric light, as you know, is the spark of a very powerful battery between two carbon points separated by a small interval. The positive carbon burns twice as fast as the negative carbon, so that we must have a regulator which keeps the carbon points at an invariable distance, and which keeps the light at the same point.

This last condition is essential in the case of lighthouses and for optical experiments, and requires the complicated clockwork regulators above mentioned. For ordinary lighting purposes where the point of light need not be in a permanently fixed position, the regulators are, of course, much less complicated, as only one carbon need be movable; clockwork may then be dispensed with. The simplest kind of electric light is certainly realised in the case of electrical candles. The Jablockhoff candle simply consists of two carbon pencils separated by an insulated layer of plaster of Paris and kaolin.

In M. Jamin's electrical candle this insulating layer is dispensed with, and the arc is kept at the end of the candle by means of an electrical current which circulates in a frame around the candle, and acts by the well-known laws of electrical attraction and repulsions.

The newest kind of electrical light is the incandescence light. The incandescence lamp simply consists of a thread of carbon inclosed in a glass globe, from which the air has been withdrawn. When the electrical current is sent through the lamp, the thread of carbon is raised to a white heat and gives a very pleasant light. It is easily understood that the air has been withdrawn in order to prevent the carbon thread from burning away. Such are Edison's, Swan's, and Maxim's lamps.

For the electric light on such a large scale batteries are not used, but dynamo-electrical machines. These machines (of which there are hundreds of varieties) are all founded on one principle: when we turn rapidly a coil of insulated wire between the poles of a magnet or of an electro-magnet, we generate an electrical current in the coil of wire. When we use an electrical candle we must choose a machine which gives alternating currents in order that both the carbons burn away equally. In electricity all our experiments are reversible; for instance, if we turn a dynamo-machine by a steam engine we get an electrical current; but reciprocally, if we send an electrical current into a dynamo-machine it turns around and gives us an equivalent quantity of movement. In the latter case we have an electromotor. This has been applied to the electrical tramway which formed one of the great attractions of the exposisition. I show you here some of M. Trouvé's electrical motors, such as he employed in his small boat, "The Telephone," with which he used to navigate on the miniature lake of the Palais d' Industrie.

Another very striking instance of the reversibility of electrical actions is shown in the accumulators or secondary batteries. They are merely voltameters with leaden plates of very large surface. The primary current is sent through the accumulator and decomposes the acidulated water. When we connect the two leaden plates we obtain a current which, theoretically, ought to be equal in quantity to the primary current. Those secondary batteries were invented by M. Planté, and have lately been improved by M. Faure.

PURE CARBONS FOR THE ELECTRIC LIGHT.

IN view of applications of carbon to production of the electric light (says M. Jacquelain, in a recent paper to the French Academy), the problem for chemists is to prepare a carbon more conductive than that of calcined wood, and if not wholly without hydrogen, at least exempt from mineral matters. To attain this end, three means seem capable of being employed, viz. (1), the action of dry chlorine directed on carbon raised to a red-white temperature; (2), the action of caustic potash or soda in fusion; and (3), the action of hydrofluoric acid on the cut crayons, operating in the cold state and by way of immersion, more or less prolonged.

The use of chlorine is quite suitable for very divided carbon; we have employed it with complete success in preparing a pure carbon which could be used by M. Dumas in his remarkable work on determination of the equivalent of carbon. Through the double influences of the chlorine and a high temperature, the silica, alumina, magnesia, alkaline oxide, and metallic oxides are reduced and transformed into volatile chlorides, and the hydrogen remaining in the carbon is transformed into hydrochloric acid, which is carried away with the chlorides.

This process, however, would be difficult in the case of purifying the voluminous masses of carbon of gas-retorts. The means we have devised to simplify the work consist in first directing a current of dry chlorine for thirty hours at least on a few kilogrammes of retort-carbon maintained at a red-white temperature, and previously cut in the form of prismatic crayons.

This first operation leaves in the carbon numerous vacant spaces, which it is necessary to fill, so as to restore to the carbons, as much as possible, their original compactness, conductivity, and weak combustibility; accordingly, the purified crayons are subjected to the carbonating action of a carbide of hydrogen, the vapour of which circulates slowly among the crayons heated to a red-white temperature, during five to six hours, in a cylinder of refractory earth. The reduction of the carbide (heavy oil of coal) to vapour, should be effected slowly, in order that the decomposition may be produced at the highest temperature, and a slight deposit of carbon may be formed; otherwise, all the crayons get covered with a layer of hard carbon, thick enough to unite them in a single block, which it is no longer possible to utilise.

Caustic soda with three equivalents of water, melted in iron vessels, offers a more prompt action, converting the silica and alumina into akaline silicate and aluminate. By washing with hot distilled water you remove the akali of imbibition with the silicates and aluminates; then, by washing with weak and warm hydrochloric water, you remove all the iron oxide with the earthy bases: lastly, a little washing with warm distilled water takes away the remaining hydrochloric acid.

---

[*] Lectures delivered by C. Detaille, at the Palais du Trocadéro, Paris.

The third process, purification of retort carbon with hydrofluoric acid, is one of the most simple operations. An immersion of the cut crayons in hydrofluoric acid, diluted with twice its weight of water, and set to react 24 or 48 hours, at a temperature of 15° to 25° C, in a rectangular lead vessel with cover, easily realises the object sought. It remains merely to wash with plenty of water, then with distilled water, then to dry and submit the carbon so purified to a carburation of 3 or 4 hours, if the earthy matters removed by the hydrofluoric acid are in small proportion. But the use of this acid, even diluted with twice its weight of water, requires many precautions if one is to avoid burns of the skin, causing purulent blisters, with acute pain and pretty violent fever. It is specially necessary to guard the sight, and to handle the substance with extreme prudence.

Such are the three processes which I have sought to apply either to gas-retort carbon or to Russian graphite.

Lastly, I have been specially occupied with the direct preparation of pure graphitoid carbon. It is shown, in lectures on chemistry, that any volatile organic substance will furnish, on being decomposed by heat, carbon in small, very thin, glittering particles. It is this mode of preparation I have utilised, with the aid of a small apparatus, at the Central School, modified to render the work more regular and more continuous.

All carbides of hydrogen furnished by decomposition, in a closed vessel, of coal, peat, schists, resins, plants themselves, are available for this decomposition, as also oil of turpentine and naphthaline. Those substances with the highest boiling-points are preferable, because of their low price, and their large yield of hard carbon, which rises to about a third of the liquid employed.

Even tar, quite as free from saline matters as the preceding carbides, since it is the first raw product of distillation, has furnished, from the first operation, bright, sonorous carbon, with homogeneous fracture, having the grain of cast steel.

M. Jacquelain indicates, in a table, the results of photometric experiments with the different carbons referred to; and it appears that the luminous power and the fixity of the voltaic arc increase at the same time with the density, hardness, and purity of the carbon.

The natural graphitoid carbon of Siberia (of which the Conservatory of Paris possesses a rich collection, given by M. Alibert) has the singular and unexpected property of acquiring, by purification, a luminous power double that which it presents in the natural state, a power exceeding by a sixth that of even pure artificial carbons.

A NEW FORM OF REVERSIBLE STEREOSCOPE.*

WITH a view to removing for others the difficulty implied in the binocular experiments on which I based the conclusions expressed in my recent papers, published in the November and December numbers of this journal, I have devised the following form of stereoscope, which has been found quite satisfactory. Persons possessing no previous muscular training of the eyes have been able with it to secure reversion of relief in the combined picture as easily as they had obtained natural perspective while using it as an ordinary stereoscope. Some of my experiments involved extreme muscular tension; these required the use of the unaided eyes, but a large proportion of the rest can be performed by the aid of this instrument without special discomfort.

The semi-lenses (Fig. 1, *l*, *l*) rest in a pair of boxes, with windows in front and behind, to transmit the light. These boxes are separated by a thin partition, on each side of which is a spring against which the thin edge of the semi-lens is pressed by the adjusting screw (*s*) at the base. In front is a pair of brass hinges (*c*, *c*); when pressed flat as in Fig. 1, each half of the stereograph is hidden from the eye on the other side; when folded, as in Fig. 2, the whole stereograph is made visible to each eye. Attached to a sliding cross-bar is a wooden screen (*b*, *b*), moving on hinges; when this is pressed down flat, as in Fig. 1, the view of the stereograph is unobstructed; when lifted up, as in Fig. 2, the window at the middle permits the left half of the stereograph to be seen by the right eye, while the right half is obscured; and vice versa for the left eye. From the top of this window is a small projection (*d*). The stereograph rests upon its movable cross-bar (*a*), which slides upon a longitudinal strip about 30 cm. in length.

The semi-lenses are easily removable at will, and a pair of prisms (*pp*), the refracting angle of which is 12°, can be substituted, but with their bases pressing against the springs instead of the screws.

To secure natural perspective through the semi-lenses press the brass and wooden screens flat (Fig. 1), and use the instrument as an ordinary stereoscope. Assuming the stereographic interval to be average, and the distance between the observer's eyes to be not greater than usual, comfortable vision will be secured by turning the adjusting screws until the semi-lenses are pressed as near as possible together. The light which enters the pupils then passes through the thicker part of each semi-lens, and the optic angle is positive and small, or the visual lines may be sensibly parallel. If the observer's interocular distance is much greater than usual, the rays of light which he receives will be transmitted still nearer the base of the semi-lens, and slight optic divergence is necessary. This is avoided by giving a few leftward turns to the screw, permitting the semi-lenses to be pressed a little farther apart by the opposing springs. The same can be done to secure comfortable vision when the stereographic interval is great; pictures 10cm. apart can thus be viewed without discomfort, and without any very objectionable degree of coloration in consequence of want of achromatism in the semi-lenses. By now turning the screws so as to press the glasses closer together, any degree of optic divergence may be attained that the observer is willing to endure, while the picture is still seen in natural perspective, distances being apparently slightly magnified, and diameters also in the same ratio.

FIG. 1

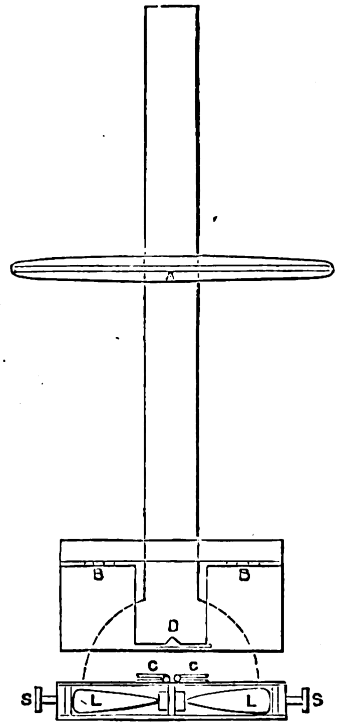

FIG. 2.

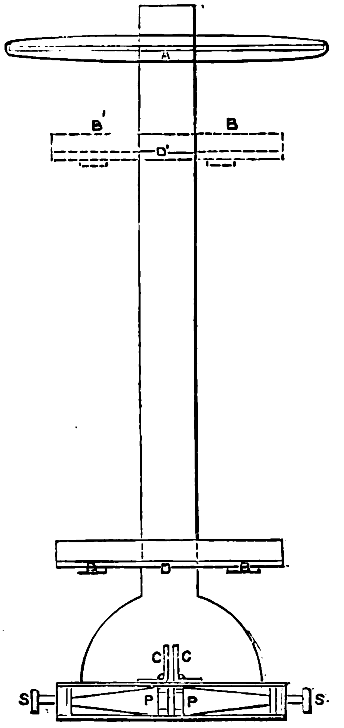

To secure reversed perspective, lift up the wooden screen, fold the brass hinges outward in front, and substitute the prisms for the semi-lenses, as in Fig. 2. Slide the stereograph nearly to the end of the stereoscope. Physiological perspective is at once reversed; whether this is enough to overpower the other elements of perspective must depend upon the nature of the picture. If the stereograph be that of the moon, the reversion is complete; if of terrestrial scenery, some objects may be apparently transposed in position while others are not. The same picture may be examined successively with each illusive effect several times in as many minutes. As soon as reversion is attained, the stereograph may be drawn up as close as may be convenient.

If both semi-lenses and prisms are discarded, the instrument becomes a direct-vision stereoscope, in some respects similar to that described by Prof. William B. Rogers in 1855. To secure natural perspective, press the screens flat, pull the stereograph up as close as possible, and gaze as if through it at a remote object, with the muscles of the eyes relaxed. The two pictures, imperfectly focalised, are dimly seen apparently to overlap. The stereograph is then pushed out to the end of the stereoscope, and the pictures are binocularly combined by optic divergence. The stereograph may now be pulled up as near as convenient.

To secure reversion of perspective by direct vision fold the brass hinges and lift the wooden screen, as in Fig. 2. Push this out (*b' b'*) as near as possible to the stereograph at the end of the instrument, then pull it up, keeping the gaze fixed upon the projection (*d'*) at the top. This grows dim as it approaches its previous position. Without changing the direction of the visual lines, except slightly to lower them, transfer the attention to the stereograph beyond. The combined picture is seen in reverse perspective, apparently much smaller and nearer than when the prisms were employed. Those who have tried this instrument thus far have usually succeeded at the first attempt, for either natural or reverse perspective, when the glasses were used. Several trials are often necessary before success is attained by direct vision, but the variation in perspective thus attained is much more striking. But little experiment is needed to prove to any one who is thus successful that in the localisation of objects in the binocular field of view presented by the stereograph, the current theory of successive triangulation by intersection of visual lines is inapplicable. The only substitute that covers the facts which the geometric theory fails to account for is that of associated muscular action, which applies to divergence as well as convergence of visual lines. The use of adjusting screws for the semi-lenses of the stereoscope is, of course, not a novelty. They were thus applied by Duboscq, about 1850, to one of Brewster's stereoscopes, and also, subsequently, by Helmholtz.

ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY—IX.*

Defects and Remedies.

GENERAL FOG.—This is probably the commonest of all faults with gelatine negatives. It consists of a veil over the whole plate, showing itself by want of transparency in the shadows. It may be so slight as to be imperceptible, except when the negative is laid face downwards on a sheet of white paper, or may be so dense as to make the time necessary to get a print to be measured by days. It is due to one of two causes, which are usually indicated by the names, *chemical fog*, and *light fog*,

The first arises from error in the preparation of the plate. By it is meant that the sensitive film is in such a condition that the silver salt is reduced by the developer without light having acted upon it. In certain cases it may be cured by soaking the plates before exposure in a solution of three grains of bichromate of potash to each ounce of water, afterwards thoroughly washing the plates, and then drying them.

---

* By W. LeConte Stevens, in the *American Journal of Science*.

* Condensed from the *Photographic News*.

To distinguish chemical fog from light fog, the best way is to develop an un-exposed plate, performing all the operations in total darkness. This is not difficult. If the plate be found to have darkened, the fog will be chemical fog, or, what is practically the same thing to the photographer, light fog, brought about by the action of light on the emulsion whilst in the hands of the manufacturer.

With the well-restrained developer which we gave in the last chapter, chemical fog is less likely to make its appearance than in the case of the feebly-restrained developers usually recommended. The bromide in the developer may even be increased beyond that which we give, but this will necessitate a somewhat longer exposure. We may state that bromide of ammonia in the developer begins to have an appreciable actual slowing effect on the plate when it is used in the proportion of ⅔ or ¾ the quantity of strong ammonia used. When the bromide equals the ammonia, the slowing effect becomes very great.

Light fog is due to the action of light generally in one of three ways: first, on account of an unsafe light in the dark room; secondly, on account of a defect in the camera or dark-slide admitting light; and thirdly, on account of over-exposure. When the fog is due to light in the camera, this will be recognised by the fact that the portions of the plates covered by the wires or rebates of the dark slides remain free from fog. When this is the case, the camera must be carefully examined by removing the focussing screen, and looking for any the smallest defects which might admit light, the head of the observer being covered with the focussing-cloth. Light finding its way through defects in the slides generally shows itself in the form of streaks or lines. Should no defect be detected, the exposure must be reduced. If fog from unsafe light in the dark-room be suspected, place a plate in the dark-slide, draw out one of the shutters halfway, and then lay the slide for five minutes on the table where the plates are changed and developed; then develop the plate. If one-half darkens, it shows that the light is not safe, and steps must be taken to render it so.

Green fog.—This defect is always due to error in the manufacture of the plates. It makes its appearance only in the shadows of the negative. If the negative be looked at by reflected light, a black object being laid under it, the shadows will be seen to be bright green. On looking through the negative they will appear somewhat pink, or sometimes a sort of "muddy" colour. Green fog makes its appearance only with alkaline pyrogallic development, and then chiefly when the plate has been under-exposed and development "forced."

A slight amount of green fog is not detrimental to the printing qualities of a negative; but if the defect shows itself in an aggravated form, the best means of preventing it is to resort to ferrous oxalate development.

Frilling consists in an expansion of the film to such an amount that it loses its adhesion to the glass, and "frills" off. The phenomenon begins at the edge of the plate, and spreads towards the centre. When it begins at the centre it is termed blistering. It is due to an error in the manufacture of the plate, but is much aggravated by a developer strong in ammonia, by the use of warm solutions, by the use of too strong a fixing bath, or by the use of very soft water for washing. When it makes its appearance only in the fixing bath or during washing, it may be prevented with certainty by placing the plate, immediately after development, in a saturated solution of alum for five minutes. This we advise in all cases; but where there is no fear of frilling, the plate should be thoroughly rinsed before it is placed in the alum solution. If the frilling be of so aggravated a form as to show itself during development, it is more difficult to prevent its occurrence. Captain Abney states that coating the plates with plain collodion before development is a perfect cure. Plates which, when newly prepared, frill frequently, after keeping for some weeks or months in a dry place, show no tendency to the defect. In fact, we have found that the keeping of the gelatine plates for some time improves them in every way.

Want of Density or Flatness of Image is usually due to under-development, or to the use of too weak a developer. A consideration of our remarks in the last chapter on development will show how sufficient density may be gained in almost any case; and we may here say that a very common cause of want of vigor is to be found in the fact that the ammonia is not so strong as is supposed. In the case of liquid ammonia of specific gravity ·880 a very short exposure to the air weakens it, by allowing ammonia gas to escape. It will be generally found that the last of the ammonia in the bottle is considerably below the standard strength, simply from the escape of the gas every time the bottle is opened. It is for this reason that we recommended the dilution of the ammonia with an equal bulk of water immediately after purchasing it. Pouring the strongest ammonia from one bottle to another will perceptibily weaken it.

(*To be continued.*)

SCIENTIFIC SOCIETIES.

ROYAL ASTRONOMICAL SOCIETY.

THE May meeting of this Society was held on the 12th inst. at Burlington House. Mr. E. J. Stone, President of the Society, and Director of the Radcliffe Observatory, Oxford, occupied the chair.

Mr. Henry George Hollingworth, of 319, Vauxhall-bridge-road; Mr. Samuel Okell, of Bowden, near Manchester; Mr. Wm. Barrett Roué, of 165, White Ladies'-road, Clifton, Bristol; and Mr. H. Goddard Williamson, of Shrigley-road, Bollington, near Macclesfield, were balloted for and duly elected Fellows of the Society.

Mr. Downing read a paper entitled "Discussion of the Observations of γ [Gamma] Draconis made with the Greenwich Reflex Zenith Tube during the years 1857 to 1875 inclusive." The author said: As the discussion of the observations with the zenith tube from 1852 to 1859, which had been made by Mr. Main, and published in the "Memoirs of the Society," appeared in some respects unsatisfactory, I have undertaken this discussion, commencing from the time when the instrument was brought into its present improved position. The period which I have taken is sufficient to include a complete revolution of the moon's node, so that a value of the constant of nutation may be also deduced. The results which I have obtained are as follows:—Constant of aberration, 20·378″; annual parallax of γ Draconis, − 0·131″; constant of nutation for 1866, 9·3353″. It will be seen that the parallax of the star again comes out a minus quantity, which of course throws some doubt upon the results; but it is somewhat smaller than that found by Main, while the constant of aberration is larger. The observations are probably affected by a periodic error, perhaps arising from the effect of temperature on the instrument.

Mr. Glaisher read a paper by Mr. T. W. Backhouse "On the Merope Nebula," in which the author stated that he had observed the nebula without difficulty with a 4¼in. refractor, *Merope* itself being out of the field. The general appearance of the nebula was similar to the drawing which had been made by Signor Tempel.

Mr. Common exhibited photographs which he had obtained, of the central portion of the nebula in Orion, in which a large amount of detail was clearly visible. The exposure had been ten minutes. The photographs had actually been made to test the efficiency of an electric control to a clock, and Mr. Common hoped that in future he might be able to obtain negatives showing still more detail.

Mr. Common then read a paper "On the Illumination of Micrometers," and exhibited a micrometer with the lamp attached, to show the arrangement of the apparatus. The principal feature was the employment of a small incandescent carbon electric light, which the author had found an extremely convenient mode of illumination.

Mr. Marth exhibited an apparatus, and read a paper describing it, entitled "Note on an Apparatus for Determining those Errors of Astronomical Observations which are caused by the flexures of an instrument, and by defects in the shape of its pivots." The author said: At the December meeting I mentioned an old proposal of mine for determining these errors, and M. Loewy has a communication in the new number of the *Monthly Notices* in which he makes some critisisms upon the method which I recommended. My apparatus consists of two object-glasses with a half-silvered mirror between them. It is placed in the cube of the instrument to be examined. One of the object-glasses has the object-glass of the instrument in its focus, and the other the wires of the eyepiece, so that a mark on the object-glass can be seen directly through the unsilvered portion of the mirror, while the wires can be observed at the same time by reflection. The amount of flexure is then determined by the displacement of the images. The same apparatus is also to be used for investigating the defects of the pivots. In reply to a question by the Astronomer Royal, Mr. Marth explained that it was not essential that the object-glasses of the flexure apparatus should be absolutely perpendicular to the axis of the telescope, as the displacement of the images showed simply the *difference* between the flexure of the two ends of the instrument.

The Astronomer-Royal said: I think that this method of determining flexure too much presupposes a rigidity in the instrument which it obviously does not possess. The cube in which Mr. Marth's apparatus is placed is the weak part of the instrument, and in the new transit circle which is being made for Melbourne, it will be replaced by a cylinder, to which the two ends are bolted. It has been suggested that the tube of the telescope should be carried right through; but there is a difficulty in this, as it would have to be perforated for the illumination, and this would weaken the tube too much. I believe Mr. Marth's mode of determining flexure is a valuable one; but I think the best method is that of reflection observations. It may be desirable to interchange the eyepiece and object-glass, or to determine flexure by means of collimators; but other sources of error may then be introduced.

The President: Mr. Marth's method appears to be a very valuable one. There may be, as Mr. Christie has pointed out, a certain amount of strain, but it would not be anything like that of the ordinary flexure of the telescope. I am much more in favour of the use of collimators for these determinations than Mr. Christie appears to be, although there is a certain amount of danger from uncertainty of temperature. Still, we cannot have too many methods, as they act as checks upon each other. In the new telescope, however, that is proposed, and which I hope still to carry out, I think we shall be able to get rid of flexure, which will be better than determining and correcting it.

Mr. Marth: Collimators will merely give the horizontal flexure, whereas this apparatus gives flexure in any direction of the telescope. The objection to reflection observations is that they are confined to 40 degrees; your results are also affected by errors of division.

The Astronomer Royal: I hope soon to have an arrangement by which the collimators may be removed when not required. We shall then be able to extend our reflection observations as far as 70 degrees. We have determined our errors of division as well as we can, and I think there is very little outstanding error in our determination.

The President: I may mention that in two cases which have come under my own observation I have met with something which was not astronomical flexure, but which produced much the same results. The first occurred at the Cape, where the error was found to be due to the lenses of the object-glass, which had become separated, and slightly shifted as the telescope was moved round. The other case was at the Radcliffe Observatory, and where an apparently large flexure was found to be the effect of displacement of the object-glass, owing to a small amount of play in the screws with which it was fixed. We see, therefore, that independently of the flexure of the tube there are errors arising from slight movements of the object-glass.

The Astronomer Royal read a paper on the spectrum of comet *a* 1882 (Wells), which had been examined at the Royal Observatory, Greenwich, on April 22nd and 24th, and May 11. No bright bands were seen, but only a continuous spectrum, which was remarkably bright from the nucleus, considering the faintness of the comet.

The Rev. F. Howlett exhibited a number of drawings which he had made of the great sunspots which had recently been visible, and read a communication in reference to them, in which he called attention to the immense size of these spots—one being nearly 3′ in diameter. His drawings also showed a very large number of faculæ, which had been visible on the solar surface.

The Astronomer Royal showed some enlargements from photographs of the same spots, which had been obtained at the Royal Observatory. He said it was remarkable that the first group appeared on the 13th of April, and three or four days afterwards a great magnetic storm occurred. There was a smaller group of spots also, which, on the 17th of April, burst out suddenly, the group rapidly becoming nearly as large as the other group. Following this, on the 19th of April there was another violent magnetic storm, lasting about twenty-four hours. A double outbreak on the Sun and two magnetic storms are interesting facts, to which attention should specially be directed.

Mr. Mattieu Williams asked if any remarkable prominences were observed in connection with these magnetic storms, and referred to the explanation which he had suggested some time ago, that prominences were the result of vortex action, producing great agitation of the vapour on the solar surface, and causing electrical disturbance, which would show itself in magnetic storms.

Mr. Knobel read a paper by Mr. Pratt on the great sunspots of April, in which the author called attention to the great changes which had taken place in the form and size of the spots. The diagonal of the principal spot, which was somewhat square, in shape, measured 2′ 7″, or about 59,000 miles.

The President gave an account of a paper by Col. Tennant, entitled "An examination of the Roorkee Observations of the Transit of Venus, 1874." The President said: Col. Tennant thinks that his observations of ingress, which have been rejected in the discussion, have not been considered so accurate as they should have been. Col. Tennant, who is an exceedingly good observer, is firmly convinced that he saw nothing like a black drop, but observed pure geometrical contact. This, however, is absolutely incompatible with the series of measures which he gives of the distances between the limbs of Venus and the Sun, so that what he considered geometrical contact was, in all probability, what other observers have seen, and called *shadow*.

The following papers were also announced and partly read:—J. B. Coit, "Determination of the Orbit of η Cassiopeiæ": J. Gledhill, "Observations of the Phenomena of Jupiter's Satellites made at Mr. Edward Crossley's Observatory, Bermerside, Halifax"; and A. Graham, "Elements of the Orbit of Comet Wells."

SCIENTIFIC NEWS.

THE comet Wells (*a*, 1882) is gradually becoming brighter, and should, if the calculations are correct, be shortly visible to the naked eye. Dr. Lamp, of Kiel, gives an ephemeris for Berlin midnight, which may possibly be of some use to our readers:—

	R. A.	N. P. D.

The perihelion passage, according to Dr. Lamp, will take place on June 10th. Prof. Lewis Boss gives an account in the *Astro. Nach.* of the discovery of the comet on March 18, and says that when he observed it on the 19th, it appeared like a great comet in miniature.

Dr. J. Palisa has discovered another small planet, the number of which will be 225.

Prof. Henry Draper has succeeded in taking four photographs of the spectrum of the nebula in Orion during the spring, about the same time as Dr. Huggins on this side of the Atlantic also secured photographs. It is too early to speak of the conclusions to be arrived at from a study of these photographs; but one thing may be asserted, that hydrogen maintains its position as an element unimpaired. Prof. Draper believes that he has evidence of the process of aggregation, or of condensation of the nebulous matter into stars.

The Council of the Iron and Steel Institute have awarded the Bessemer medal for 1882 to the late Mr. Alexander Lyman Holley, and have decided to forward it to his family through the American minister.

The deaths are announced of Mr. Charles Hockin and of Mr. Thomas Dunman. The former was well known in scientific circles as an authority on his special subject, for although only forty-two at the time of his death, he had made his talents known in the electrical world, and was a collaborateur with Dr. Matthiessen, Sir W. Thomson, and Prof. Clerk-Maxwell.

The Burt prize for the best means of ventilating ships, awarded in connection with the Shipwrights' Exhibition, has been gained by Messrs. Robert Boyle and Son, whose system is as simple as it is efficient.

An application of the electric railway has recently been made in the linen bleachfields of Le Breuil-en-Ange, Calvados, for gathering in the bleached cloth. A Siemens dynamo and the collecting apparatus are placed in one vehicle, a set of Faure accumulators in another, and the cloth is carried in a series of trucks. The line of railway has 21 branches, each about 500 metres in length, and the pieces of cloth, being connected at their ends, are gathered up in long lengths, 5,000 metres being rolled up by the machine in half an hour, whereas by the old method such a length was a day's work.

Professor Edlund contends that a vacuum is a good conductor of electricity. In a vacuum tube he distinguishes two resistances to passage of the current—one is that of the column of rarefied gas, the other exists at the places of contact of the electrodes with the gas. As the gas is increasingly rarefied the former decreases, but the latter increases, and at length becomes so great that the current cannot surmount the obstacle. Professor Edlund has furnished proof that this obstacle is due to an electromotive force giving a current opposite in direction to the principal current. One evidence that vacuum presents very little resistance to passage of electricity is that if electrodes be dispensed with, electric movements so considerable as to give light may be produced by induction at a distance, or by friction, in a tube in which the air is too rarefied to allow of a strong induction current passing between electrodes. The new view, if accepted, would require us to part with the conception that ordinary matter is necessary for propagation of electricity. Indeed, the various material substances are to be thought of merely as offering more or less resistance to that passage; their *rôle* is not active, but passive. The idea of "conductivity" loses its old significance.

The French Government has resolved to establish a zoological laboratory on the shores of the Mediterranean, at Villefranche, near Nice.

Spain has been badly off hitherto for railway communication with France and the rest of Europe. The Pyrenees, with a total length of some 500 kilometres, is crossed with railways only at two openings, one in the west at Irun, the other in the east at Port Vendres. The triangle formed by joining the ends of the range with Madrid contains in part the rich provinces of Arragon, Catalonia, Navarre, and Castille. Recently, the Spanish Cortes has authorised the construction of a new line which will cross the range between the others. Starting from Huasca, it will go through the Col de Canfranc, and join the French lines at Oleron. It will penetrate the mountain mass near Gomport, and its traffic will be directed towards Toulouse, Bordeaux, and Nimes. The distance between Paris and Madrid will be shortened by 100 kilometres (say 62 miles). The recent law specifies the conditions of execution of the line, which will receive a subvention of 60,000fr. per kilometre. The work is to be completed in six years. The Spanish Government will bear half the cost of the tunnel, which will be 6,600 metres in length (about four miles), and so the shortest of the great international passages. The Mont Cenis is 12,233 metres; the St. Gothard, 14,920 metres; the Arlberg, 10,270 metres; the Simplon, it is estimated, will be about 18,000 metres; and the Channel Tunnel 34,000 metres. The means of execution will be those now familiar, unless, perhaps, an economical application of electrical force takes the place of the remarkable machinery applied so successfully in the Mont Cenis and the St. Gothard.

Liquid ozone must be a highly interesting substance. MM. Hautefeuille and Chappuis have recently obtained it in the form of liquid drops of a deep indigo blue colour. The liquid could be kept nearly thirty minutes under a pressure of 75atm. Its vaporisation is not very rapid, even at atmospheric pressure. The liquefaction was effected by compressing, at about 125atm., a mixture of oxygen and ozone in one of M. Cailletet's tube-shaped vessels, which terminates above in a capillary part bent downwards. This descending part was exposed to a jet of liquid ethylene, a new method whereby M. Cailletet gets temperatures as low as − 105°C. The blue coloration is very distinct in the cooled part. On releasing the pressure the tube becomes instantly colourless, but a dark blue liquid drop remains at the end; this liquid ozone may be examined either through liquid ethylene, or by momentarily removing the cooled tube from this liquid.

It is stated that a new shell has been recently invented at Krupp's works, the effects of which, owing to the explosive matters used, and the mechanism causing explosion, are equal to those of torpedoes. Further, a new gun there devised, is mounted on a pivot furnished with mechanism which quite suppresses recoil. Notwithstanding large calibre (30 to 40ctm.), the smallest gunboats may be armed with it.

We learn from a Swiss source that superior effects have recently been obtained with a rifle invented by M. Hess, a gunsmith, in Zurich. The peculiarity of the weapon is, that it is only rifled about 12in. in front of the chamber, the rest of the bore being smooth and of calibre slightly less than that between the partitions. There is no cone of connection between the smooth part and the rifled part. After firing 200 shots, the rifle can be perfectly cleaned by working the scouring rod in it two or three times.

Underground telegraph cables are at present being laid in the North of France. The line between Paris, St. Quentin, and Cambrai is already completed. In order that lines may be quickly repaired in case of rupture, chambers called *marmites* are formed at intervals of 555 yards in the plains, and at shorter intervals where there are curves; these are so many guiding marks. The arrangement is such that from a telegraph-station connected with the cables it is easy to determine to what chamber a workman should go to repair a broken wire, and the precise spot at which he has to dig down to the cable is indicated. These underground cables are not meant to replace the air lines, and they are not for private telegraphy. The Government at present retains them at its disposal.

A new self-exciting dynamo-electric machine, the invention of MM. Dandeu and Chertemps, is described in *L'Electricité* as giving remarkable effects. A wooden board is pierced with holes in which are solidly fixed six coils, and is fixed on a support. Through a hole in its centre passes a movable axis. In a plane perpendicular to the board are two groups of three horseshoe magnets, with coils similar to those in the board, and making 1,200 revolutions per minute. It is on the fixed board that the currents are collected, by an arrangement which allows of grouping them in as many currents as there are cylinders, less one, the electricity of this latter cylinder not being used for exterior work, but serving to excite the moving electro-magnets. It appears that the machine consumes a motor force of only four h.p. while supplying ten Jablochkoff candles in a normal way. The special merit of the machine is said to consist in the suppression of the induction currents which are produced in the heart of the iron pieces facing each other in other generators.

The city of Paris has granted the Society of Agriculture and Insectology a piece of ground of more than 4,000 metres, in the park of Montsouris, for formation of a school of insectology. This will comprise the study and practical treatment of useful insects (bees, silkworms, &c.), the study of auxiliary insects (useful to plants), and investigation of the best means of combating noxious insects. Already the society has provided lectures, this year, on bee culture (by M. Hamet), in the Luxembourg Garden; these will be repeated at Montsouris, where an experimental apiary is constructed. Ere long, instruction about silkworms will be given, and a silkworm nursery, with mulberry trees, formed. For the study of auxiliary and noxious insects, a building is required to accommodate collections and apparatus, and will probably soon be erected.

The Swiss watchmakers at Geneva and Neuchatel have derived great advantage from the chronometric observatories at those places. With a view to benefiting the same industry in Franche-Comté, the French Government, in concert with the town of Besançon, have lately decided to institute an observatory in this town. The difference of longitude between the site for this new observatory and the observatory at Montsouris has been carefully determined by MM. Barnaud and Leygue. They arrive at the result, 14m. 36·267s.

If two metallic surfaces be placed for a few moments opposite each other, at a short distance (a small fraction of an inch), it is generally found that each metal has undergone a slight superficial alteration. The change increases with time, then tends to a limit. When the influencing metal is withdrawn, the metal affected reverts gradually to its previous state. These observations have been made by M. Pellat, who detected and estimated the alteration by measuring the difference of potential. He shows reason for believing that the action is not electrical, but purely material. It depends essentially on the nature of the influencing metal, being great with lead, less with copper, and *nil* with zinc. It is as though the metals emit at ordinary temperature a volatile substance, which, being deposited on the surface of objects, modifies their nature chemically. When the influence of the metal ceases, the volatile body gradually leaves the surface to which it has attached itself.

With delicate apparatus, Herren Wolffhügel and Hüppe have investigated the penetration of heat into meat in ordinary cooking. In boiling of pieces that weighed 3 kilogr. (7½lb.), the inner temperature in 2½ hours was 92° or 95° C., according as the meat was placed directly in boiling water, or in cold water, which was raised to boiling. A ham of 4·5kg. acquired in 4 hours' boiling an internal temperature of only 88° C. The roasting of 3kg. of veal produced 92° to 98°; and that of a piece 14·25kg., 71°—89°. In a second series, tins of corned beef, the contents of which weighed 730g., 2,500g., and 6,300g., were put in boiling water, boiling salt solution, and in a steam-boiler with a bath temperature under 100°, the inner parts never reached 100°, but the temperature varied between 87° (in the larger) and 98° (in the smaller). Heating over 100°, the temperature in the larger tins only reached 72°—98°. These facts, according to the author, explain why the larger tins of American meat often contain bad parts.

LETTERS TO THE EDITOR.

"INTAMINATIS FULGET HONORIBUS"—STAR ATLAS FOR AMATEURS—SURVEYING: FINDING GEOGRAPHICAL CO-ORDINATES WITH A THEODOLITE—SPECTRAL PHOTOGRAPHY—THE GALILEAN TELESCOPE—AN UNPREDICTED OCCULTATION—COMET *a* (WELLS)—PROPERTIES OF LENSES, &c.—COCKROACHES—TRIPLE STAR IN MONOCEROS—HORIZONTAL POINTS OF SUNRISE ON THE LONGEST AND SHORTEST DAYS—CONSTRUCTION OF MAPS.

[20035.]—ASTRONOMERS will learn with gratification that the University of Glasgow has conferred at least as much honour upon itself as it has upon Mr. J. R. Hind, F.R.S., by making him one of its honorary LL.D.'s. We may now, perhaps, hope that one or both of our older universities of Oxford and Cambridge will at no distant date confer a similar distinction upon this eminent servant of science. Comparatively few men outside of the circle of professional astronomers know to what an extent we are indebted to the indefatigable and well-directed labours of Mr. Hind. Of the thousands who use the *Nautical Almanac*, but few, indeed, give a thought to the share which its superintendent has had in bringing it to its existing condition of perfection. It is, I imagine, incontestable that no one could employ the materials at his disposal more admirably and efficiently than Mr. Hind has done. I have, on more than one occasion, called attention in these columns to the shortcomings of the Predictions of the Phenomena of Jupiter's Satellites; but no man can make bricks without straw, and as long as he is confined for his materials to the imperfect tables published 46 years ago by Damoiseau, just so long must we exonerate the superintendent of the *Nautical Almanac* from blame for the errors which continue to disfigure this part of his work. If a small part of the money so indefensibly wasted on that trumpery imposture, "The Committee on Solar Physics," had been applied to the production of new and trustworthy tables of the Jovian Satellites, the solitary blemish in the work so admirably supervised and conducted by Mr. Hind would assuredly have been long since removed.

I regret to say that in the absence of my XXXIVth. Volume at the binder's, my memory fails me as to the exact nature of my original answer to Mr. Bridle, to which he refers in letter 19993 (p. 193). Doubtless, though, my reference was to Proctor's "Star Atlas," which is incomparably the best one for the amateur that I am acquainted with. I prefer the large edition myself, for several reasons. Every object in Webb's admirable "Celestial Objects," visible to the naked eye (and numerous others), will be found so clearly laid down in it as to render the identification of a given star or nebula certain on comparison with the sky.

Adding to the imaginary outfit of "Young Aspirant" (query 46768, p. 204), the *Nautical Almanac* and a book of mathematical tables, I will try to show him what he may hope to effect with the means at his disposal. Under any circumstances the results he will obtain can be only regarded as approximate, but with careful instrumental adjustment they will probably be sufficiently so for his purpose. With reference to his theodolite, he should have the ordinary system of wires removed from its eyepiece and the diaphragm of a transit substituted for them. This, as he may have heard or read, consists of five equidistant vertical spider-lines crossed centrally and accurately at right angles by a single horizontal one. I take it for granted that your correspondent is familiar with the adjustments of the theodolite, and knows how to level and collimate it, &c. We will then suppose him to be in some unknown part of Tasmania, with his instrument set up and accurately in adjustment. His first step will be to determine his meridian. This he will, of course, know more or less roughly from a compass or the position of the midday sun. Hence, he will have set up his theodolite with the 360° division pointing somewhere towards the north. Now let him select a bright star at some considerable distance to the east of the meridian, bisect it with the horizontal wire in his eyepiece, and note the reading of the horizontal circle. The diurnal motion will at once carry this star above the wire, and it will continue to mount and mount until it arrives on the meridian. Thence it will descend until, when it is as far to the west of the meridian as it originally was to the east, it will obviously have precisely the same altitude. All that we have to do, then, is to leave the altitude circle clamped, and to follow our star by a movement in azimuth alone until it is again threaded on the horizontal line. Then the theodolite will point, as I have said, exactly as far to the west of the meridian as it originally did to the east of it, and a point on the horizontal circle midway between the two readings will be in the meridian. Suppose, for instance, that "Young Aspirant" notes that when a bright star is 42° 21′ 8″ high to the east of the meridian, the horizontal circle of his theodolite reads 283° 6′ 9″, and that when, some hours afterwards, this star has the same altitude to the west of the meridian, the circle reads 85° 20′ 31″; then, quite evidently the Meridian must be half-way between the two points, so that if he makes the vernier read 4° 13′ 20″, the telescope will cut out a true north and south line in the Celestial vault. Having now got our theodolite into the meridian, we may proceed to determine our latitude. The most simple way to effect this is to measure accurately the meridian altitude of a star whose declination is known. Then 90°—this altitude = the star's zenith distance. If the latitude and the star's declination have the same name, the sum of the zenith distance and the declination will be the latitude. If they have different names, the declination must be subtracted from the zenith distance, and the remainder will be the latitude. I will illustrate this rule by a hypothetical example. Of course we are in south latitude in Tasmania. Very well, let us measure the meridian altitude of Antares, a star whose south declination is 26° 10′ 13″; and suppose that we find it to be 74° 2′ 20″. From this instrumental altitude we must subtract 17″ for refraction (as we shall find by reference to a proper table). Then the true altitude of Antares will be found to be 74° 2′ 3″, and taking this from 90° we get 15° 57′ 57″ for its zenith distance. Finally adding to this, according to the precept, the declination of Antares 26° 10′ 13″ (because both latitude and declination are south), we obtain 42° 8′ 10″ south as the latitude of our station. Had we employed a star with north declination (such, say, as δ Aquilæ), the calculation would have stood thus: Star's apparent, or instrumental, altitude 44° 59′ 43″. From this, following the table, we deduct 58″ for refraction; the remainder 44° 58′ 45″ being the true altitude, and obviously 45° 1′ 15″ the true zenith distance. From this (latitude being south and declination north), we *subtract* the star's declination 2° 53′ 5″. The remainder will be 42° 8′ 10″ as before.

To obtain longitude accurately is a matter of the greatest difficulty, nor can I pretend to furnish "Young Aspirant" with any method of determining it, save approximately, by aid of the means at his disposal. If his chronometer has been brought out from England, and indicates Greenwich time, its error and rate moreover being accurately known, the matter will be much simplified, inasmuch as he has only to determine his local time in the manner to be immediately explained, and the difference between this and that shown by his chronometer (when corrected for error and rate), will give his longitude by inspection. I must suppose, though, that his chronometer only shows his local time. In order to utilise this he must know our longitude roughly. We will imagine that we are, as nearly as we can guess, about 9½ hours east of Greenwich, and that we are observing on July 18th, 1882. Turning to p. II. of the month of July in the *Nautical Almanac*, we find that the "Sidereal Time at *Greenwich* Mean Noon" will be 7h. 44m. 46·41s. It will, though, be found, from p. 494 of the same work, that if the place of observation be not on the meridian of Greenwich, the Sidereal Time must be corrected by the addition of 9·8565 seconds for each hour (and proportional parts for the minutes and seconds) of longitude if the place be to the west of Greenwich, but by its subtraction if East. Tasmania being East of Greenwich, we take the correction of 1m. 34s., which this precept gives us, from 7h. 44m. 46.41s., and get 7h. 43m. 12·41s. as the Sidereal Time at our local Mean Noon. Now, on the night of July 18th, the right ascension of η Ophiuchi, a convenient star for our purpose, is 17h. 3m. 40·68s., *i.e.*, that is the time which a sidereal clock should indicate at the instant of the transit of η Ophiuchi over the meridian. Our hypothetical chronometer, though, shows Mean Time, so we proceed thus: From the star's right ascension, 17h. 3m. 40·68s., we subtract the Sidereal Time at Mean Noon 7h. 43m. 12·41s.: the remainder, 9h. 20m. 28·27s., is the number of *Sidereal* hours, minutes, and seconds after our Local Mean Noon, at which η Ophiuchi will cross our meridian. This we turn into Mean Time by the aid of the table on pp. 480 and 481 of the *Nautical Almanac*, so:—

h.	m.	s.		h.	m.	s.
9			=	8	58	31·5340
	20		=		19	56·7235
		28	=			27·9236
		·27	=			·2693
				9	18	56·45

If, then, we set the chronometer to indicate 9h. 18m. 56·45s. at the instant that η Ophiuchi is on our meridian, it will show absolutely correct local mean time. Having obtained his local mean time, probably the most available way for the surveyor to determine his longitude is by the aid of what are known as Moon Culminating Stars; for which he may consult pp. 367 to 396 of the *Nautical Almanac*, and the explanation given on pp. 504 and 505. He must be particularly careful, however, to multiply these observations, and, notably, to observe both limbs of the Moon. To confine his observations to either limb singly is to insure the observer being wildly out. The disappearance of Jupiter's 1st Satellite in Eclipse, as observed with a small telescope, will give an approximate longitude by comparison with the predicted Greenwich time in the *Nautical Almanac*. To expect to obtain accurate longitude, however, with a theodolite, and nothing else, is akin to hoping to execute delicate ivory-carving with an American axe. I don't quite know what "Young Aspirant" means by a "micrometer attachment to telescope of a theodolite." If he means an eyepiece-micrometer (albeit I have never seen such a thing attached to a theodolite), he might find the distance of an object of known height or width by dividing such height or width by the tangent of the angle it subtended at his eye. In this way; A gum-tree exactly 86ft. high subtends an angle of 1° 2′ 15″, how far is it off?

86 log. 1·934498
Log tan of 1°2′·15″ 8·257913

4748·8ft. log. 3·676585, or 0·8994 mile.

Any high-class optician may be depended upon to furnish excellent surveying instruments.

"Cinquanta" (query 46778, p. 204), should obtain Mr. Rand Capron's excellent and useful work "Photographed Spectra," published by Spons. He will find a full description of the apparatus employed, photographically illustrated, in it. No intelligible reply to such a query as 46778 could be compressed into a paragraph in a letter.

Did "Aqua Fortis" (query 46819, p. 205) ever see an opera- or field-glass in his life? or is he ignorant that telescopes with concave lenses have been used as "spy-glasses" since the year 1609, when Galileo invented this form of instrument? The field of view becomes so constricted with deep concave eye-glasses, as to render the employment of a really high power upon this form of telescope impracticable.

I can, I am sorry to say, only give negative evidence with reference to the subject of query 46822 (p. 205). I know of no 6th magnitude star that lay very near the Moon's path, as viewed from the South or centre of England on the night of April 26th; but I can say quite definitely that it was *not* 9 Sextantis which was occulted, inasmuch as the Moon was at some distance to the North-West of that Star at the hour specified by my querist.

Had Mr. Fleming (letter 20013, p. 216), read the predictions with reference to the increase in brightness of Wells's comet a little more carefully, he would have noted that it will not become a daylight object until it has passed too far to the south to be visible in the British Islands at all. In a 4in. achromatic, last night (the 11th), with a power of 40, it presented a very interesting appearance, the nucleus being apparently stellar, and the tail extending more than $\frac{1}{2}$° from it in a *n.p.* direction as a bright beam of nebulous light, and being traceable at least 15′ farther by averted vision.

As "Orderic Vital" (letter 20022, p. 217) gives no reference to the number or page of the query of "Lens," I am rather at a loss to know what it is with regard to which your very able correspondent has referred such querist to me. Meanwhile, I do not know whether it will be of any use to "Lens" to say here that Sir George Airy shows, in his "Undulatory Theory of Optics," that if e be the radius of the aperture of a telescope in inches, the extreme diameter of a star disc in seconds to the first black ring will be 2·76 divided by e. Some very interesting micrometical measures, made by that eminent double-star observer, Mr. George Knott, in the course of an experimental investigation into the accuracy of this theory, will be found on pp. 87 and 190 of Vol. XXVII. of the R.A.S. *Monthly Notices*. Possibly, too, a paragraph in a letter of my own (18314), on p. 494 of Vol. XXXII. of the ENGLISH MECHANIC, may be of some service to "Lens," if I rightly gather the tenor of his question from what "Orderic Vital" says.

"Brickwall" (query 46861, p. 226) must consult some work on systematic Entomology for minute details; but I may say here that the filthy Blatta orientalis, Cockroach or Black-beetle, belongs to the order of Orthoptera. The most immediately patent difference between this and the order of Neuroptera consists in the fact that in the latter the four wings, generally equal in size, are traversed in all directions by very numerous nervures (a dragon-fly's wing furnishes a good example of this), whereas the nervures of the hinder wings in the Orthoptera always radiate from a central point to the circumference. These radiating folds and nervures are wholly absent in the posterior wings of the Coleoptera, which are really used for flight. A cursory examination of the wings of the Blatta will show how unfit they are for any such purpose.

Writing on the day of the appearance of query 46870 (p. 227), in the middle of May, I can of course not examine a region of the sky which is on the meridian between 2 and 3 o'clock in the afternoon; but as there is no triple Star anywhere near the position indicated by Mr. Tindale, except 11 Monocerotis, I can only conceive that that is really the one which he has got hold of, malgré the seeming discrepancy in his position angles. Unless he either observed the object when actually on the meridian, or his telescope is equatorially mounted, he may easily have made a mistake in his estimation of them. He did not reckon that of C B did he (taking C as the initial point)? because this would bring him rudely into his position angle of 305°.

"Neo" (query 46888, p. 227) would appear to be unaware of the fact that the points at which the Sun appears in the horizon on the longest and shortest days respectively, vary with the latitude of the place of observation. The simple trigonometrical formula for determining them is this: Sin. Sun's declination × sec. latitude = sin. of amplitude (amplitude being the distance of the Sun from the east point measured on the horizon). Let me illustrate this by an example. Whereabouts does the Sun rise at Beaumaris (lat. 53° 17′) on the longest day?

Sun's Declination North 23° 27′ sin. 9.599827
Latitude of Beaumaris ,, 53° 17′ sec. 0·223402

41° 43′ 49″ sin. 9·823229

Therefore, on June 21st the Sun will rise at Beaumaris at a point 41° 43′ 49″ to the north of east. On the shortest day it will pretty evidently rise precisely as far to the south of east.

I am afraid that Hughes, on "The Construction of Maps," published by Longmans, has run out of print. If not, it is the very book for Mr. A. J. Smith (query 46902, p. 227.)

A Fellow of the Royal Astronomical Society.

WELLS' COMET.

[20036.]—IN your journal for August 21, 1874, you kindly permitted me to describe a method for finding a comet's orbit by projection. I have employed that process to find an orbit for Wells' comet from observations of my own with the following result: time, June 13, 1882.

$$\begin{array}{lll} \pi & = 48^\circ\ 20'\ 0'' \\ \Omega & = 211\ \ 10\ \ 0 \\ \iota & = 78\ \ 20\ \ 0 \\ \text{Log. } q & = 9\ 0899. \end{array}$$

These elements differ a little from those that have been published in the MECHANIC, and I give two positions indicated by the above orbit near which I think the comet will be. June 1, R.A., 4h. 12m., Dec. N., 50° 50′; June 8, R.A. 4h. 42m. Dec. N. 36° 35′. The comet will be nearest to the earth on May 17th, about 85 millions of miles from us, its distance will then slowly increase; on May 25th, it will be 86 millions of miles; on June 1st, 90 millions; and on June 8th, 96 millions of miles from us, while its distance from the sun on those dates will be 61; 44; and 22 millions of miles; the motion of the comet in its orbit at the same times will be 113,160 miles, 133,400 miles, and 193,200 miles per hour respectively; while on the 13th June, when nearest to the sun, about 11 millions of miles, its rate of motion will be 276,000 miles an hour. The comet will not be a very conspicuous object. Owing to its great distance from us it will appear small, and from the increasing twilight and moonlight and its approach to the horizon after sunset, its splendour will be much diminished.

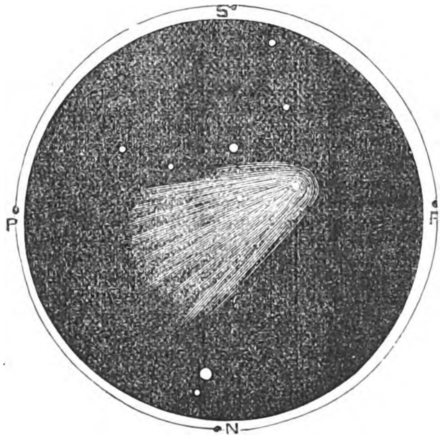
I have noticed that comets when approaching the earth rapidly increase and brighten much more than their nearer distance would warrant; when they are nearest, their brightness usually varies very much, and when they are departing from us they fade away very quickly; of course, this is modified according as the comet is approaching to, or departing from the sun: I should be glad if some one could say what theories (if any) have been formed to account for this phenomenon. Also, I should be glad to know upon what data the predicted brightness of the present comet has been estimated. An answer to the above from some correspondent will greately oblige.

J. Lane.

29, Wyvis-street, Bromley-by-Bow, May 13th.

[20037.]—ON Saturday, the 13th May, I had a fine view of the new comet (Wells'), with 12¼in. mirror, and power about 130. With this aperture it presented a bright and conspicuous object, at once attracting the eye in sweeping for it.

The tail was much better defined than hitherto, not requiring indirect vision to show its spreading outlines. In the immediate vicinity of a corona of small stars, it was quite interesting to observe how rapidly the comet advanced, changing its relative position with the stars manifestly and quickly. As some of the readers of the ENGLISH MECHANIC may desire to see how this object will appear by-and-by to the naked eye, I furnish a drawing, made at the telescope about 10.30 p.m. At that time, a faint star was visible shining through the tail, showing its extreme thinness. A fine orange star, with a companion in the N. preceding field, completed a view of no ordinary beauty, and which my diagram attempts to represent.



Droylsden Rectory. **S. Mills.**

[20038.]—IN your last week's issue, you kindly reported my observations of Wells' comet up to May 6th. Since then I have seen it three different times—viz., May 8th, 10th, and 13th; each time between 10.30 and midnight. On the 10th it was exactly below Gamma Cephei, and on the 13th it had entered Cassiopeia. On that night the nucleus, stars 23 and 21 Cassiopeiæ, were in a straight line, each being equidistant from the other. The tail extended beyond these two stars and embraced them; the stars shining brightly through.

The night was very fine, and the view as good as any I have hitherto had. It is keeping close to the path indicated by Mr. Hind. It does not appear to me to be brightening much, and I doubt whether it will ever become a conspicuous object, as it is travelling fast into a light region. Knowing where to look for it on the night of the 13th, by the aid of the two stars above noted I could just pick it up by the naked eye, and this was fully as much as a friend and I could do. This was after seeing it through my telescope, and thereby ascertaining its exact position. **L. T. Fleming.**

Berwick-on-Tweed, May 15.

WENHAM'S NEW MICROSCOPE.

[20039.]—I SHOULD not have noticed letter 20021 as it is written by an anonymous writer, had he not insinuated that I pirated the idea, or derived my "inspiration"!! from Dr. Edmunds. This I totally deny. I had not even read his remarks, published in the *Journal* of the Royal Microscopical Society.

On the first appearance of the "Wale" microscope, I made some diagrams with the arc struck from the object-point as a centre; the result was unsatisfactory, as no substantial room could be obtained on the limb for clamping the arc up to 90°, or from the required horizontal to the vertical position. There can be but little claim to invention in this idea, as it might readily occur to anyone looking at the illustration of the "Wale" microscope then published.

A description with figures had been sent to me of an equatorial telescope, designed in the year 1868, and published in *Carl's Repertorium für Experimental-Physik*, in which all the motions were derived from the eye as a centre, so that the observer need not move in the least from his position in viewing every portion of the heavens. This gave me the idea of a microscope in which all the motions would be round the object-point as a centre.

As the writer of letter 20021 had no access to the workshop of Messrs. Ross, it is absurd for him to assert that the microscope proved a rickety and unmanageable contrivance, when the fact is, that it has the firmest standing, and is more free from tremor, than any microscope of the class that has preceded it, as the centre of gravity is unusually low, and if it appeared some months later than the instrument of Messrs. Watson, it is because this was a business arrangement; there is no antagonism between the firms.

The design was a mere matter coming within the scope of my duties, and having been patented, is, therefore, not honorary. I have already experienced sufficient ill-will this way, from persons who have claimed as novelties ideas published by myself many years before.

Dr. Edmunds has described nothing new or practicable; the mere suggestion that he made has not even been illustrated by him, and I understand that he failed in the attempt to get together a microscope of the "Wale" form, with the arc struck from the object-point, and the instrument has never seen the light. **F. H. Wenham.**

[20040.]—OUR attention having been called to the letter of "Another F.R.M.S." in your current issue. It is not our intention to enter into a controversy with the writer as to the origin or construction of the above microscope, preferring to leave your readers to form their own estimate of his remarks, which appear to us to savour more of malignity than fair criticism.

Ross and Co., Opticians.

112, New Bond-street, London, W., May 15.

WENHAM'S AND WATSON'S MICROSCOPE STANDS.

[20041.]—IN the current number of your valuable paper I see a letter (20021) by "Another F.R.M.S.," in which he does Mr. Wenham and the inventor of the microscope known as "Watson's," the honour of pointing out that the origin of their instruments is due to certain words spoken by Dr. Edmunds at a meeting of the Royal Microscopical Society on the evening of November 10, 1880.

Permit me, Sir, to give to this statement an unqualified denial. I know it to be untrue in both cases, but will leave Mr. Wenham to meet the statement touching himself (should he think it worth while) in his own way.

But, as the inventor of the stand known as "Watson's," I beg to state that its origin was not in the remotest degree connected with anything that Dr. Edmunds ever said, wrote, or thought. It was devised—as is well known to many—long before the words quoted by your correspondent were uttered, and primarily for a purpose in the perfecting of microscopic vision, which, to judge from his letter, he has as yet failed to grasp.

John M. Moss.

19, Eldon-place, Patricroft, May 12.

A TADPOLE SLIDE.

[20042.]—"VOLVOX" (see letter 20020) would find it easier to construct a special slide for his tadpole than to use the method he advises. His method prevents the use of a higher power than the ½in., and never insures the tail lying flat from end to end. The use of chloroform, too, retards the circulation. I send the description, with a drawing, of a slide, easily constructed, that enables the microscopist to view with an eighth of an inch glass the circulation in any part of a tadpole's tail; and that without injuring the object. Two pieces of vulcanite ring are fastened to an ordinary 3 by 1 glass slide, so as to form a small oval cell, just large enough to admit the body of the tadpole. The cell must have a free opening, so as to allow the tail to project out of it, and lie along the slide. Close to the opening of the cell an ordinary square thin cover glass is cemented on the slide by means of Canada balsam, for the purpose of raising the tail to its proper level with the body. On each side of this must be cemented two small oblong pieces of thin glass (made by dividing one of the little square covers in half); these will then form a kind of cell for the tail to lie in. Take a tadpole out of the water with a dipping-tube, and place the body in the oval vulcanite cell, when it will be securely held there by capillary attraction; the tail will then project along the slide, and may be held there by a square cover glass being placed over it. Another small square being placed over the body, it will be found that the tadpole is quite comfortable, and can readily be examined with high powers by the hour, without a chance of his moving. It is well to make these with the cells of two or three different sizes, to fit tadpoles of different stages of their growth. It is necessary that the cell should be only a trifle larger than the body of the tadpole, so that it is impossible for him to get his tail curled round the body, there not being room for it: hence it must be outside.

Paddington Vestry, W.

ASTRONOMICAL — ELECTRIC LIGHTING DANGERS — STRING VIBRATIONS.

[20043.]—Not having any of the works mentioned by "Ascalon" in letter 19992, I cannot compare his diagrams with theirs; but very likely they show either the formation of an image or how achromatism is maintained, so he cannot expect them to appear so "simple" as his, which show nothing. If Mr. Johnson had said that the current from Edison's dynamo could not pass through his body, he would have been nearer the truth. I should think I had to state six times in as many days after the statement appeared that it was all humbug, and if "Sigma" had not saved me the trouble I should have criticised it in "ours," so G. A. Moore's letter is only a waste of space.

"Fiddler" also fills nearly a column in order to extract information which a query of two lines would have brought forward, and in going "out of the beaten track" to attempt an explanation of a well understood fact, he gives a rough imitation of an exp. I saw worked last July by Professor Guthrie, who proved experimentally that when a string is fixed at one end to a vibrating fork (the other end being carried over a pulley and weighted) the number of segments is, within certain limits, inversely proportional to the sq. rt. of the stretching weight. Stick a shilling on one prong of a small tuning-fork, and see how long it vibrates, and then don't wonder that your hair-pin will not vibrate and carry a greenhouse shelf, or at any rate its own weight on one leg. The vibration of the thread is produced by the vibration of the hair-pin, and not by its sound, which is merely a sensation produced by its vibrations. The G string responds to the vibrations of the soundboard when produced by the upper G, and as the length of a string is inversely as the number of its vibrations if G vibrates in unison with its upper octave, it can only do so when it is divided into two equal parts by a node at its centre.

The production of overtones is not caused by weight, but by bowing the string near one end (the bridge). If weight did produce overtones you would require a strong "third finger" in order by stopping the D to put four times the tension on the G that the latter obtained in turning by peg.

J. M. Stocks.

TO MR. BRASHEAR, "ORDERIC VITAL," AND "PRISMATIQUE."

[20044.]—I tender my thanks to Mr. Brashear for his full reply about the colours of the first and second order. I shall have occasion to use the information when I come to the working of flats, which I am afraid will be some time yet, for no one knows how much time is taken up in trying all the experiments necessary to the satisfactory elucidation of all the laws that govern the various processes involved.

I am glad "Orderic Vital" (19968, p. 172), thinks the rule I use the correct one; it is perhaps a difficult matter to demonstrate it mathematically. The way I decided which rule to adopt was simply, judging from the discussion that was carried on in our columns some time ago, although not a sufficient mathematician to prove it for myself, I judged from the arguments for this rule and for Dr. Draper's, that Dr. D. was mistaken, and it appears my judgment as to where the truth lay was correct. Can any one prove the rule to be wrong? Some, I know, think it is; but they will have to explain how it is that when a speculum is worked to this rule the outside, intermediate, and centre rays have all their foci at one point for parallel rays; this fact confirmed me in the adoption of the rule. I should like to know whether this rule strictly applies to a speculum one-third its focal length in diameter, as it seems very nearly to do to a speculum one-ninth its focal length in diameter. It may be only an approximation to the truth for the latter speculum, and considerably out for the former; this is important to know if we wish to make short Cassegrain or Gregorian telescopes. "Orderic Vital" suggests that those who have a Calver or a With speculum should test theirs by this rule, and see if they answer to it. Now, many who would like to help to settle this question and have a Calver or a With speculum may not have the necessary apparatus to prove it, much as they may desire to know if their specula are according to it. I, therefore, offer to any such that if they will trust me with their Calver or With speculum, and will send it to me, I will test it for them, and this will, as "O. V." suggests, be a very practical way of helping to settle the matter; but surely it may be settled by mathematical proofs, and I hope that now the question is on the anvil, all who can help, either practically or theoretically, will strike the iron while it is hot, and besides, not allow the correspondence to degenerate into a mere assertion of opinion, and mere lengthy letters; let us all unite to settle the matter once for all; whatever previous opinions we may have to give up, truth is certainly worth confirming to those who have it, and far more worthy of the space that error now occupies in the minds of those who have perhaps long cherished it than that error As to the use of the eyepiece in testing at the centre of curvature, I have discarded it for some time. I did not find it so convenient, nor so delicate in my hands. One great objection to its use is the great care necessary to get the axis of the eyepiece in an exact line with the axis of the cone of rays, but if any wish to try the use of the eyepiece, I shall be happy to describe how I did it. I think it is not the best way, but those who think it is may like to try it for themselves.

I am always glad to see a letter from "Prismatique." It is bound to be brimful of practical information. I fully admit the force of all he says in his letter (19969, p. 172), about grooving, &c.; yea, I admit its truth, and hope to give paper a fair trial; perhaps if I had as much practical knowledge of the polishing with paper as I have of the polishing with pitch, I might be able to recommend it in preference to pitch. I am sure of this: we are all much privileged in having one in the trade (I question whether there is another in all England) who so thoroughly will throw off the trade reserve. No one but he who so loves his art as to be above its mere gain, could thus come forward to our help: his letters are like a good gold-mine, to be carefully preserved and looked over by those who know the worth of real gold.

H. A. Wassell.

Addenbrook Villa, Love-lane, Stourbridge.

GRINDING AND POLISHING GLASS SPECULA.

[20045.]—A very simply constructed apparatus can be made to melt and strain the pitch at the same time, if an oven is used. An earthen pipkin, glazed inside, with a capacity of at least three times that required for the pitch; a wooden rod long enough to project over the sides a few inches, and a square of muslin, are the tools required. The pitch procured at the chemist's shop in the boxe is the best; the lid of the box only need be taken off, the box then, bottom up, placed in the centre of the muslin, the corners of the muslin gathered up and tied round with a string, dumpling fashion, the ends of the string tied to the wooden rod. Now suspend the muslin bag at a short distance from bottom of the pipkin, and place in the oven. Care must be taken not to have the oven hot enough to scorch the muslin, or it will be weakened, and the pitch break through. Straining and melting is thus done at once. When all is run out, have ready a pail of cold water, and lift out the bag and drop bag and contents into the water; a lot of trouble is avoided by this plan. It usually takes four hours of simmering to drive off the oil of pitch sufficiently, very frequently much longer. When the pitch has simmered four hours, it is well to test it roughly. With a clean stick drop a small quantity on a face-plate or other cold smooth surface; let cool; if, when cool, it sticks quickly to the finger pressed upon it, it requires more boiling. It should take the impress of the skin, and leave the finger clean when boiled enough.

There have been many ingenious plans adopted by amateurs for testing by allowing a small weight to rest on a mass for a given time. The late Mr. Lassell used a sovereign standing on its edge; but as the speculum was a metallic one, his test of "three impressions of the milled edge of the coin in one minute" would prove the pitch too soft for glass specula. One impression in one minute, if the specula is upwards, and two if the polisher of light wood is used upwards, would be nearer the mark for this test.

A moment's consideration will satisfy anyone that the test is not a common workshop test even now; as a sovereign is not always ready at the workman's hand: the rule of thumb is usual. The literal rule for the thumb-nail is the workman's testing tool, and I find it difficult to describe the application. The amateur, however, can generally get over these little difficulties in another way. In working, dragging is a sure proof that the pitch is too hard or the temperature too low. If, on the first examination of the surface, after using the pitch polisher, the surface presents a blue stained appearance (like the surface of tarry water), the pitch is too soft, and must be scraped off, and fresh, harder pitch tried. The method described by Mr. Brashear seems a very good plan when that form of polisher is used; but for the wooden-backed polisher it is better to roll the pitch into rods, and lay them along the edges of the laths. If the pitch is of dough-like consistency, and quickly managed, this is not a difficult job. There need be no great thickness of pitch, say, ¼in. at most. By moulding quickly, the faces of the ridges only need warming. Then, by the use of the "marra" tool and tissue paper, as described, the transverse grooves only need cutting in: the longitudinal are already formed, and need trimming along the edges to something like uniformity.

Prismatique.

ELECTRO-MAGNETIC MOTOR.

[20046.]—Mr. Huxley, in letter 19997, has not given any factors for the determination as to whether or not it is possible to use the alteration of state in magnetising and demagnetising soft iron for motive power, and until are known, 1st, the amount of contraction, and 2nd, the electric force necessary to produce it, speculations on results must be very wild indeed. Mr. Huxley assumes the force is enormous, whereas the probability is the force is very minute, in fact, just sufficient to overcome the friction of the particles of iron. It is also probable the elasticity of iron would completely baffle any attempt to employ the alteration of state as a motor in the manner suggested by Mr. Huxley, and if the iron be under any stress, the electric force would probably have to be increased to the extent of that stress, so as to overcome it.

There is, however, one method that might be employed to produce motion, which is as follows:—

It is evident if a system of long electro-magnets be balanced round an axis, and each magnet be contracted when it enters one half phase, and remain so until it emerges into the other half-phase, the centre of gravity would be altered, and rotation would follow. Again, it is not difficult to magnify this result by making each electro-magnet carry a piece of thin lead shaped so as to form the segment of a cylinder at the free end, and thus one might even have a few pounds' weight of thin lead falling through a space equal to the diameter of the cylinder in a continuous stream, and that from a very small electric current. **A. C. Ponton.**

Viewfield, Parkstone, Dorset, May 8.

NOTES ON DYNAMO-MACHINES.—II.

(*Continued from p. 176.*)

[20047.]—15. If R is the resistance of the field-magnets in an ordinary dynamo-machine, and R_1 the resistance of the armature, then that ratio of work to waste may be a maximum. R_1 should be somewhat greater than $R + R_1 / 2$. The exact value depends upon the susceptibility of the iron in the machine; the forms, magnitudes, and relative positions of the wires, &c.,—quantities not derived theoretically.

16. In the shunt dynamo, if E be the resistance connecting the terminals of the machine, it is best to have, approximately, $E = \sqrt{R \times R_1}$.

17. Since the E.M.F. created in a closed coil is proportional to the rapidity with which lines of force cutting the coil are added or subtracted, it follows that no E.M.F. can be induced in a coil moving *parallel to itself* in a uniform field. If, however, the coil be caused *to rotate* about an axis passing diametrically through it, and lying perpendicularly to the direction of the lines of force (as in the Siemens continuous current machine), a current will be generated in the coil. The current will be reversed when the greatest number of lines of force cut the coil, and will reach a maximum when no lines of force cut the coil.

18. In a magneto-electric machine, the E.M.F.

is simply proportional to the number of turns of the armature per minute, and $C \times R$ is a constant for any given speed of the armature; hence, for a given resistance, the current is proportional to the speed.

19. In the dynamo machine, the E.M.F., or $C \times R$, for any fixed speed, is variable, depending on the magnitude of R. If R be too great, the dynamo will not magnetise itself. In the ordinary dynamo, where the field-magnets are in circuit with the lamps, the current, when an extra resistance is introduced, is diminished, for two reasons —(1) Because, with a given field, if R increases, C diminishes; (2) because, by reason of C diminishing, the magnetic field is weakened, which further diminishes C. In the shunt dynamo, where the field magnets are wound as a high resistance shunt to the main circuit, an additional resistance in the main circuit causes a stronger current to flow through the field magnets; hence, the magnetic field is made stronger, and this compensates for the additional resistance in the main circuit, in such a way as to make the current practically constant under considerable variations of R. Experiments have been made to determine the constancy of the current generated by the shunt-dynamo as compared with that generated by the ordinary dynamo, with these results:—The speed was in each case constant, and the current varied from 40 to 30 ampères in the shunt-dynamo, as resistance was increased from 1 to 2 ohms in the external circuit; while in the ordinary dynamo the same variation of resistance caused the current to vary from 50 to 25 ampères.

20. The shunt-dynamo, with 20 per cent. to 25 per cent. variation of resistance, gives a pretty constant current. But the fact that the current cannot be regulated to any great extent by varying R, renders it inconvenient for many purposes. One of the reasons why cast iron has been adopted for the field magnets in later dynamos is to obtain, to some extent, the steadiness of the shunt-dynamo, even at the expense of current. Cast iron, although incapable of being magnetised to the same extent as wrought iron, is less liable to become demagnetised, and the magnetic field is consequently less liable to vary with every slight variation of R.

21. With a uniform field, as in a magneto-machine, the E.M.F. is proportional to the revolutions per min. of the armature; hence, if the current circulating round the field magnets be kept constant in a dynamo, the E.M.F. will increase directly as the number of revolutions. Let r be the internal resistance of a dynamo, R the external resistance, and N the number of revolutions per min. of the armature. Since N is proportional to $(R + r)$, so long as C remains constant it follows that if a new resistance $= (R + r)$ be added to the resistance R, so as to double the total resistance, the speed of the machines can be doubled without any danger of overheating, the current being the same as before, but the external to internal work being now in the proportion of $(2R + r)$ to r, instead of R to r. The mechanical friction is obviously doubled also, it may be a little more than doubled.

22. In a dynamo where the magnetic field is constant, the E.M.F. is proportional to the number of coils connected in series. Suppose we have a machine on the armature of which there are twelve coils. These coils may be connected up in several ways (*e.g.*, the twelve in series, in six pairs, and the pairs in parallel circuit, &c.), but if the resistance of each coil is the same the E.M.F. is proportional to the square root of the total resistance of the armature from brush to brush.

23. The work done by the current is proportional to the square of the current multiplied by the resistance. Let H.P. = the work in horse-power, then, if R = resistance between any two points between which it is desired to measure the energy expended, C = current in ampères, and E = E.M.F. in volts between those points $H.P. = C \times E \times \cdot0013409 = C^2 \times R \times \cdot0013409$. **E.**

Errata.—On p. 176, for *does not increase* in note 6, read *increases*, and for *but* in the following line read *and*.

[20048.]—I have been waiting for several weeks in hopes of seeing an answer to "Fritz" (letter 19758, p. 591, last Vol.), as I am in the same predicament. With regard to dynamo machines, I have made a machine of the same type as his; but instead of being so small as "Fritz's," it has an armature 15in. long by $2\frac{1}{4}$ diameter, wound with four layers of No. 14 cotton-covered copper wire, and the machine gave an excellent current. But the E M F was so low that it would not overcome the resistance of an ordinary Swan lamp of 20 candle power, nor even ring a bell; so I wrote to the Editor of the journal in which the instructions appeared from which I made the machine, to know the cause; but, instead of inserting my letter, the Editors answered themselves, and said it could be remedied to any extent by winding the armature with finer wire and a greater number of convolutions. I have accordingly wound it with eight layers of No. 18 cotton-covered wire, with commutator in same position as formerly, but the machine will not now produce the faintest spark. I have altered commutator, reversed wires of field-magnet, and tried everything I can think of without success. Will "Sigma" or Mr. Lancaster or any experienced electrician come forward and help us? I want the machine to light a Swan lamp and charge Faure batteries. In conclusion, I may say the field magnet is wound with 12lb. of No. 14 cotton-covered wire. **Fainthearted.**

DR. HAY'S SIMPLE BAROMETER.

[20049.]—I hope Dr. George Hay (20024) is not laying the flattering unction to his soul that his simple barometer is an invention. No one doubts its efficiency; but to my knowledge it has been used in Scotland, and, I suppose, in many other countries, for a great many years among farmers and others whose faith in the barometer has been shaken by observing the mercury standing at, perhaps, 30·5 and rain coming down in torrents. Apart from knowing of its existence in this manner, I find it mentioned in a little book (almost worthless otherwise) called the "Weather Indicator." The principle has been well known for many years, although the particular mode in which Dr. Hay makes it may not have been generally adopted. As taking a considerable interest in all kinds of home-made barometers, I have used for more than a year a storm-glass, which must be familiar to many readers of the Mechanic, and which, I know, is well known among seafaring men on the south coast of England, and also among the fishermen in the Orkneys, although in intermediate parts it seems to be very little known or appreciated. It consists of a pickle bottle with a large mouth, almost filled with water, and a Florence flask inverted, and the water rises and falls within the tube of the flask in correspondence to the weather. It acts exactly as the storm-glass of which Dr. Hay speaks, by the different tensions of the atmospheres outside and inside the flask. The difficulty with it, as with all home-made barometers, is that it is very subject to temperature, but when kept in a room such as a bedroom, on the shady side of the house where no fire is used, it acts with great satisfaction, and predicts storms of wind and rain as quickly as any barometer. I have made repeated experiments extending over several months with a thermometer and a barometer alongside the storm-glass, and I find that it is very much more subject to atmospheric pressure than temperature.

I find that a rise in the thermometer of 10° is nearly equal to a fall of the water in the tube, caused by the expansion of the air in the flask, of $\frac{1}{3}$in., the diameter of the tube being about $\frac{1}{2}$in. It is easy, of course, to paint lines on the tube to notice the rise and fall. I could give many instances where such a storm-glass has been of great service to small coasting vessels, which do not carry barometers, and I know masters of large vessels trading to the East who carry the two bottles regularly, and would not be without them for anything.

Glasgow. **R. H.**

MEDICAL REPLIES.

[20050.]—Scrofulous Glands in Neck (46852).—Read my recent reply on scrofula,

Skin Disease (46920).—Sufferer from sycosis for 23 years asks, "what is the application which I should use after the hairdrawing and poulticing already recommended?" This is a practical question not quite answerable without seeing the patient. But the object is to kill the parasite with a poisonous substance that can be made to penetrate the skin and hair follicles, and yet not injure the skin. Generally, my choice would lie between the following:—(1) a 5 per cent. solution of carbolic acid; (2) freshly precipitated yellow oxide of mercury in very fine division, mixed thoroughly into soft vaseline—say, 1 part of oxide to 7 of vaseline; (3) the nitrate of mercury ointment, commonly called citrine ointment. The latter is of a citron colour, the former of a fine golden yellow: if touched with a knife or other metallic substances, they blacken and spoil. Go gently to work, so as not to produce erysipelas of the skin. Should the skin become inflamed, stop the parasiticide, bathe with warm water, return to the poultice, and, on recommencing, use weaker preparations. Give one application an exhaustive trial before commencing another, or use different applications on different parts of the skin, so as to test them accurately. Do not mix the applications. It should be recollected that sycosis is infectious.

Grafton-street, Bond-street.

SMALL MILLING MACHINE.

[20051.]—"J. K. P." describes a milling machine which he has fitted to one of his lathes, on page 185, Vol. XII. It seems a very nice arrangement, and I should like much to see it. I think "J. K. P." would afford useful aid to many if he gave in your pages a drawing of his pulley there described, carrying the following divisions. 300 outside, then 11, 13, 14, 17, 19, all in one row (I do not understand how they can be arranged to be all in one row), 216, 140, 96, 84.

I have two lathes, and would like to take his advice, and add his milling machine to one of them.

I have also, in same vol., page 156, been looking at Mr. Plant's description of his geometric chuck, first part. Would "J. K. P." kindly say if it would do to try and make such a chuck, using Lloyd's 14-pitch wheels for the purpose. My lathe, to which I thought of applying it, is one with a gap, which allows a face-plate 18in. in diameter, to swing. It is very similar to those advertised in your columns by Selig and Sonnenthal, 5in. centre, 6ft. bed, with two driving-wheels.

I purpose using a 96-toothed wheel instead of the 120 one, and a 72 in place of the 96 ratchet-wheel.

There would be some labour in turning down the wheels to about half their present thickness, leaving a boss, but I fancy with them a very inexpensive chuck might be made. Of course its power would be rather less than "Plant's" one, as the 96 wheel would only divide ten times in place of fourteen, as the 120 does. **Gereb Admi.**

ORNAMENTAL SLIDE-REST.

[20052.]—I beg to thank "F. W. G." for his endeavour to explain by diagram the clamping action of his longitudinally-divided nut upon the leading-screw of a slide-rest. No doubt the nut would so act, as shown in the diagram, where there is, as there represented, a new and unworn nut and screw. But the question is, what would be the action when the nut has been worn by use? And if "F. W. G." had drawn on a larger scale the sectional form of this worn thread, he would, I think, have seen that the wedge action is effectually prevented by the two corners or "steps," which are formed in any case, and which stop the nut from closing sufficiently upon the screw to produce a wedge action. The effect of thus clamping the nut on the screw will, in fact, be to part the surfaces of the threads, which should be in contact, and all the work will be thrown instead on the end of the screw-thread, which will work upon the steps until it wears it away by friction, when backlash will again ensue, as I remarked in a former letter.

The external thread of the leading screw, whether the outside is flat or rounded, has by friction enlarged the internal thread of the nut, in the case of backlash, beyond its own sectional size, and nothing smaller than this enlarged cavity can fill it and act as a wedge. "F. W. G." allows this to be the case in the flattened screw, and I think he will find but little difference when the thread is rounded. Continual screwing up of the nut and wearing away the step bit by bit must be resorted to until "backlash" is exterminated, and all this time the screw will have been working in the nut under most disadvantageous circumstances for a slide-rest.

I think "F. W. G." will admit that the steps will be formed in any case, and that he would be glad to part with them. Prevention is better than cure; and the only remedy I see is to make that portion of the internal thread of the nut, which is in the engraving unoccupied by the truncated thread of the leading screw, square instead of angular, or rather a little more than this portion. No corner or step would then be formed by wear, and the nut, when screwed up, would work upon the whole of its thread surface and backlash would be extirpated.

There would not be much difficulty in cutting this small depth with a specially formed internal screw-chaser.

This mode of curing backlash would then be better than that which I advocated, inasmuch as my plan throws all the wear on half the screw-surface of the nut; but I question whether the superior action of a square-threaded screw and nut does not decidedly outweigh this consideration.

M. A.

FOUR-JAWED CHUCK.

[20053.]—One of your correspondents having expressed a wish for a description of a good four independent-jaws chuck, I give illustrations of one I have in use myself. It is an exceedingly useful chuck for anyone who works much in metal, and I also frequently use it for woodturning. In many ways it is superior to the American self-centring chucks, though not so good for holding twist-drills as the latter, and for a few other purposes the American chuck is very handy. I have two of them myself; for not only is it very easy to centre accurately a round article in the independent-jaws chuck, but it will hold almost any irregular shape.

Fig. 1 is a front, and Fig. 2 a back view; the latter shows the mechanism. Mine, which is $10\frac{1}{2}$in. diameter, is cast with hollows in it, as seen in Fig.

2, for the sake of lightness, and the raised ribs give it rigidity; but for a smaller lathe it might be left solid; but in any case, the slots through which the jaws work ought to be cut out of solid metal. Mine is cast iron, as it is much easier to do so than to true them up when cast hollow.

FIG. 1.

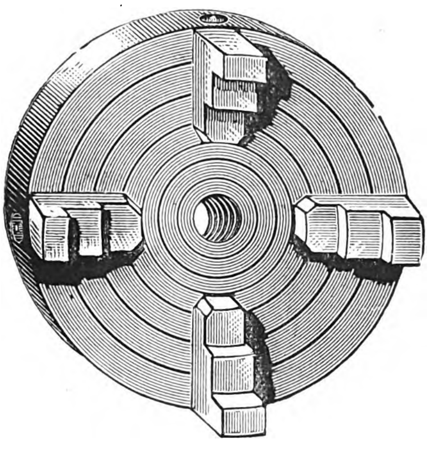

Fig. 3 shows how the jaws are made; they should be of steel, or well-hammered iron casehardened; the part A should be a good deal broader than the slots, so as to take up a good bearing on front of chuck; they are turned out in three steps—for a smaller lathe two might be sufficient—in order that they may take in articles varying considerably in size without much movement of the leading screws, and these steps should be equally proportioned. The part B, Fig. 3, must be nicely fitted to pass through the slots without side-shake, and it is in cutting out slots like these, that the milling attachment of my lathe (which I formerly described), acts so well, as it cuts them out true and parallel very rapidly, though of course they can be made by drilling and filing; but in doing them this way a considerable amount of skill with the file is required, more than most amateurs possess. The four holes, two of which are seen on rim of chuck, are drilled with a pin-drill the same size as the collar C, Fig. 3, of the leading screw, and the screw is secured from moving endways by a semicircular groove being turned in the collar in which two steel pins, one on each side, engage, which are driven through the chuck, as shown in Fig. 2. After the screw is in its place the holes for these pins are so drilled that when in their places half the pin is in metal of chuck and half in groove of collar. The jaws are moved by turning the screws with a box-spanner, Fig. 4, which is inserted into the holes on rim of chuck, the squares on end of leading screws being flush with rim. The plate and nut which secure jaws are shown in Fig. 3; the slight step on plate fits the slot and prevents it turning round. A number of concentric circles are cut on front of chuck, Fig. 1, which assist greatly in centring work, and the steps of the jaws must be turned true in their places. This chuck, to be efficient, requires to be made strongly and carefully, and is a very expensive one to buy, costing as much or more than a slide-rest for the same sized lathe, but to anyone who cares to make it will amply repay their trouble. The leading screws in my chuck are ⅝in. diameter, but for a 4in. centre lathe ½in. would probably be strong enough, and if one has a screw-cutting lathe, are better made square-threaded; the chuck should be as large as the lathe will take in. Now, a few hints with regard to centring work in this chuck: if it be round, see which of the concentric circles on face of chuck is nearest in size to it; move in your jaws to this circle, and fix article between them.

FIG. 2.

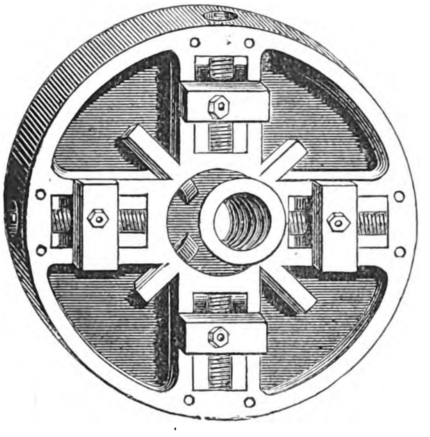

FIG. 3

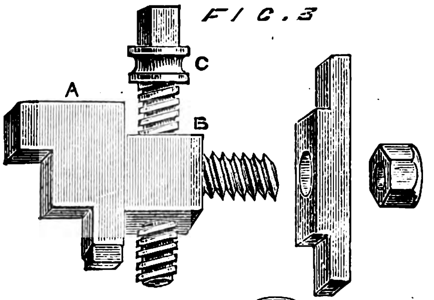

FIG. 4.

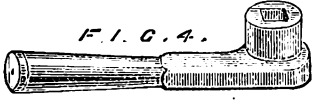

It is most convenient to have two spanners, for by fixing them on two opposite screws and turning them simultaneously in the same direction, one jaw moves towards the centre and the other from it, and so the work is carried, still held fast between the jaws across the centre of chuck, and by revolving it and holding a piece of chalk against the edge of work you can see when it is running true. If the work to be chucked is not circular, the best way is to make a dot with a centre punch at the point you wish to be the centre, and having fixed work between the jaws, bring up the back centre of your lathe to it, and move screws of chuck until the point of back centre drops into the centre punch-mark. I need hardly mention that the leading screws must be steel, as there is considerable strain on them. **F. W. G.**

CHANGING-BOX FOR USE WITH DRY PLATES.

[20054.]—The above sketches represent a form of changing-box, which is designed for use with ¼-plates. It consists of a box of ½-deal, of dimensions shown, dovetailed together (Fig. 1). A longitudinal partition is fixed in it at 3⅜in. from the front, and two cross partitions between it and the front, forming the boxes (*a*, *b*, and *c*), the two outer ones being thus of a size to hold ¼-plates. These boxes have sliding covers of ¼-mahogany grooved into the front of the longitudinal partition. A narrow strip of wood screwed on the top of each serves to move it; the long space *d* holds the camera and dark slides for travelling. The box shown was made to suit a small Lancaster's "Merveilleux." The box is covered in by a double cover, as shown by the dotted lines. The outer one consists of black twill, and the inner one of yellow twill. They are fastened together only at the ends of the sleeves. The latter are 6in. in diameter and 12in. long, with elastic bands for the wrists, and are sewn on at *e*. The cover is attached to the box, as shown in section (Fig. 2). A groove along front and ends of box, and lid ⅛ wide and ¼ deep. The cloth is laid in it, and a strip of wood glued and sprigged in above it; *a* is the cloth, *b* the fillet. The inner edge of box is chamfered off, as at *c*, to allow of the lid being closed. Fig. 3 shows the mode of packing the plates. The tape *t* is fastened to bottom of box, and led to and fro between batches of, say, four to six, plates, which can thus be lifted out. The box *a* is for fresh plates, and *c* for exposed ones. The space *b* may be fitted to hold developing measures, &c. A small turn-button keeps the lids from shifting about when filled with plates. The box may have either hooks in front or a lock at each end, and a handle in front to carry it by.

N.B.—The sleeves are omitted in sketch (Fig. 1) to save space. **S. G. Horton.**

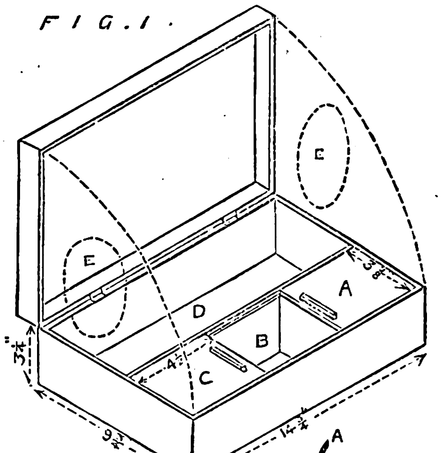

FIG. 3.

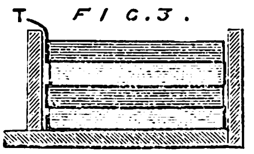

FIG. 2.

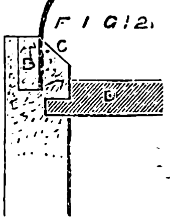


REFRIGERATION SIMPLIFIED.

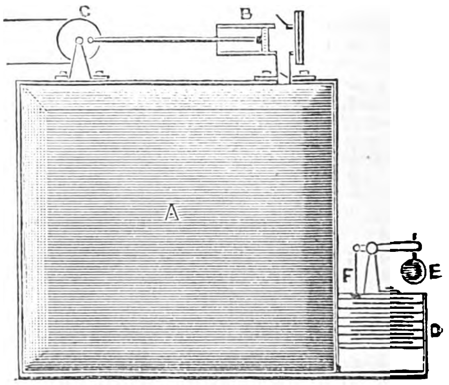
[20055.]—Many of us have, no doubt, read of the man who was dying of thirst close to a river, but unable to partake of it. In such case are the people of this country when they hear of millions of cattle killed abroad for the sake of their skins only, the meat being left for the vultures, while we are here paying famine prices for meat.

There is good reason to hope that with a simple, easy, and cheap process of refrigeration a remedy may be found which would break up the butchers' monopoly, and also avoid the host of common sense which is allowed to be patented.

This invention dispenses with the use of ice, chemical salts, ammonia, ether, compression, &c., which are troublesome, expensive, and in some cases require time for cooling, recrystallisation, &c.

The process here proposed is continuous, and avoids all the inconveniences above enumerated. To explain, when we ascend a mountain at a certain height, we find perpetual snow. This always corresponds with a certain reduction of pressure, or partial vacuum, which fact, taken as our guide, exhibits a principle which enables us to construct a simple refrigerating apparatus.

The figure is shown in section. A is the refrigerating chamber, connected at its top with the exhausting cylinder B, where the two valves may also be observed. The piston-rod is connected with a band wheel C, which is rotated by a band from some part of the steam-engine. At the right hand lower part will be seen the valve F (to which may be adjusted the weight E), so as to give way at an excess of vacuum. This opens inwards to the air-drying chamber D (if such chamber is found necessary), where the air will successively pass over a number of trays filled with chloride of calcium or other suitable deliquescent salt, and enter at the bottom part of the chamber.



A small cylinder only will be required, as after the vacuum equal to the reduced temperature as per thermometer is obtained, the air only requires removal to make up for heat penetrating the outer casing. Thus is the cooling process continually renewed.

Barry-road, S.E. **J. H. Huxley.**

IRON MOULDING—NO. IV.

[20056.]—Having got the thickness on all the blades, the face of each is coated with water-blacking, and some dry parting-sand shook over afterwards. The top part or cope of each blade is now required to be made. There are several ways of making the cope. The way in this case will be by casting two plates for each blade, 7in. in breadth and 1½in. in thickness; the length and shape of them will depend on the breadth and form of blade (see Fig. 1). Along the centre of plate there is a row of 2in. square holes, about 4in. apart. The one end of these plates lies on the top edge of bearing, and the other on the bottom edge; the end of each extends over the building on each side 6in. The round holes in the end are for the purpose of lifting the cope off or on, and also for making it fast to the bottom when casting. When the ends of the plates are resting on the bearing, that part of the plate that is over the blade should at the least be 1in. clear for loam. As these plates will have 7ft. in length of a cope to lift, one of them will be placed 20in. from the boss, and the other the same distance from the outside end of the blade, and the one parallel with the other. Cast-iron bars are made 1½in. square and 7ft. long. The bars are now inserted in the square holes in the outside plate, and passed on through the holes immediately opposite, and to within 2in. of the boss, the holes in the plates being larger than the bars, so as wedges can be driven in, and the one made fast to the other. To the end of the top and the bottom bars an angular piece of ½in. iron is made fast with wire, and kept clear of the joint that has been carried from the bottom (up to 4in. above the boss) of the outside of the blade opposite; from this angular piece of iron to the ends of the other bars more pieces are attached, so as to make it firm and secure. These irons are for supporting the building that covers this part of the outside of boss. A coat of red loam is now put over the face of mould, and over it some building loam, as it is less expensive, and answers quite as well. Building brick is now dipped in clay-water, and inserted in between the cast-iron bars, and pressed through the loam to within ¾in. of the face of mould. Some parts of the cope are more deep than others, and will require the brick to go endways. Where the blade joins the boss, the same care should be taken as in the bottom part—viz., put in loam brick, or keep the hard brick well back so as to allow the sharp edge to be rubbed round. When the cope is all bedded with brick, the joints, if any are open, are filled with loam, and the surface made level. Afterwards, a coat of clay-water is applied with a brush, which, when dried, makes it more firm and compact. The joint is pared and marked all round, so that when dried and finished, and about to be closed, the marks will guide it into the same place. The remaining blades go through the same process. All is covered now, excepting the top of the boss; what has been built stands 4in. higher than the boss, and serves as a guide for the top covering. It is slightly bevelled to allow the covering to be lifted easily off or on. A joint is made with paper in the same manner as the other joints; it is now filled with red loam, and a round plate bedded in with a round hole in the centre, large enough to admit one end of the core, that is afterwards put in the boss; on the one side of this plate there are projections (commonly called dabs), the length they require to be is 1in. less than the depth of loam. There are also four holes a little outside of the centre hole, and placed so as there shall be one over each end of the blades. These are for what is termed flow-gates. (When the mould is full of metal it rises up into the flow-gates, into which a small rod is inserted, and made to work up and down in the manner of a piston, so as to have communication with the boss, that fresh metal may be injected to supply the shrinkage that takes place while the metal in the mould is passing from the fluid to a solid state. The higher the flow-gates stand above the mould and kept full of metal, the more solid will be the casting.) The building of the mould is now completed; stakes are driven down each side of the base-plates to serve as guides. Two handles are on each side for the purpose of lifting them. When made fast to the crane and started from their bed, each one is slid back, so as in the hoisting the boss end of the blade will be free of the boss that is left standing; or if the moulder wishes, the top covering of the boss can be dried, or made stiff enough to lift off, and the building of the boss can be taken down (as it is now no longer required), and the base or building of each blade lifted straight up and put in the stove to dry. In any case the covering of the boss must come off first if the blades are to be dried in the stove or on the floor. When all is in the stove one piece remains on the floor; that is the bottom of the boss. It is dried where it sits.

Foundry.

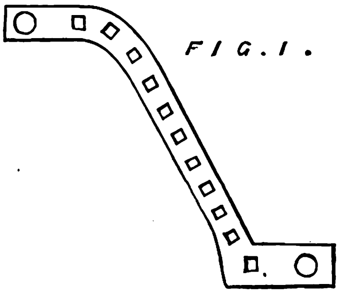


FIG. 1.

[20057.]—I HAVE read "Foundry's" letters. In No. 1 he says the spindle should be turned. Now, this is not necessary, and, as to the making of a cross or socket for the spindle to work in, my plan is to run up a core on the spindle, so that when it is cast in the cross it forms a recess: the spindle then has two bearings at top and bottom, it then works much steadier than bearing all the way (see Fig. 1).

I fail to see the use of the step shown on outside bearing in (Fig. 1, letter 2); all that is necessary is simply a flat bearing. I am proud to say, in my experience, Fig, 3 is a thing of the past. Wheel weight and right angle arm are all laid on one side for a more improved plan—that is to build the blades first, then build the boss, then fill in with loam brick. In some shops two blades are built at one time, and in some all four (see Fig. 2).

Cast Iron.

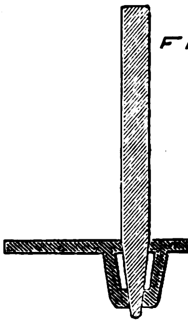

FIG. 1.

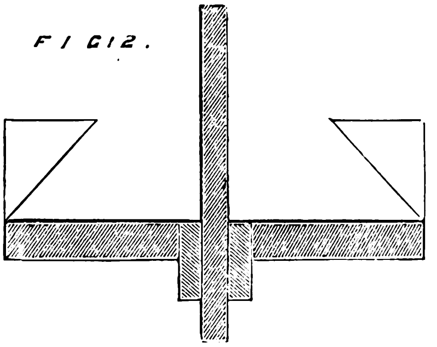

FIG. 2.

CHARLES DARWIN, AN EXAMPLE OF THE SCIENTIFIC METHOD — EYEPIECES — CASSEGRAIN TELESCOPE.

[20058.]—WITH every word of the first paragraph of letter 19991, p. 192, all students of science must agree, and I should like to add my word to the wail now being sent up by the whole world for the loss of the intellectual giant. It is yet too soon to calmly estimate the effect of Darwin's writings on science. My intention just now is to point out a characteristic peculiarity in those writings, and that is, his consistent search for *truth*. Nowhere do you find a fairer statement of each side, nowhere more logical conclusions, than in his writings. Those accustomed to debate, feel, after reading an ordinary book, scientific or otherwise, that there is another side to be read. Darwin's books never leave such an impression. One feels that it is useless to look elsewhere for adverse facts; the most that can be done is to disagree with the conclusions drawn from them. Recollecting this, we begin to understand how he has succeeded in changing the entire course of scientific thought in such a short time.

Echoing "F.R.A.S.'s" quotation, let me sorrowfully commend Darwin's works to all lovers of truth.

It is indeed remarkable that so much carelessness and inaccuracy should be exhibited by writers on astronomy when they speak of the principles of the construction of telescopes. Those "Ascalon" (letter 19992, p. 193) quotes seem fair samples; I don't know Guillemin's "Heavens," though, and it may be right. "Ascalon's" diagrams are quite right, but in the second one the focus is rather far from the field-lens, and in the first the rays should cross as near the field-lens as the diagram puts them to the eyelens.

The greater complexity of some diagrams mentioned by "Ascalon" arises from their representing a relatively large image. "Ascalon" will notice that his image is only a point, as if of a star; if, therefore, he was considering the result of looking at an object having a sensible diameter he would see that such object would be made up of innumerable points, from each of which a series of rays would pass through the telescope as "Ascalon" has drawn them, each series, however, holding a slightly different position. Suppose "Ascalon" to be looking at the moon. An image of the moon would be formed where the lines cross in his diagram, and every point on the moon's surface would send a series of lines through the telescope, and converging to corresponding points in the image. If only a few of the infinite number of series of rays are shown in a diagram it must necessarily be very complex. The apparent difference at first sight between a diagram representing one series, and another representing several series of rays, is a rock over which most self-taught students of optics stumble.

When powers are mentioned in a letter they always mean the actual magnification, the focal length of the o.g., as well as the equivalent focal length of the eyepiece, being, of course, taken into consideration.

The rule given in letter 19971, p. 172, for finding the distance between mirrors in Cassegrain telescope is the simplest and best I have seen, and was given by "A. N. H." (letter 18685, p. 209, Vol. XXXIII.)

Paugul.

A PORTABLE BEDSTEAD TABLE.

[20059.]—ENJOYING the luxury of quietness, and having but few rooms in my house, I contrived to turn one of my bedrooms into a study. I got a carpenter to make a table to perform the double duty of study table by day, and bedstead by night. The following is the arrangement:—Length, 6ft.; width, 3ft. The top of the table is made in the usual style of library tables, with American leather centre, and polished-wood border, with "thumb" moulding. The legs are turned in the usual way—in fact, externally it differs not from an ordinary table. To get your bedstead the top is made to lift off. The sides are made deep enough to screw on their inner lower edge bearers 1½in. wide, which support laths, on which rest the mattress and bedding. While at your breakfast, the servant throws open the windows, makes your bed, puts on the table-top, which shuts all in as in a box. The whole thing is portable, as the legs unscrew with the usual bedscrews; the holes for these are covered with shifting ornamented panels made to fit over, or turned knobs fitting in the holes.

Beta.

METEOROLOGICAL.

[20060.]—THE simple barometer of Dr. Hay (letter 20024) is not a new device, but, as a mere "weather-glass," it is far better than the mercurial barometer itself. The appearance of the drop, depending as it does upon the atmospheric pressure and its humidity together, must be as certain an indication of rain as we can have. A combination of the barometer and hygrometer to indicate the approach of rain was devised by Herr Klinkerfues, of Gottingen, some time ago, and briefly described in these columns (Vol. XXXIV., p. 278).

By some mistake a magnetic storm (Vol. XXXV., p. 215) has happened prematurely. The sun-spots have not mustered in sufficient numbers yet to account for such a phenomenon.

The Australian drought, too, is altogether out of season, for this ought to have been a wet year by rights. The *Scientific American* says that Australia is a land of contradiction, this drought having occurred to confute "the 19 years' cycle theory." Can this be yet another cycle? Let us hope it is a misprint.

An enterprising investigator has compared the statistics of rainfall and the fire insurance returns, and has been rewarded by the discovery of a remarkable connection. He has demonstrated the well-nigh incredible fact that fires are more numerous in dry than in wet weather! But, strangely enough, he has omitted to take the next step, and prove that fires are most prevalent when sunspots are few.

LEGAL REPLIES.

[20061.]—WILLS AND TRUSTEES (46860.)—I know of no way by which any officer of the Court of Chancery can be appointed trustee of a will. If the querist chooses to invest a sum of money over £20 in the name of each of his children, he can make them wards of Chancery by taking the proper proceedings, and then the Court of Chancery would look after their property upon his death. He might also appoint one of his children, or some other person, executor of his will, with a direction that the assets should be administered by means of a suit in Chancery. But undoubtedly either of these modes would be very costly and wasteful of his little property, and he should find some suitable trustee and leave a careful will.

AUCTIONEERS' RESPONSIBILITIES (46868).—In this case, if the broken part of the article injured can be mended, and so the whole restored, it is clear that the price of this part only is the legal measure of damage. In refusing to fetch the article away, and in claiming the full value of the whole, two mistakes were made. The proper course to adopt in this case is to have the article repaired and sue the auctioneer for the amount paid for so doing; while as to warehouse room, seeing that the auctioneer was presumably to blame at the beginning, I do not think any judge would allow him to charge for warehouse room under the circumstances.

Deeds (46918).—The deeds go with the law is the rule at law. I presume that when A. paid off the mortgage he took a re-conveyance or assignment from B., so that he obtained the legal title. With this he should have had the deeds, for he then had a clear right to their possession. It is nonsense to say that the last deed is the only one A. needs, as he would soon find if he tried to sell the property. A.'s proper course is to write formally demanding these deeds of B., and if they are not handed over, he should bring an action against B. for their unlawful detention.

THE "ENGLISH MECHANIC" AMATEUR PHOTOGRAPHERS' SOCIETY.

[20062.]—It is proposed to found a Society, to be called "The English Mechanic Amateur Photographic Society," on the same plan as the Microscopical Society, a project for the starting of which appeared a short time ago in these columns. The following paragraphs state the objects and contain some of the proposed rules of the Society, subject, however, to the consideration of the members, and any alteration or modification if necessary:—

1. That the purpose of the Society be for the circulation of prints, negatives, &c., &c., and for the advancement of the science and art of photography amongst its members, each of whom will be requested to send in one print of each ¼ or ½-plate he may take for insertion in a scrap-book, together with a few brief notes respecting its reproduction, kind of plate used, lens, exposure, light, locality, &c., &c.
2. That a note-book be published with each scrap-book, in which members may jot down any useful hints or information, interesting experiences, &c., &c., which may, if suitable, be compiled and published, each member receiving a copy.
3. That, for the benefit of beginners, bad prints, as well as good ones, be circulated, together with notes on them.
4. The country to be divided into districts, through each of which one scrap-book shall be circulated at a time, when, having gone the round of members in that circuit, it shall proceed to the next.
5. That a certain period be determined upon for each member to detain scrap and note-books (say two or three days, as decided upon), when they are to be forwarded to the next name on the list circulated with the said books.
6. That a committee be annually appointed, who shall have the management of affairs.
7. That every member pay an entrance fee of 2s. 6d., and an annual subscription of 5s., payable in advance.
8. That if the Society flourish numerically and financially, and it be found advisable, a magazine be published at convenient intervals.

The undersigned will be glad to receive the names and addresses of persons desirous of helping to form such a society, and giving any practical suggestion, &c., &c.

Stoke-on-Trent.

PROPELLERS.

[20063.]—I read letter 20008 by "Milford," on propellers, with interest, as it coincides so closely with one I made that to all appearance worked well, but I could not afford to try it on a larger scale. It was two vertical shafts at each end of the boat through the bottom, a crank at both ends of each; the inside ones were driven by a small engine. Attached to the outside cranks was a framework working to touch the bottom of the boat, hinged to which were twelve floats, concave shape, about 16in. wide by 9in. deep, set at a slight angle towards the stem, hinged so that at the forward stroke they all laid to the bottom of the boat; at the back stroke they stood out. The shock they gave to the boat every time they took the water was fearful, and again the forward stroke went like a shot out of a gun.

The floats in the position I describe gave very little slip in my case—too little; they fairly lifted the boat forward the full stroke; but they were out of all proportion to the boat. It went at an immense speed—I should think almost the speed of the travel of the engine; but it shook the whole affair to wreck in a very short time. **Mc.**

COAL-TAR PRODUCTS.

(*Continued from page* 61.)

[20064.]—These fractionnaters will be found useful to those who wish to value commercially samples of crude naphtha and light oils. In the case of once-run naphthas, the percentage of commercial benzols and toluols can generally be obtained by taking, say, 400cc. of the once-run naphtha and distilling in large ordinary retort; the portion of distillate which distils over up to a temp. of 140° C. will contain most of the benzol and toluol present: thus, 400cc. of 45 per cent. once run distilled in ordinary retort yielded 280cc. distillate at the temp. of 140° C. This 280cc. distillate was transferred to flask connected with fractionnater and distilled to a temp. of 100° C., it was found that 148cc. had distilled over. On testing, this proved to be 90 per cent. commercial benzol. The portion of distillate following this up to the temp. of 120° C measured 72cc., and on testing showed boiling point 107° C., and yielded 90 per cent. at 120° C., that is, it was commercial toluol. The estimation of the solvent naphtha can be made by fractionnating the heavy portion left in retort after first distillation. It should, however, have been mentioned that the once-run naphtha requires to be rectified or washed with sulphuric acid, as stated in a former article, before estimation is proceeded with. The sample of once-run naphtha thus tested yielded, calculated on 100 gallons—

37	gallons of	90 per cent. benzol
18	,,	90 ,, toluol
31	,,	Solvent naphtha
2	,,	Heavy burning naphtha
12	,,	Loss
100		

In order to arrive at the commercial value of the once-run tested, it will be necessary to calculate the value of the finished products at the current prices, and from the total result to deduct discount, cost of freight, working, materials used, &c. These vary in different works.

To estimate the value of a sample of light oil, it is necessary to first estimate the crude carbolic acid present by washing with about one-third the volume of a solution of caustic soda, sp. gr. 1·070, or 14 Tw., neutralising the resulting carbolate of soda, collecting the carbolic acid, and testing by methods to be afterwards described. The light oil, after extraction of carbolic acid, is distilled in large retort up to a temp. of say 200° C.

The portion of distillate up to this temp. is then redistilled and fractionnated in a similar method to that adopted in the case of once-run.

A sample of light oil testing:—

Sp. Gr.	B.-P.	160° C.	170° C.	180° C.	190° C.
980	138 C.	8	16	31	42
					200 C.
					62 per cent.

yielded, on fractionnating, per 100 gals.:—

3	gallons	50 per cent. benzol.
4	,,	90 ,, toluol.
16	,,	solvent naphtha.
30	,,	burning naphtha (sp. gr. ·970).
8	,,	crude carbolic acid.
26	,,	creasote or dead oils.
13	,,	loss.
100		

Benzol, benzene, or phenylic hydride C_6H_6, when pure, has a boiling-point of 80·5° C. Dr. Hoffman first pointed out the existence of this compound in coal-tar in 1845. But to Mansfield we owe its commercial production. Since 1847, the yearly production of benzol kept increasing; but it was not till the introduction of the aniline colours into commerce that the benzol trade assumed any magnitude. The present annual production of benzols in Great Britain is probably over 2 million gallons, worth about half a million pounds sterling.

For the methods of producing nitro-compounds, aniline oils, and the aniline colours I must refer the reader to works on organic chemistry—the last edition of Miller's, Roscoe and Schorlemmer's, Richardson's and Watts's "Dictionary of Chemistry," and numerous other works. A large amount of information on fractionnal distillation is also given in the *Journals* of the Chemical Society for 1879.

Carbolic acid, or phenol C_6H_5Ho, discovered by Runge; sp. gr., 1·065; B.P., 370° F., or 187·7° C. Absolutely pure phenol, first prepared by Mr. Chas. Lowe, crystallises at 104° F., or 40° C. It is a powerful caustic, heated in closed vessels, under pressure, with ammonia. Phenol is transformed into aniline. It is extensively used for medicinal purposes, and in a cruder form as a disinfectant. But the greater portion of the carbolic acid produced is used in the manufacture of aurine and picric or carbazotic acid. Salicylic acid is obtained from phenol, by dissolving phenol in caustic soda, evaporating down, and heating the residue in a current of carbon-dioxide.

Crude carbolic acid is obtained from that portion of the distillate from coal-tar, which has a sp. gr. of from ·920 to 1·000, and also from the lighter or first portions of the creosote oils. The oils are agitated for one or two hours with about one-third their bulk of a solution of sodic hydrate (caustic soda), the sp. gr. of which in different works varies from 14 to 20° Twaddell or 1·070 to 1·100. After agitation, the soda solution containing sodic carbolate, which on account of its density forms the lowest stratum of liquid, is run off into lead-lined tanks, where it is neutralised with sulphuric acid, when the crude carbolic acid rises to the surface of the resulting sulphate of soda solution, as a brown oily liquid with a sp. gr. of about 1·060, and containing from 14 to 16 per cent. water. It is, after separation from the sulphate of soda solution run into store tanks in order that any sulphate of soda solution which may be mechanically retained by the crude acid may separate. The carbolic acid is sold in this crude state to the manufacturers of crystallised carbolic acid. There are at present two methods of commercially testing this crude acid—viz., the bottle test and Lowe's test, the latter being the most general. The bottle test consists in taking 10 fluid oz. (ounces) of the crude carbolic acid and distilling in glass retort; after the whole of the water present has distilled off, and the oil, which has passed over along with water, and formed a layer beneath the water in receiver, shows 7½ per cent. on the 10oz. taken, the carbolic acid which is now distilling over is collected in bottles measuring exactly half an ounce. The portions of distillates in these bottles are then tested for crystallising point, a crystal of carbolic acid being introduced to facilitate crystallisation. According to the number of bottles which have a crystallising point of 60° F., or over, the acid is valued; thus a sample of crude carbolic acid yielding seven bottles crystalling over 60° F., and the eighth bottle crystalling at 60° F., would be called eight-bottle acid. Ordinary crude carbolic acid of commerce tests from six to twelve bottles, and should not contain more than 14 or 15 per cent. water.

Lowe's test was introduced by Messrs. Charles Lowe and Co., and is as follows:—Take 1,000 grams of the crude carbolic acid and distil in 6oz. retort; a 1,000 gram burette is placed as receiver; after the water present has distilled off and 10 per cent. oil along with it, the receiver is changed, and the distillate collected in a clean dry burette till it measures 625 grams: this 625 grams is thoroughly agitated, and a small portion placed in a test tube and tested for crystallising point, by inserting a thermometer in the liquid, and noting the point at which it crystallises. In order to facilitate the crystallisation, a crystal of carbolic acid is introduced into the acid to be tested. Whilst the acid in the test-tube is cooling, it must be kept continually in motion by moving the bulb of the thermometer briskly round the interior of the tube. Enough acid should be taken to cover the bulb of thermometer to depth of ½in. Should the test-tube require to be inserted in a cooling mixture, as is usually the case in hot weather, care must be taken that the cooling does not proceed too rapidly, and the acid must be, as before mentioned, continually agitated by the thermometer, otherwise the crystallising point may appear to be a little higher than it really is. The thermometer used should be graduated to half or quarter of a degree Fahrenheit. The usual crystallising points of commercial crude carbolic acid, tested by this method, range from 55° Fahr. to 70° Fahr. The temperature at commencement is 212° Fahr. When the water has distilled off, the temperature varies from 360° Fahr. to 370° Fahr.; the temperature at end of distillation being from 375° Fahr. to 390° Fahr.

The purified crystalline acid of commerce is obtained from the crude carbolic acid by several distillations and crystallisations of the various fractions of distillate from the crude acid—the crystalline acid being distilled with one or two per cent. of sulphuric acid, for the purpose of rectifying or decolourising.

Patents have recently been granted for improvements in the method of obtaining the crude carbolic acid; the improvement consisting in using carbonic or sulphurous acid gas for neutralising the carbolate of soda solution, instead of sulphuric acid, as now used. Should these improvements become adopted, the cost of production of crude carbolic acid should be materially decreased, since the by-products obtained would be carbonate or sulphite of soda, instead of, as at present, the almost valueless sulphate of soda.

Naphthalene ($C_{10}H_8$) is present in large quantities in the distillate from coal-tar, having a density of from 1·000 to 1·040. If the oils having this density be exposed to cold in shallow pans for a few days, naphthalene will crystallise out. The fluid oil is drained off, and the naphthalene submitted to pressure in hydraulic press, in order to to remove all adhering oil. The pressed naphthalene is now placed in a vessel and melted by means of a steam coil. When the whole mass has been rendered fluid, it is agitated with 5 to 10 per cent. by weight of sulphuric acid, sp. gr. 1·850 or 170 Twaddel. After agitation, the waste sulphuric acid is run off, and the naphthalene washed twice with hot water, and finally with water slightly alkaline. The washed naphthalene is transferred to a still and distilled, and the portion of distillate collected, which distils over between 212° and 214° C. Care must be taken that the still-pipe leading to condenser be kept hot, and the water in condenser kept boiling, in order that the pipes may not be blocked with solid naphthalene.

Good commercial naphthalene should not become discoloured on exposure to the rays of the sun for two or three weeks, and on distillation the boiling-point should not vary by more than one degree Centigrade from commencement to finish of distillation.

The demand for naphthalene is so limited in comparison with the enormous quantities of naphthalene present in coal-tar oils, that it is a matter of importance to many tar-distillers how to get rid of their crude naphthalene. In consequence of this limited demand, pure naphthalene may be obtained in any quantity at the low price of £10 per ton. It is so easily obtained in a state of purity that it is rarely, if ever, adulterated.

Anthracene was first obtained from the last fractions of the distillation of coal-tar by Dumas and Laurent in 1832. They, on analysis, gave it the formula of $C_{15}H_{12}$, and as this is half as much again as naphthalene $C_{10}H_8$, they named the new substance para-naphthalene; but this chemical composition and the low melting-point, 180° C., prove that they did not obtain anthracene in a state of purity. Fritsche described in 1857 a compound obtained from coal-tar which had a melting-point of 210° to 212° C., and formula $C_{14}H_{10}$.

Anderson, in 1862, confirmed these results. In 1866 Limprecht obtained it by heating chloride of benzol with water in sealed tubes at 180° C.

He also showed that toluol alone, a mixture of styrol and benzol, or of benzol and ethylene, passed through a red-hot tube, furnished anthracene.

In 1868 two German chemists, Graebe and Liebermann, engaged in investigating the class of bodies known as quinones, succeeded in obtaining anthracene from alizarine. Having obtained anthracene from alizarine, which is the principal colouring-matter contained in madder root, they attempted to convert anthracene into alizarine. This they succeeded in doing, and thus for the first time a vegetable colouring-matter was artificially produced. The tar-distillers at once set to work to produce anthracene on a large scale. The Germans, as usual in all matters relating to organic chemistry, were the first in the field. Several works were erected in Germany and one in England for the manufacture of alizarine from anthracene.

Thus anthracene, which previously had been sold in a crude state as a rough lubricant, suddenly became an article of great commercial value. In the year 1867, a few months before the discovery of Graebe and Liebermann, Dr. Letheby, in a lecture he delivered on Coal-Tar Compounds, said, speaking of that portion of coal-tar distillate which contained anthracene, "The greasy matter or green oil, which follows the dead oil in the distillation of coal-tar, is used for making railway grease, with resin, oil, &c."

Anthracene is obtained from that portion of the distillate from coal tar which has a density of from 1·060 to 1·110, or 12 to 22° Twaddell. This portion of the distillate is allowed to stand in cooling pans for several days, when the anthracene crystallises out. The oil containing the crystals is filtered through long cylindrical bags, suspended from a frame, or through filter press; the crystals being retained in the bags or filter press in the form of a yellowish-green paste. The paste is now placed in strong canvas bags and submitted to pressure in hydraulic press. The clear oil which filters from the crystals is reserved for further distillations. The anthracene paste, after pressing for several hours, is obtained in the form of a hard cake containing about 30 per cent. anthracene. After being disintegrated or reduced to powder, it is sold to the alizarine manufacturers. Some tar-distillers increase the percentage of their crude anthracene to 50 per cent. by washing with light oil or naphtha, and refiltering and pressing.

The quantity of anthracene obtained from coal-tar is very small; in fact, a yield of 7lb. of pure anthracene from 2240lb., or one ton of tar, is considered a fair yield. This equals about 0·31 per cent. on the tar. Thus, to obtain one ton of pure anthracene you must distil about 400 tons of tar, which equals about 4,000 tons of coal. Yet, although the quantity of anthracene obtained from coal-tar is so small, it is now made in such quantities that the madder-root has been practically driven from the market this last few years. Prof. Roscoe estimated that in the year 1880 there were produced 1,400 tons of pure alizarine.

Anthracene Testing and Valuing.—When anthracene became an article of commerce, it was necessary that some method of testing should be devised by which its value could be approximately ascertained. The first method introduced by Dr. Gessert, and known as the alcohol test, was based on the insolubility of anthracene in alcohol, the melting-point of the anthracene insoluble in alcohol being also taken. Following this method came the bisulphide of carbon test and Perkin's test, in which both petroleum spirit and bisulphide of carbon were used to dissolve the impurities found in crude anthracene. The percentage of anthracene by each of the above methods being determined by the quantity of hydrocarbons insoluble in a certain measured quantity of the solvents, the results obtained by these methods were very unsatisfactory. In 1873, Mr. Luck, a chemist at Meister, Lucius, and Brüning's, published a method which, in a modified form, is now universally adopted. It is known as the "Anthraquinone test."

"Take one gram of the crude anthracene, place it in a flask of 300cc. capacity, fitted with upright condenser; add to the one gram anthracene 45cc. of glacial acetic acid, and heat to ebullition. To this solution, which is kept boiling, add, drop by drop, a solution of 15 grams of cromic acid in 5cc. of water and 5cc. of glacial acetic acid. The addition of the chromic acid solution should occupy about two hours, the solution being allowed to drop down the condenser tube by means of tubulated and stoppered funnel. After the whole of the chromic acid solution has been added, the contents of the flask to be kept boiling for two hours to complete oxidation. The flask is then allowed to cool for several hours, and the contents afterwards made up to 200cc. with water.

The precipitated anthraquinone is now collected on a filter and washed—first with pure water, then with a boiling solution of sodic hydrate containing 1 per cent. of alkali; and again with hot water: the anthraquinone is now washed from filter into small dish, a little sodic hydrate solution (1 per cent.) added, the contents raised to boiling-point, and one or two drops of permanganate of potash solution added, and the boiling continued for five minutes; if the permanganate becomes decolorised, a few drops more must be added till there is no further decolorisation on boiling. To the solution, after cooling, is added a slight excess of dilute sulphuric acid, and a few crystals of oxalic acid; the whole is now filtered, washed with warm water, then with 1 per cent. alkaline solution, then with warm water, and the filter paper and anthraquinone transferred to water bath for drying. When dry, the filter and contents are weighed, the anthraquine brushed off filter paper by means of a fine brush, and filter paper reweighed, thus the weight of the anthraquinone is arrived at. In order to correct for the slight loss due to the solubility of anthraquinone in dilute acetic acid, ·010 is added to the anthraquinone found. In order to estimate the percentage of anthracene, the weight of the anthraquinone is multiplied by 0·856, and then by 100; thus anthraquinone weight is 0·351

correction 0 010

0 361

·361 × ·856 × 100 = 30·9 per cent. of anthracene present in the sample.

Chemistiana.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[46378.]—**Bevil-Wheels.**—I should prefer the larger pair of wheels.—Glatton.

[46396.]—**Terrestrial Eyepieces.** — "Aldebaran" now says (p. 198)—"the emergent rays cross immediately in front of B." Without stopping to inquire what meaning the word "emergent" can possibly have in this sentence, we are surely entitled to ask why "Aldebaran" did not show them crossed in his diagram? It is clear enough to me that "Aldebaran" is troubled by diagrams that show an image of a large object. On this matter he may perhaps find my letter in present issue. It is only necessary to know the very rudiments of optics to be able to calculate exactly where images are formed, and the amount of convergence or divergence. Surely "Aldebaran" can do this. If the rays (of each series) are not divergent between B and C, how is it that the power is increased by further separating the eyepiece from the erector? With regard to the diaphragm, I thought the merest indication would have sufficed to point out the absurdity. The diaphragm must be in the focus where it can best be seen; the image has to be viewed by the help of the same lens, and therefore must be in its focus. Hence the diaphragm and the image must occupy the same part of the tube. Is that clear enough.—Paugul.

[46467.]—**Rheocord.**—A line drawn by a lead-pencil has been used as a resistance in a voltaic circuit. I do not know what the resistance would be, but it must be immense.—Glatton.

[46503.]—**Jamming of Tapered Journals.**—Many thanks, "J. J. A.," for your reply; but it is still short of my requirements. As I stated on p. 178, I merely instanced a lathe-mandrel for convenience of reference. I want a general rule, which would be equally applicable to the pivot at bottom of a turbine-shaft or to a friction-clutch, for example. I did not give the weight tending to force the cone into its matrix, as I conceive that, if it means to jam, it will do so with almost any force; whereas, on the contrary, if the angle (whether A B C or A B D in diagram, p. 91, is the angle is the question I want solving) exceeds by ever so little the angle of repose, no amount of pressure can make it jam. It would doubtless be more correct to speak of the angle of repose as the "angle of friction," in the case of a swiftly revolving mandrel. Of course "J. J. A." understands what the angle of repose means, and is only poking fun at me when he says, "I don't know, &c."—Glatton.

[46525.]—**Botanical.**—If "Robur" wants the flowers for the herbarium, he should dry them before a hot stove, pressing them between newspapers loaded by a weight. The fire must be sufficiently strong to rid the flowers and leaves completely of their moisture. He should not be in the least hurry, but let the plants dry entirely; and should keep the pressed flowers in a dry place. I have seen flowers which were treated in this way, and had not lost their colour after nine years; but the dampness prevailing in England is very disadvantageous for any such collection. For microscopical purposes, I should advise "Robur" to use Farrant's solution for small specimens. In this case he should press the flower together with the covering glass in a spring press. This solution is best made by dissolving four parts (by weight) of picked gum-arabic in four parts of cold, distilled water, and then adding two parts of glycerine. The solution must be made without any heat, the mixture being occasionally stirred, but not shaken. It must be used cold, and soon viscifies without cracking. As other preservative media, I should advise the use of aqueous solution of carbolic acid, or a mixture of one part of glycerine and two parts of camphor water; or, finally, a mixture of three parts of pure alcohol, two parts of distilled water, and one part of glycerine. The last mixture can only be used as a preservative medium for minute preparations; and a cement cell should be used, taking care that the alcohol and water evaporate before the cell is closed (which is done in the ordinary manner).—A Medical Student.

[46528.]—**M.R. Engines.** — The M.R. Co. possess 30 bogie engines; ten are 6ft. 6in. coupled, and the remainder 7ft. coupled. Full dimensions will be found in back vols. The latter class were built by Dübs in 1877. Later on in the year ten passenger engines were built at Derby with a single pair of leading-wheels. These engines, numbered 1347-1356, were in other respects similar to the bogie engines, with cylinders 18 by 26. These engines ran trials with the bogie engines, and the result showed that both classes did their work excellently, and that the single leading-wheels worked as well as the bogie. The result is that no more bogie engines have been built. 1400-1409, 1472-1491 (M.R. Co. 1879-81) have driving-wheels 6ft. 8in., and cylinders 18 by 28. 1492-1501 have 7ft. wheels, and were built by the company in 1881. They belong to exactly the same class as 1347-1356 (which I forgot to state were renumbered 101-110). The last class of passenger engines are 1502-1531 ("Neilson," 1881), driving-wheels, 6ft. 9in.; cylinders, 18 by 28. 111-115, built by the Co. (1880) have driving-wheels 6ft. 6in. There are 30 passenger engines ordered now, I believe, from Kitson and Co.—Meteor.

[46531.]—**Yacht's Deck.**—Not until too late for last week's insertion did I notice "W. R.'s (Liverpool)" reply to this query. I do not think "W. R." is sufficiently explicit in his advice, and if "J. J. A." follows it, ten to one his deck will be nothing better than a riddle to let the water through, for he gives no instructions as to how the seams are to be made watertight. And let us note, the more seams there are the more room for leaks. When I penned my reply to this query, I thought that "J. J. A.," having this yacht, and, like most of us, not overstocked with spare cash, proposed to do all he could towards putting on his deck himself. If that is the case, I say the less seams he has the better for keeping deck watertight; and if he, as I suggested, gets a journeyman shipwright, or an elder apprentice, to give him a hint or two on the spot, it will be the best for him. Another thing makes me think my suggestion is the best for "J. J. A." is, if he had the capital to have a deck put in at a yacht builder's on the finest lines, he would not be asking queries in "ours."—Working Tom.

[46549.]—**Science Questions.**—I should propose the following method:—Since CO_2 and HCl are soluble in KHO, let the whole mixture pass through a tube containing KHO, which, as well as the mixture, has been weighed before the test. Then the weight gained by KHO tells us the quantity of CO_2 and HCl as a whole. Now estimate the quantity of Cl contained in the solution of the KHO, and hence calculate the quantity of HCl. Having found this, we can easily find the quantity of CO_2. This is, of course, equal to the difference between the weight gained by the KHO and the weight of HCl. The other constituents, being insoluble in KHO, can be treated separately, in the following manner. Introduce a certain quantity of O, and explode. Then H_2O and CO_2 is formed. From the quantity of water we can readily calculate H. Without difficulty CO_2 can be got now, and hence CO. Thus only O and N is left. Subtracting the quantity of O introduced from the quantities left by the water and the dioxide, and the quantity present in the free state (which can be found by means of copper or potassic pyrogallate), the original quantity of O is obtained. In this way we have found all constituents but N. In order to get this last quantity, subtract the obtained quantities from the original quantity of our mixture. The difference gives us the quantity of N. (2) 100 parts of $CaCO_3$ yield 44 parts of CO_2.

$$\therefore\ 1 \text{ part of } CaCO_3 \text{ yields } \frac{44}{100} \text{ part of } CO_2.$$

100 parts of $SrCO_3$ yield 29·847 parts of CO_2.

$$\therefore\ 1 \text{ part of } SrCO_3 \text{ yields } \frac{29\cdot847}{100} \text{ part of } CO_2.$$

But $(1\cdot3332 - x)\ CaCO_3 + x Sr$ yield 0·5104 CO_2.

$$\therefore \left(\frac{1\cdot3332 - x}{100}\right) 44 + \frac{29\cdot847}{100} x = 0\cdot5104.$$

$$\text{Or}\quad (1\cdot3332 - x)\ 44 + 29\cdot847\, x = 51\cdot04.$$

$$\therefore\ 14\cdot153\, x = 7\cdot6208.$$

$$\text{And hence, } x = 0\cdot538.$$

Therefore, under the above conditions, 1·3332 grain of the mixture contain 0·538 $SrCO_3$. But since 147·05 parts of $SrCO_3$ contain 87·2 parts of Sr, 0·538 part of $SrCO_3$ contain 0·319 part of Sr. Thus we get—

$$1\cdot3332 : 0\cdot319 :: 100 : x.$$

$$\text{Or, } 31\cdot9 = 1\cdot3332\, x.$$

$$\therefore\quad x = 23\cdot9.$$

Therefore, the percentage of Sr is about 23·9.—A Medical Student.

[46568.]—**Revolving Gas-Burners.**—These act on the principle of Barker's mill—the jets issuing in one direction to the side. The portion carrying the jets is either a simple sheath to the gas-tube or revolves on a needle point.—T. P.

[46577.]—**Telegraphy.**—The querist should refer to your XXXth volume, wherein he will find Mr. Preece's lectures "On Telegraphy"; and on pp. 397, 425, I think the duplex and quadruplex are explained. The lectures are published in a collected form by the Society of Arts at 2s.—E. G. M.

[46639.]—**Power of Water-wheel.**—To E. Morgan.—In calculating motive power there are three quantities to take into consideration—namely, time, distance, and weight. See answer to query 46410 to find velocity of discharge from pipe. A 4in. pipe, 100ft. long, with 15ft. of fall, will give 29 cubic feet per minute, taking water at its greatest density: there are 62·5lb. per cubic foot. Multiply 62·5 by 29 = 1812·5lb. flowing per minute. We have now got two of the quantities, time and weight. Then the fall or distance, 12ft. × 1812·5 = 21,750 foot-pounds. As 33,000lb. raised one foot high per minute is one horse-power, then 21,750 ÷ 33,000 = ·66, nearly. This is the theoretical horse-power. The effective power is one-third less. ·66 × 2 = 132 ÷ 3 = ·44, nearly half horse-power.—W. H. S.

[46660.]—**Sutton's Secondary Battery.**—In reply to Mr. J. Hezmalhalch, jun., when I said that I had indiarubber between top and bottom of the plates to prevent contact, I meant what I said. I have simply two pieces of indiarubber pipe fixed on to the copper plate, one at the top and one at the bottom. Everything is done according to the description given in "ours" some weeks back, and the cell was charged until all the copper was deposited, and the solution left clear and almost colourless. This could not have been the case if I had entirely covered the plates with indiarubber, as suggested by our friend.—W. Stutchbury.

[46704.]—**Blake Transmitter.**—I am extremely obliged to those gentlemen who have answered my query. I have not got the "E. M." referred to by "J. P. M."; would he, therefore, as he offers, kindly lend me the one he has? I will take great care of it. The sketch sent by "Yoshi" has enlightened me a great deal. Will he please state (1) What is the use of the hole in the centre of bar F (in the Fig.), by which the microphone is adjusted? (2) Does the spring, tipped with platinum, touch the diaphragm and the carbon, or only the carbon.—John H. Rider, 48, Southville, Bedminster, Bristol.

[46712.]—**Yacht.**—"Minim" would probably find a boat made of canvas, stretched tightly over a light frame work, the best to answer his requirements. Such boats, called "Curraghs," are used by fishermen on the west coast of Ireland, and are extremely light, one that will carry three men, and as many hundredweight of fish, being easily carried by one man, bottom upward upon his head. A boat 12ft. long, 3ft. or 3½ft. beam, and 18in. deep, would carry "Minim" and a friend upon a draught of about 5in., and would weigh about 60lb. Ballast would be as difficult to carry about as a heavy boat; but two light cylinders of tin-plate fitted to the bilge on each side, and filled with water before sailing, would do equally well. A canvas boat, with a deep false keel, which must be added after the boat is finished, oiled, painted and varnished, will sail very well, even on a wind, and a single paddle dextrously used by a person sitting as far aft as possible, will propel her in a straight course if becalmed away from land. A bamboo mast, about 10ft. high, and a standing lug-sail, with a lighter bamboo for a yard, and a lighter still for a boom, would be the handiest rigs. If "Minim" will send me his address, I will forward him full directions, with sketches to scale, of boat and fittings.—Robinson Crusoe.

[46713.]—**Bleaching Clothes.**—Make a weak solution of chloride of lime, and steep the clothes in it over night; then wash well in clean water, and dip the articles into water made only sour with vitriol; then a final wash, using soap. Your things ought then to be white as new.—John Brown.

[46734.]—**M. R. Engines.**—"Meteor" asks for the number of the Midland engine sent by Fairbairn and Co. to the 1862 Exhibition. It was No. 479. The 270 to 279 class were built by Thompson, Kitson, and Hewittson, of Leeds, 1852; the 280 to 289 class were built by Stephenson and Co., 1853. Both these classes have all been rebuilt or replaced. The present 480 class were built by Stephenson, 1856 and 1857. These numbers were then 381 to 385, and 400 to 404. These old engines have been rebuilt and placed in the 480 class; the old 480 engines have been rebuilt, and now are 480A. These numbers will be changed shortly, as they will be put in the place of 10 worn-out engines.—A Driver.

[46735.]—**Eames' Locomotive.**—Errata.—Line 26, 2nd column, p. 202, should read: The boiler is fed by two injectors, pumps *not* being used; and in line 26, "smokebox" ought to be firebox.—E. W.

[46739.]—**Nitro-Glucose.**—I have experimented according to Mr. Robinson's instructions, on p. 205, and have totally failed. I placed the vessel with the acids in a stream of water to keep cool; but when I added the ground sugar, after a short time, it boiled up and threw off dense brown fumes. Will W. Robinson, or any of the chemical readers of the Mechanic, give me further particulars?—G. Thomas.

[46745.]—**Stopping Teeth.**—To "W. B. A."—Does carbolic acid simply drug the nerve or destroy it? What would destroy it? I have some decayed teeth that make themselves particularly "offending" during this part of the year. A "tiny crystal"—can it be obtained other than in a liquid state?—John Alex. Ollard, F.R.M.S., Enfield.

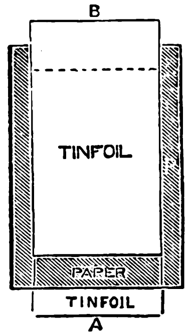
[46765.]—**Periosteal Rheumatism.**—To "R. A. V."—Observe temperance in eating and drinking, and take only plainly-cooked and nutritious foods. If you take intoxicating drinks, limit yourself to one pint of good sound ale per diem. If you smoke, continue the habit. Pay attention to state of your bowels, keeping them regularly moved. Obtain a small quantity of colchicum wine (½oz.) from some first-class chemist in your town, and take fifteen drops in water three times per day. I should like to know if you get relieved. For a purge, when wanted, take ½oz. of sulphate of magnesia, or, as it is called commonly, Epsom salts, combined with half a teaspoonful of ground ginger.—Junior Practitioner.

[46769.]—**Silvering Mirrors.**—Having had considerable experience in silvering mirrors by deposition, I may be able to give a little assistance to "Signed Chemist, No. 50." I first published the process in the *British Journal Photographic Almanac* for 1873, and further remarks thereon in the *Almanac* for 1876; see also hints contained in an article on "Silvering the Front of Glass," by Professor Piazzi Smyth (Astronomer Royal for Scotland) in the *Almanac* for 1881. Make a 20-grain solution of nitrate of silver, and a 10-grain solution of pure caustic potash; also a solution made as follows:—Loaf-sugar, 2,700 grains; distilled water, 20 oz.; nitric acid, 2 drachms; alcohol (strong), 10oz.; distilled water, to make, 80oz. The solutions are mixed for use in the following manner:—Take one part of silver, and one part of potash solutions; add ammonia to just dissolve the precipitate, and two parts of distilled water. Now add a further quantity of silver solution till the silvering fluid is decidedly turbid. The amount to be added will depend upon the quantity of free ammonia remaining. Clean the glass to be silvered with a little of the potash solution and tripoli on a piece of cotton wool, and well rinse in clean water, finishing with distilled water, and keeping it wet till brought into contact with the silvering solution. When all is ready, add to every ounce of silvering solution one drachm of the sugar solution or reducing agent. Take care to make the reducing agent a week before you want to use it: it improves by age. Keep all the solutions and distilled water in a warm room. Rub a little paraffin or beeswax on the stopper of bottle of potash solution, or it will become fast. The metallic scum is caused by the hot water; pinholes are caused by solid particles in the solution or on the glass. The coating of silver should be perfectly opaque by transmitted light. Small mirrors are best dried on a pad of blotting-paper, and after warming, may be polished with rouge and chamois leather, taking care to first rub it with a piece of leather without rouge, till the rubber passes smoothly over it.—H. J. Burton, Tyne Villa, Hanwell.

[46775.]—**New Form of Cheap Battery.**—If I might step in between this questioner and the gentleman appealed to, I would advise your readers not to waste time in making the battery described. It may be all that it is painted, but I should only believe the statements made on ocular demonstration, or when certified to by some such authority as "Sigma." Nothing very marvellous in the way of batteries, whether in constancy, power, or cheapness, is to be expected nowadays, and anything very good would be almost sure to be patented.—Nun. Dor.

[46782.]—**Explosion in Firebox of Loco. Engine.**—To explain satisfactorily this explosion it would be necessary to know something of the nature of the previous bursting of the tube and of the rent caused thereby. However, I will attempt an explanation that may probably be the true and only possible one. When the boiler was emptied after the return to the shed, there remained some steam in the tube as well as some water. The cold water afterwards introduced, would, of course, condense the remaining vapour, and through that a vacuum would be created. The simple loosening of the plugs has caused the air to enter violently, and fill up the vacuous space. This phenomenon is of course accompanied by noise, and projection of all that there might be in the tube, such as soot. This will explain why the man got his face marked with black spots. The re-entrance of air through the rent would help to this considerably.—Ed. Gobert.

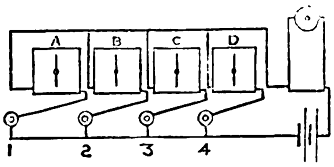
[46787.]—**Condenser.**—I made my condenser of 50 sheets of tinfoil 6in. by 5in., separated by sheets of paraffined white foolscap-paper, 7in. by 6in. Build up sheet by sheet, and notice the increase of spark at the secondary end, and diminution of spark at the contact-breaker. Carefully examine all the sheets of paraffined-paper to have them free from pinholes. Lay down, say, four sheets of paraffined-paper; then, a sheet of tinfoil, projecting as shown at A; then one sheet of paraffin-paper, and then a sheet of tinfoil projecting as at B, and so on alternately projecting over the paper. One series of tinfoils, A, to be connected to the spring, and the other series, B, to the upright carrying the platinum-point of the contact-breaker. When the condenser is finished, keep it hot and put it under pressure; this improves it very much.—Thos. N. Andrews, Silver Medallist Advanced "Telegraphy" City and Guilds of London, Plymouth.



[46790.]—**Stirling Castle.**—436ft. long, 50ft. broad, 33ft. deep, 4,300 tons registered; engines are of the three-cylinder type, cylinders in line fore and aft. 2 l.p. cylinders, each 90in. diameter; 1 h p. cylinder, 63in. diameter; stroke 5ft. 6in. Engines indicated on trial, 8,058 H.P., with 100lb. boiler-pressure, 28in. vacuum, 66½ revolutions per minute; mean speed, 18½ knots.—S. W. J.

[46793.]—**Glueing Belt Splicings.**—Several things are recommended, but I believe there is nothing better than good glue to which tannin has been added until it becomes "ropy."—Nun. Dor.

[46801.]—**Sub-Circuit to Indicator.**—If "Bor" will connect his rooms with indicators as per sketch, he will find no difficulty as to the circuits interfering with each other. 1, 2, 3, 4, pushes, A, B, C, D indicators.—H. J. J.



[46802.]—**Early Rising.**—I take a common American 6s. 6d alarm-clock, and, removing the spring which holds the wire that makes the alarm act, I substitute a wire spring attached to the right-hand side of the plate. To this I fix one end of the wire connected with the battery, so that when the alarm is set, the end attached to the spring does not quite touch within a small glass tube the other wire connected with the battery, which has been fixed within it. Upon the alarm going off, the spring which has held it flies forward and bears with it the end of the wire attached, which touches the other wire completing the circuit.—W. F. R.

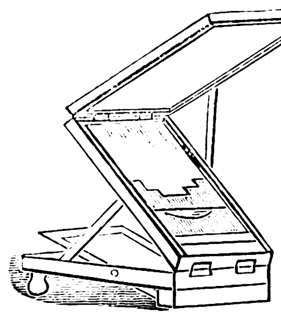
[46811.]—**Re-varnishing Dog-Cart.**—Well wash in water quite free from grease, dirt of any kind, then rub down with a wet cloth and pumice-powder until it is quite dead or without gloss, wash and dry with a washleather. If it is not well rubbed down with pumice-powder the varnish will not adhere as it should. Give two coats, the second as soon as the first will stand working upon. Varnish with best copal varnish, ironwork with japan; get it from the coachmakers.—James Parkinson.

[46813.]—**Dry-rot.**—"R. N. H." will find the only cure for the above is plenty of ventilation. We have tried all ways to get rid of it out of our works but cannot persuade it anyway, but find ventilation the best way of keeping it down.—James Parkinson.

[46813.]—**Dry-rot.**—Dr. Zerener recommends a preparation which he calls "autimerulion." In the liquid form it consists of boracic acid, common salt, and silica. I think you would find a strong (a saturated) solution of borax effective, letting it soak into the wood until the pores were filled with borax.—Nun. Dor.

[46814.]—**Caledonian Engines.**—The class "R.N.H." refers to were Nos. 136, 137, 138, 139, 140, 141, 142, and 143. They were built in 1853. They had saddle tanks. With the exception of 136 and 142 they were all altered to six-wheeled engines, leading and driving wheels being coupled. Nos. 136 and 142 ended their days as tender engines, with intermediate shaft as before, and running on four wheels only. None of this class are now running. The other part of the query is somewhat ambiguous. Does "R.N.H." mean the old six-wheel coupled engines or the modern ones? If he means the old ones, I may say that 96-100 class, by Jones and Potts, of Newton, and 122-131 class, built at Greenock, both came out in 1850. The latter class had originally cylinders 17in. by 24in., but were altered to 16in. by 22in. The six-coupled wheels were 4ft. 6in. The coupling-rods were removed from the trailing wheels, which were removed and a smaller pair substituted. In this form there are two still running now numbered 182 and 183; I am not sure if all were altered to four-coupled engines. In their first form 122 class were very powerful engines, though, of course, the pressure was very low. The modern six-coupled engines are Nos. 631 to 669. I think that class made its appearance some seven or eight years ago; they were built by Dübs and Co. The six-coupled wheels are all in front of the firebox, reducing the wheel-base to about 10ft. 6in. They have 18in. cylinders, 24in. stroke, and the wheels are 5ft. diameter. I am afraid I do not remember either dates or numbers asked for in 35398. A great many of the "Jenny Lind" engines came out in '48 and '49, though some appeared on the scene earlier.—Carstairs.

[46831.]—**Photographic.**—The annexed rough sketch will give you ample instructions to work from. At the bottom there is a reflector, or a piece of white paper will do instead; the bottom piece and bed are made in one piece, and sawn afterwards; then you will have both exactly the same size; the top piece is simply a flat board clamped; dovetail the bottom and bed. There are a number of notches for the carrier to fit upon, in order to raise the negative or lower as desired; there is a piece of very fine-ground glass in the bed for the negative to rest upon; the easel is easily adjusted by the brass clips, as shown at the side. If you cannot dovetail, get some spare pieces of wood and work away till you can; if you simply sprig them together you will have a botch of a job. Every amateur photographer should be his own cabinet-maker. In the last four years I have made apparatus which would probably have cost £25. If the amateur can manage this, then his "hobbie" is in reality a pleasure.—James Parkinson.



[46833.]—**Bumping Noise in Engine.**—Thanks to "J. K. P." and "J J. A.," I may say that the keyway is already sunk in the main shaft and properly fitted, also that the steam enters the cylinder just at the end of the stroke and cuts off a little over the centre. Will they or any other reader kindly advise further?—One in a Fix.

[46833.]—**Bumping Noise in Engine.**—Although addressed to "Sunlight," it will, perhaps, do no harm for another to state causes of the above he has met with in a course of 15 years' experience. As you refer to main shaft and crank-pin, just see both are square with cylinder at all portions of stroke. If shaft is square, try for crank-pin. I have known pin to be not put in true—i e., hole in crank not bored true; same for boss. Examine slide for lift and length of stroke; piston on rod; also look at cylinder covers if piston touches. And last, though not least, look for the *least leetle* drop of water in cylinder at the end of each stroke. Remedy will suggest itself.—R. A. G.

[46833.]—**Bumping Noise in Engine.**—I think the bumping noise in the engine is neither in the crankpin nor the neck bearing, as, after many years of experience with all kinds of engines, I have found that engine-makers do not allow in their valve-setting sufficient cushioning to bring the piston softly to the end of its stroke before it receives the steam admitted by the lead to cause its return stroke. Now, "One in a Fix," should take off his steam-chest cover, and move his engine round, and take notice of the lead of the slide-valve, which, in an engine of the size he mentions, should be about 1-32nd of an inch. He will probably find that the port is open to the exhaust until the piston is just going to commence the return. Should this be the case, he should knock the key out of the eccentric disc (usually a hollow one with no keyway on the shaft), making a mark on both disc and shaft to show original setting, then describe a circle on paper or board the exact diameter of the crank-shaft at the fit of the disc: divide the circumference of the circle into twelve parts equal to one another, and setting his dividers to one division, advance his eccentric disc to that distance from the original mark, in the direction of the engine's motion. Then key up and move round by hand again, and it will be found that the cushioning is rectified, but that there is too much lead. Now cut and drill two strips of iron or brass, and rivet them upon the two *steam* edges of the valve, and file them off until there is 1-32nd inch lead when the crank is just past the dead-centre on both sides; equally, if an horizontal engine; on the weight side more lead if a vertical engine. I am certain that though the noise *seems* to proceed from the bearings, such is not the case, if they are moderately close; and if "One in a Fix" likes to try my simple plan, he will find, like I have done, a silent servant in his engine instead of a noisy one. —Fred. Walker.

[46845.]—**To Mr. Davies.**—I am much obliged to "Ted Arthur" for his good opinion, but I am afraid he would prove himself but a bad exponent of the feelings of the musical portion of our readers were I again to trouble them with the dry details of piano-tuning. I will, therefore, refer him to No. 830 of the E. M., where the matter was exhaustively treated, though should he get into any difficulty I shall consider it a privilege to assist him. I am glad to tell him that by making himself familiar with the stringing he has removed one-half of the difficulty, it being usually just that part amateurs are most afraid of. The best position of the bearings is from the F on the fourth line in the bass to the next E above it. The first note tuned is the C between them, which should be set to the tuning-fork, these 12 notes forming the base from which the rest of the notes are tuned.—W. H. Davies.

[46846.]—**Engineering.**—To "Seaweed."—I should like, as a foreigner, to say a few words on this subject. The *Engineer* of last year inserted two or three letters of mine on the "Education of Engineers." This subject is naturally akin to the present one. There is no examination required in England to become an engineer. The usual thing, as you know, is to serve an apprenticeship in the works of some well-established mechanical engineers, or in the office of a competent civil engineer. There are, nowadays, many examinations conferring a diploma, either of M.E. or C.E. in connection with universities, such as Glasgow, Edinburgh, &c. But no competent man will accept a young man provided with these diplomas, if he has not served the regular apprenticeship. Of course, there is good in both university training and workshop practice. But it is likely that the latter will hold long yet. I advise you, feelingly, to go into some good engineering works or offices, and at the same time devote your leisure to the acquirement of theoretical knowledge. Abroad, especially in France, the diploma is everything, so that we get people that are apt at everything, but good for nought. They get laughed at by the workmen. The German system (Berlin Academy) is the best, as it combines in the course of five years, a thorough, practical knowledge of the shop and tools with a good, theoretical training. Let us hope that we shall see such useful institutions developed here, and we shall have then, no more useless members of the profession. There should be examinations, but no one should be permitted to pass them who has not been trained in some workshop of good repute. If you refer to my letters in the *Engineer* of last year, you will find this matter more detailed than I can do it here, for fear to trespass on valuable space.—Ed. Godbert, B.Sc.

[46850.]—**Electro-Magnet.**—Your magnet did not work either because the insulation was imperfect, or else one coil was wound to reverse the action of the other. A bichromate cell should work such a magnet easily. An electro-magnet will work with one large coil only, very near as well as with two small ones.—J. Sutcliffe.

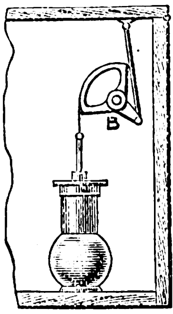
[46850.]—**Electro-Magnet.**—If you wind both legs equal, and put as much wire round them as your core is in diameter (which is being constantly repeated), you will have no difficulty in making your magnet work with only one cell. No one can inform you what power it will take to work the magnet unless they know what it has to do.—Wallington.

[46850.]—**Electro-Magnet.**—You do not give gauge of wire; but even under the circumstances you name, a trace of magnetism should have been apparent. Rewind the limbs evenly, and place a piece of paper between each layer. Try the battery fitted up for tension if wire is thin; but if the wire is No. 20, or larger, connect up for quantity. Probably the iron of your core is too hard—you might soften it a little. If the wires are not evenly wound, of course good results are not to be obtained. Are you sure the wires on your magnet were wound in one continuous direction? If not, the failure is easily traced.—H. Stooke.

[46850.]—**Electro-Magnet.**—The result of wrapping unequal quantities of wire round the limbs of an electro-magnet is that one pole becomes stronger than the other, the strength of a magnet being proportional to the number of turns. I therefore do not think that the unequal number of coils alone were the cause of your magnet not "working." See whether your wire is perfectly insulated, especially whether there are no uncovered places touching the core. I should advise you to equally divide your wire, and wrap it properly upon two wooden bobbins, into which the limbs are fitted. If this is properly done, one single cell will give you a strong magnet.—Kauthack.

[46855.]—**Cayenne-Feeding of Canaries.**—Some friends, whose birds are of a particularly fine colour, attribute its excellence to their practice of mixing cayenne pepper with hard-boiled egg, chopped fine, and supplied to the old birds to feed their young ones with. When grown up, they occasionally revert to this diet.—Glatton.

[46854.]—**Mechanical Action.**—In a sketch *a* is hinge of case; *b* is an axle running the length of case, and connected by a short lever and a rod to lid, as shown. This shaft will then make a portion of a revolution every time box is opened, or closed. Any number of cells may be connected to pulleys or (as in sketch), to quadrants on this shaft by strings, so that when the lid is closed the zincs are raised, and *vice versâ*. If you want dimensions you must give me depth of chest, largest diameter of cell, distance through which zinc is raised, and height from bottom of chest to top of zinc-rod when zinc is pulled up out of action.—Glatton.



[46856.] — **Electrotype.** — Power too strong. Violent action. Soft porous pot.—H. Stooke.

[46858.]—**Organ-Playing.**—It is impossible for you to execute pieces on the organ till you have gained a thorough mastery of exercises and scales. It is, no doubt, the fingering where you find your difficulty. You will find the piano a great help. Purchase an organ primer; though you have no pedals, you will find great assistance. —James Parkinson.

[46858.]—**Organ-Playing.**—You may improve your fingering by learning Bach's "Twelve Petite Fuges," price 6d., and more advanced studies by his "Fifteen Inventions," 1s. 6d., Enoch and Sons, Holles-street. Here are some astonishing ideas produced in a simple manner by the greatest master. Take your time, and play to time. Try Rink's "One Hundred Preludes" for a change, 1s., at any bookseller's.—Fiddler.

[46858.] — **Organ - Playing.**—"Poor Quill Driver" wants to acquire speed in playing the organ. Let him get hold of any good book of exercises, and placing a board or something over his hands, so that he cannot see the keys, work away until he gets the exercises off to his satisfaction without watching his fingers. The rest will come easy enough then, if he has intelligence and taste. When he gets an instrument with pedals, adopt the same plan; never look at the pedals, but let the feet find them. A little resolution is required, but that is the way to master the keyboard.—Organon.

[46861.] — **Cockroaches.** — The cockroach (Blatta [Periplaneta] orientalis) belongs to the order of the Orthoptera. These are ametabolous insects, the majority of which have two pairs of similar, or more or less dissimilar, wings in the adult state; and when the wings are absent, it is probable that they are aborted, not typically absent. The locusts and crickets (Grillidæ and Locustidæ) belong to this order, and are quite distinct from the Neuroptera and Coleoptera. The former have two pairs of wings of a delicate reticulated structure, generally nearly equal in size. The latter, on the other hand, have four wings, the anterior pair of which are not adapted for flight, but are converted into stiff horny elytra, serving as protective covers to the metathoracic wings. The Coleoptera are readily distinguished from the Orthoptera, including all those insects commonly known as "beetles." The order, Orthoptera, may be divided into three sub-orders: —(*a*) Cursoria, from *curro*, to run; (*b*) Raptoria, from *rapio*, to plunder; (*c*) Saltatoria, from *salio*, to jump. The Blattidæ are the only family belonging to the Cursoria, while the locusts form a member of the Saltatoria. The specimen you had must have been a male, for only the male Blattæ have two pairs of wings, of which the anterior are brown, and of a stiff texture. The posterior wings, on the contrary, are membranous, and, in a state of rest, are folded longitudinally upon themselves, the folded edge being internal. The female has very small movable anterior wings, which are, in fact, mere rudiments of the anterior wings of the male. The posterior wings are indicated by little triangular areas on the tergal portion of the metathorax, in which the integument is very thin, exhibiting markings which simulate the nervures of the wings. The cockroaches do not use their wings often; but they are, nevertheless, adapted for flight, and are made use of in the hour of danger. I think that every insect provided with wings is able to use them for flying, or at least for locomotion, for nature has no useless ornament.—A Medical Student.

[46862.]—**Telegraph.**—An insulated wire does not offer more resistance when straight than when coiled, and the strength of current does not affect resistance, but resistance affects it. If R = resistance of wire, S = its section, K = its conductivity, and l = its length, then $R = l / KS$. Try the effect of joining another cell or two in series, or put more turns of wire on instruments or a thicker line wire well insulated.—J. M. Stocks.

[46862.]—**Telegraph.**—No. 26 cotton-covered wire is a little too large for the coils—it should be about No. 30 and silk-covered. For the conducting wires it is much too small; these should be from No. 16 to No. 20; you don't say how many cells you use or of what battery. A wire of the same sectional area always offers the same resistance, but in the secondary of an induction coil there is a small quantity of current but at a high tension.—Kappa.

[46862.]—**Telegraph.**—Your instruments are too weak. Use No. 28 silk-covered wire for interior if needles are worked by electro-magnet, and finer still if worked by a coil. There is not too much resistance in No. 26 cotton for the distance. Are you sure there is no leak and all connections clean? A fine wire (insulated) offers the same amount of resistance when coiled as when straight, but an induced current overcomes a greater resistance.—Wallington.

[46862.]—**Telegraph.**—A couple of Fuller's cells should work your apparatus well, even under existing circumstances. I do not know how your line is fixed, but should say you have great leakage —i.e., if wire is out of doors. I rarely use less than No. 18 conductor for line purposes. No. 20 would do, but No. 26 is rather too fine. Wire in line presents same resistance as in coil. If well insulated in both cases, and under same temperature, I might say that S. N. Telegraph coils generally have 36 s. c. wire on them.—H. Stooke.

[46862.]—**Telegraph.**—The sized wire used for the telegraph ought to answer perfectly well. Will "A. H. B." please state what battery power he uses? I think that is where the fault lies. If they work well over 6 yards, they ought to do so over 60. Most likely the battery used is not powerful enough to work them over the increased distance. If querist were to use No. 22 or 20 for conducting-wires, he would obtain better effects. He should try to balance his battery power with the resistance of the line and instruments, making the resistance of the external (line and instruments) equal to the resistance of the internal (battery). Three cells of the Leclanché pattern ought to work the instruments spoken of. The current obtained from an induction-coil is of a different kind to that produced from a battery. It has a much higher intensity, and can therefore overcome much greater resistance than a battery. It will not, however, perform the work required in a telegraph. If not plain, write again.—John H. Rider.

[46864.]—**Canvas Canoe.**—From the dimensions he gives, "Rob Roy" has probably made the bottom of his canoe semi-cylindrical—the form of least stability for floating bodies. A round log lying in water will revolve upon the slightest touch. If "Rob Roy" will reconstruct his canoe, with a little more beam and less depth (say 27in. or 28in., by 9in. or 8in.) and make her bottom as nearly as possible flat for four-fifths of the middle part—not quite so, as canvas does not stretch well upon flat surfaces—making the ends as sharp as he pleases, he will require no ballast, and he will be able to sit her at ease, and, perhaps, even stand up in her. "Rob Roy" might reduce the length of his canoe to 5ft., or even 4ft., and still have buoyancy to spare; but she would neither look so nice nor go so fast. Every cubic foot of capacity will support 62lb. dead weight—that is the weight of a cubic foot of water displaced; hence the term "displacement" to express the dead weight of a ship. "Rob Roy" would much improve the appearance of his canoe by covering that part of framework above the water-line with pasteboard under the canvas. He can make a strip 6in. or 7in. wide in one length of 8ft. or 9ft., by pasting three or four strips of continuous cartridge-paper together, and letting them dry between two flat boards.—Robinson Crusoe.

[46865.]—**Cod-Liver Oil.**—If the stomach rejects, it is no benefit. Have you heard of glycerine as a substitute, in cases exactly like yours as to rejection? It is worth your inquiry.—Fiddler.

[46865.]—**Cod-Liver Oil.**—If "Leeds" will get some respectable chemist to put into an 8oz. medicine-bottle 5oz. of pale cod-liver oil and 3oz. of lime-water, in which has been dissolved 1oz. of powdered lump-sugar, and 30 drops of essence of bitter almonds, I think he will have a mixture which any child will take. Of course the chemist must take care to add the water very gradually, and it should be well shaken when administered.—A.P.S.

[46866.] — **Photographic.** — 1. Thin plates, over-exposure; it is impossible to get dense negatives from thin plates. 2. If you want good negatives do not try and spin your emulsion out to the greatest possible extent; allow about 1dr. A clay pipe is a very useful ladle for coating with. 3. I find one thickness of ruby with a lamp perfectly safe with Swan's 20 times. 6. I use nothing but rapid plates, and never fail to get density, but apt to get too much.—James Parkinson.

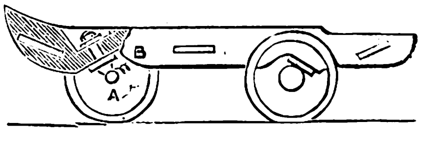
[46867.]—**Bichromate Battery and Intensity Coil.**—There is no intensity coil that can increase the power of your battery. The trough Bunsen described recently by "H. T. B." is as good as any, if the trough is well made. It has a high E.M.F., and can be constructed to work for a long time—two good points when the current is required for amateur electric lighting.—J. M. Stocks.

[46867.—**Bichromate Battery and Intensity Coil.**—There was a machine described in Silliman's *Journal*, some 30 or 40 years ago, which may be what "Jack" wants. It was made by laying a coil of secondary wire over the electro-magnet of an electromotor-engine, when the engine was connected to a weak battery, and the magnet-armature rotated by a hand-wheel, a current of electricity was caused in the secondary wire which would decompose water and give a spark between charcoal points, although the battery-current would do neither. A bichromate battery does not lose force by exposure to the air, but is not suitable for the electric light. Use Bunsen's or Grove's instead.—J. Sutcliffe.

[46872.]—**Staining (?) Walnut.**—Before you repolish, stain the light places with brown umber, or, if that is not dark enough, use Vandyke brown. Grind smoothly in oil, and thin with half polish and methylated finish. You can put any amount of figure in light walnut with the above, following the present grain in the wood.—48 W.

[46876.] — **Circular Saw.**—Holtzapffel gives 900 revolutions per minute as the speed of saw, and estimates power required at 2 horse-power. To do satisfactory work, I have no doubt that quite that power would be absorbed. According to the American practice, the saw would make 2,000 revolutions per minute; 18in. is far too large for manual power; you will find 7in. or 8in. quite as much as you can manage comfortably.—Glatton.

[46877.]—**Wheel Skates.** — The wheels are mounted on "bogies" or T-pieces. The stalk of the T must slant as shown, so that, on leaning over to one side, the wheels on that side approach one another, while those on the other side recede from each other. A spring *a b*, which may be either of wire or indiarubber, is placed at each end of each T (making four springs to each skate), so as to keep wheels straight when not being forced out of that position. The wheels are of boxwood, I believe, and about 2in. or $1\frac{3}{4}$in. diameter, by $\frac{3}{4}$in. broad.—Glatton.



[46878.]—**Respiration and Ventilation.**—In all probability in the proportions given, the oxygen was supposed to be replaced by nitrogen.—Kappa.

[46880.]—**Analysis of Water.**—Five cells of trough battery described by "H. T. B." recently are sufficient to decompose water, and it is not difficult to make; a couple of pt.-tipped copper wires, a plain glass tumbler, and two test tubes will work the exp. as well as the most expensive piece of apparatus.—J. M. Stocks.

[46880.]—**Analysis of Water.**—The most suitable, and, in fact, only suitable, forms of batteries for electrolysis in a lecture-hall are the Grove or Bunsen batteries. You should use 4 to 6-quart cells if you want to obtain anything worthy of a lecture-table. To ignite the detonating gas by a "spark," you cannot use this battery alone. Generally the Leyden-jar is employed, which, in the absence of an electrical machine or electrophorus, could be charged with a glass rod. You could obtain the explosion, using the battery only, by following a plan similar to that described in answer to query 46727, but I hardly think it would answer your purpose.—Kauthack.

[46882.]—**Dynamite.**—The explosive force of this is no more downward than that of gunpowder. The force in each case is exerted in every direction; but gunpowder placed on a stone burns slow, and the pressure gently lifts the air, leaving the stone intact; but dynamite burns fast, and before the air is lifted the stone has received a blow which breaks it.—J. M. Stocks.

[46884.]—**Varnishing.**—Good oak varnish is suitable for newly-painted Windsor chairs; but Windsor chairs are seldom painted, they are generally stained, the backs and seats polished, the legs and rails varnished.—Anxious to Help.

[46888.]—**Astronomical.**—I have asked myself the same question when at Stonehenge, in Wiltshire, and should like to repeat "Neo's" query.—H. STOOKE.

[46888.]—**Astronomical.**—If "Neo" possesses a celestial globe he can easily find the "points in the heavens" at which the sun will be first seen on the days mentioned. On June 21st, when the sun's northern declination is 23° 28′, the point of the horizon at which he rises is 41° north of east, and on the same day the point at which he sets is 41° north of west. The length of time it takes him to describe this diurnal arc is about 16½ hours. On Dec. 21st, when the sun's southern declination is 23° 28′, the point of the horizon at which he rises is 39° south of east, and the one at which he sets is 39° south of west. This diurnal arc is described in about 8 hours. The rule for finding the above points by the globe is: elevate the pole to the latitude of the place, find the sun's place in the ecliptic, bring this to the eastern part of the horizon, and the degrees intercepted between the sun's place and the eastern point will be the rising amplitude, and the number of degrees intercepted between the point at which the sun sets and the western part of the horizon will be the setting amplitude.—A. MANOCK.

[46892.]—**Japanning.**—You require white-lead, thinned with turpentine only (no oil only what is in the white-lead as you buy it). Add any dry colour to required tint; give two coats, letting each dry, and then varnish.—48 W.

[46894.]—**Covering Silk Balloons.**—You should varnish the silk with a thin coat of varnish before sewing it together; wash the oil out with methylated spirit and turpentine, and then varnish with 4oz. benzoline, 1oz. boiled oil, ¼oz. indiarubber; this varnish will dry slowly in a week. Put on two or three coats of varnish as thin as possible.—J. SUTCLIFFE.

[46897.]—**Powerful Bichromate Battery.**—This form of battery can never be used for electric light purposes, as it is so far from constant. Grove's, Bunsen's, or Fuller's should be used.—KAPPA.

[46901.]—**Watts' Parallel Motion.**—The links, according to Molesworth, are usually ½-stroke of engine in length. I do not think that altering the length (unless made very short) would alter the path of middle point of link.—GLATTON.

[46903.]—**Electric Bell.**—Bend stem of hammer back until, when armature touches face of magnet (which should have a little varnish or a thin piece of paper over it to prevent actual contact with the metal), the hammer is about 1-32in. from the bell. The wire should be wound on core till the diameter of bobbin is 1⅛in.—GLATTON.

[46903.]—**Electric Bell.**—I expect your hammer does not strike near enough to the edge of the dome.—H. STOOKE.

[46903.]—**Electric Bell.**—I have had a good deal of trouble with a 10s. electric bell. The armature had been broken, and I thought it must be on that account. I read, in your journal, of the polarisation of batteries, and I thought my battery (a 3s. 6d. Leclanché) must be at fault, and I sometimes found it would work when I put on fresh wires, and then thought it was the fault of the connections. I doctored the battery, without avail; improved the connections by running the two line wires round the wainscot instead of under a carpet sometimes trodden on, and still the bell would only ring sometimes and variably. I finally unscrewed the electro-magnet and adjusted it to the armature in such a way that the bell rang perfectly directly the adjusting-screw touched the armature on the other side, and before any considerable pressure was brought to bear upon it—and now, notwithstanding that the broken armature is very stiff, and an old Leclanché battery is used, the bell rings constantly, perfectly, and invariably, and has done so for months, after some 18 months' bother over it.—L. B. B.

[46904.]—**Secondary Battery.**—My battery was made simply as an experiment, consequently, I used what came in handy. It consisted of three copper plates, each about 5in. by 4in., and two amalgamated lead plates the same size. The copper and lead plates were placed together alternately, being separated from each other by strips of ⅜in. wood, dipped in paraffin top and bottom; the whole were held in place by two strong indiarubber rings. The containing vessel consisted of a rectangular cod-liver-oil bottle with the neck cut off. The solution was saturated sulphate of copper, diluted with one-twelfth part of sulphuric acid. Having inserted the plates in the containing vessel, fill up with solution to within a short distance of the top; connect all the copper plates together by wires, also the two lead ones together. Procure two quart Bunsen batteries, connect them together in series, and lead a wire from the carbon terminal to the lead plates, and another one from the zinc to the copper plates, charge until the copper solution goes colourless. It is, in order to observe this, that you require the containing vessel to be of glass. Of course, you know what I mean by connecting the Bunsen cells in series—namely, the carbon of one is connected to the zinc of the other. It will be also as well to mention that there is no particular virtue in having two lead and three copper plates; one of each would answer quite as well if they had the same area. The vessel containing the sulphate of copper need not be any larger than necessary to contain plates. Further information with pleasure.—J. HEZMALHALCH, jun., Felliscliffe, via Leeds.

[46905.]—**Incandescent Lighting.**—These kind of cells will never be suitable for the electric light. See reply to query 46897.—KAPPA.

[46906.]—**Swiss Watch.**—You have got too much shake or play in your balance. Put a piece of paper under the balance-cock or bar behind the screw; keep slipping the piece of paper nearer the screw until the balance has no shake, then slip the paper gradually back again until the balance is free. If you are not successful, write again.—A FELLOW-WORKMAN.

[46906.]—**Swiss Watch.**—The "clinking" noise complained of by "Harris" may proceed from several causes, so that no definite one may be described. The bars of the "balance" may catch on the tips of the regulator pins, or may be against the hair-spring stud, or maybe the 'scape-wheel trips in the cylinder-notch or passage. Other faults may produce the noise. If the noise is intermittent, one or more teeth of the 'scape-wheel may be bent; if constant, then I should imagine the balance touches somewhere. To discover the fault, remove the movement from the cases, and hold it in all imaginable ways, examining the escapement at the same time, and so notice where the fault is located. The cylinder should have the barest amount of end-shake at the pivots: too much, one way or the other, will frequently bring about the fault complained of. A minute piece of tissue-paper placed under the end of the "cock" before screwing down will generally put the "shake" right if too great. If this is so, and the "shakes" are corrected, and yet the noise is heard, then examine at the pins and stud before mentioned. If at the pins, shorten them a trifle with a slip of Arkansas; very little may suffice. If at the stud, file a little off the face if it will not endanger the pinhole by doing so. Otherwise, the bars of the balance must be "bumped." Great care is required in "bumping," so, unless you have a light hand and hammer, don't attempt it. If you can ascertain the actual fault, I can the better advise you. The concluding query has been answered so recently as two or three weeks ago.—ALFOJOE.

[46909.]—**To "H. T. B."**—If you will advertise your address, I will send you a description of my gravity lamp, which is an improvement on the mercury regulator which I alluded to in my letter. I cannot publish an account of my lamp, as I find it would invalidate any subsequent patent, and I may wish to patent it. I guess by your query to Mr. Hawkins that you wish to make a cheap battery. If you will wait till next week, I will send directions for making quart Bunsens at about 1s. a cell. Of course these don't look much, but for power and constancy, they are equal to the most expensive.—H. T. (not S.) B.

[46910.]—**Calculating Watch Mainspring.**—Take an empty barrel, put in arbor: now, two-thirds of the space left in barrel should be filled up with spring, the other one-third is left for working space; also there should not be less than nine coils, and not more than 13. In cases of small lever-barrels, where the spring is very short, you must follow first rule.—A FELLOW-WORKMAN.

[46912.]—**Medical Coil.**—I have recently made a good one, though small, on a circular stand, reel 2¾in. in diameter at flanges, 3in. high, and core ½in. I do not care for the induced current for medical purposes, so I have no primary and secondary wires. I simply used ½lb. of No. 26 cotton-covered, wound evenly upon my reel, and had a piece of soft iron, ½in. diameter and 3in. long, with the usual contact breaker fixed over it upon the top of the reel. I regulate my current by means of a series of wires I have soldered to every third helix upon my coil, and terminating in a series of brass points, arranged in a semicircle on the stand, with a lever centred so as to reach them all in turn, so as to regulate the strength of the shock. If you like to make one on this principle, I shall be happy to furnish you with a full description of connections and sketches of general details. Mine gives a good result with one Daniell's cell.—FRED. WALKER.

[46913.]—**Stopping for Decayed Teeth.**—To "ALFOJOE."—In reply to "J. S. R." I must say I cannot imagine in what way his difficulty has arisen if he has used pure, or comparatively pure, silver and pure quicksilver. Possibly an excess of the latter has been used, or the two have not been sufficiently blended before packing into the teeth. The amalgam should be made so stiff as to be only just short of being hard. If an excess of quicksilver is present, I imagine it will not set. I mixed mine in the palm of my left hand with a penknife, and pressed out the superfluous quicksilver with my forefinger. The teeth cavities should be prepared before the amalgam is made, a piece of wool being used at the last minute to thoroughly dry the hollow spaces. The amalgam must be pressed with all possible or bearable force into the hollow. As I already have said, the nerves must be absolutely destroyed previously to using the amalgam. Dentists use a variety of stoppings, but I am acquainted with only a few of them. I think I am right in stating that one kind is made from a species of shell-fish. Where one's pockets are well lined with gold, the teeth may be "lined" with the same choice metal. This is packed in carefully in the form of "leaf." It is necessarily an expensive process, but is far the best, as, owing to the absence of chemical action from the acids of the mouth, no unpleasantness of taste is experienced. Reverting to the silver amalgam, let me add the silver should be an almost impalpable powder. Coarse filings will not do.—ALFOJOE.

[46915.]—**Die-Sinking.**—I never heard of any work on the subject, besides, it would be of very little use; the die-sinking has to be learnt by patient hard work. But for my reply in detail to a similar query, see last vol, No. 861, p. 72.—M.M.I.Sc.S.

[46917.]—**Raising Water.**—What natural source of power have you? Is there a stream, and what is its width, depth and velocity? It will be near enough to measure the latter by floating bodies, such as a stick or thin plank. See how long it takes to float, say, 50 yards. If a slow stream, could it be dammed up, and to what depth? Failing this, is there any small stream—a spring, for instance, the water from which could be collected in a reservoir and used to work a hydraulic ram? Is there sufficient wind to depend upon a windmill in your neighbourhood? What is your own notion as to the power most convenient to be obtained—wind, water, or steam? I conclude, from the wording of your query, that water is to be pumped along a horizontal pipe 70ft. long, and then up-hill through 40ft. of pipe, making 110ft. of pipe altogether? Is that correct? How much water should you want per diem? 20 gallons a man is a very usual allowance.—GLATTON.

[46919.]—**American Organ.**—Take the front board off and raise the swell by the knee-lever, and you will see the vibrators. Take a hook something like a crochet-needle, but much stronger, and place the hook in a slot in the vibrators made for the purpose, and draw gently.—W. H.

[46919.]—**American Organ.**—Either "B. M.'s" American organ must be an extraordinary one, or he has gone out of his way to make a mystery of what is very simple. If he will refer to No. 655, p. 117, he will see a section of the usual arrangement, and if he will then compare that with his instrument, he may succeed. The fact that the "person" from whom he purchased it (assuming he means a dealer) cannot tell him how to get at the reeds, would indicate that it is some extraordinary design; but, supposing it is not, let "B. M." take out the front slip in which the lock is placed; then, putting the knee-lever over, he should see the swell lift. If the stops are drawn, one row of reeds will present their heels to his delighted vision, and with a hook he can draw them out. For the back row it will perhaps be easiest to take out the back of the case—the upper part—and lifting the swell he will again see the reeds. Did it never strike "B. M." that a reed instrument must be made so that the reeds can be got at, and that—at least in so simple an instrument as his—it is scarcely likely makers give themselves unnecessary trouble? "Joiner's" sketch on page 219, has probably helped to open his eyes.—ORGANON.

[46919.]—**American Organ.**—Presuming that the instrument in question is a properly constructed American organ, there will be no necessity to remove the keyboard in order to get at the reeds. If the instrument contains two rows of vibrators, the front row can be got at by removing the board in front of the keys; then by raising the swell and drawing the stop which raises the mute, the ends of the reeds will be visible. They are then easily taken out with the reed-hook. The back set is got at by unscrewing the backboard, then raising the swell, which is controlled by the forte stop as well as by the knee-lever. Afterwards draw the respective stop and the ends of the reeds will be visible. American organ reeds, if made of good spring brass and firmly riveted, seldom require tuning. The reeds should be firmly secured to the blocks by two (not one, as in inferior organs) iron or steel rivets. An American organ is often condemned and thought to require tuning when it goes a little out of tune, which is caused (in ninety-nine cases out of every hundred) by the dust adhering to the reeds. In such a case as this, if the reeds are taken out and carefully cleaned with a piece of chamois leather, the proper tuning will be restored. I have in preparation a paper containing instructions how to rectify defects in American organs and harmoniums, which I shall send to the editor shortly. The reeds of an American organ should be taken out and cleaned at least once in six months. This will, to a great extent, prevent any muting of any particular reed.—G. FRYER.

[46921.] — **Organ or Harmonium.** — To "BETA."—If you had stated precisely what you required, it would have been easier to answer you; that is, the pitch, quality, and compass of tone. Do you want the half-rows for variety's sake? If so, put them on the top of the other rows, and save five-sixths of the labour involved in the channeling. But if you want the 16ft. tone throughout from the sub-bass, with another 8ft., you must place them at the back. Any reeds placed at the back, nearest the bellows, will sound loudest; that is why this position is favourable for sub-bass reeds. Some makers even place them so that they protrude into the mouth of the reservoir. Now, if you place channels under them leading to the other pallets, of course your present rows will have first chance of the wind, and that is where you would place a loud-voiced set if you wanted them; while the tone at the back would be much quieter. Get a few strips of wood, and make a specimen cell and channel for a sub-bass reed and satisfy yourself, for I do not think the loudest tone, even for sub-bass, to be always the best. When you have decided on channels, you had better cut grooves ⅛in. deep across the underside of your soundboard, to suit your new boards, and glue strips 1in. by ⅛in. in these grooves; then prepare another thin board, and having grooved it and cut the pallet holes, glue it on the channels. Failing this grooving, you had better prepare your strips ¾in. by 3-16in., and put them on with glue and a liberal supply of fine screws. I do not like the idea of parchment covering for the channels (rubber drill would be better), as the slightest leakage just here will cause the notes to run together and spoil all. Where the sub-bass reeds come you might make new pallets, and cut the pallet-holes 7in. long. If your bellows are the size mentioned (?) they should do; but why not put down a chord on the instrument which shall be equivalent to your intended alteration, and decide for yourself. As to altering or enlarging them. I should think it out of the question, as I am not aware that anything will compensate for lack of space, to say nothing about the patching which must be done.—JOINER.

[46925.]—**Water in Gravel-Pit.**—The well would be of little or no use in your case I am afraid. If you could hire a steam-engine and centrifugal pump, you would soon be able to pump up the water, but a channel of some sort would be needed to lead water away to river or some neighbouring pond. I am afraid, however, that if gravel-pit does not drain itself, the evil will still remain, and every shower of rain will help to fill it again. If you decide to pump it out, your best way would be to advertise for tenders for the job, and let some contractor do it for you.—GLATTON.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Test for Mineral Acids in Vinegar.—Chiaffe gives the following as a test for mineral acids in vinegar:—The colour of a solution of Paris violet (methylaniline violet) is converted into ultramarine blue by even very dilute mineral acids, whereas organic acids do not alter the colour.

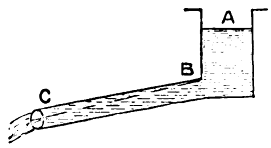
IN concluding a report on the collision that occurred on the 29th March at Stoke Station, on the North Staffordshire Railway, Colonel Rich says, "If this train had been fitted with continuous brakes, the collision would probably not have occurred."

QUERIES.

[46928]—**Diphtheria.**—To DR. EDMUNDS.—The following extract from a South African paper has reference to the cure of the above: "We can vouch for the efficacy of the following remedy for diphtheria. A few years ago, when this dreadful disease was raging in England, a very simple and rapid remedy for it was discovered by the celebrated Dr. Field. He put a teaspoonful of flowers of sulphur into a wine-glass of water, and, when well mixed, gave it as a gargle. Brimstone destroys every species of fungus in man, beast, and plant. Instead of spitting out the gargle, Dr. Field recommended its being swallowed. In extreme cases, when the fungus was too near closing to allow of gargling, he blew the dry sulphur through a quill into the throat; and, after the fungus had shrunk sufficiently, ordered the gargling, and he never lost a patient from diphtheria." As the subject is of great interest to many, would Dr. Edmunds kindly say if there are any pathological grounds for believing diphtheria to be fungoid in character, and if he is aware of the cases alleged to have been so successfully treated by Dr. Field?—H. NOLAN, Clifton Villas, W.

[46929.]—**Iron.**—Will some of your well-informed correspondents kindly tell me how I can get rid of iron, present in water in the form of carbonate? The plan I adopt at present is that of exposure to the air; but this process occupies about 10 days, with the water standing to the depth of 3ft. Without making costly alterations in my works, precipitation by boiling cannot be adopted. But it occurs to me that some scientific reader may be able to tell me how the iron may be otherwise rapidly precipitated without injuring the water for drinking-purposes? For such information I should feel much obliged.—TEN YEARS' READER.

[46930.]—**Hydraulics.**—Given a tank (see sketch),



a constant head of water being maintained therein at A, a pipe (truly cylindrical) issuing from, or nearly from, the bottom of the tank at B, and inclined at any angle from the horizontal line to outlet at C, the pipe to be of any length. Will the pipe be quite full, or only partially so, at the outlet C.? Some of my friends attempt to demonstrate mathematically that, by the velocity acquired by the flowing water it is "thinned down" somewhat as shown by dotted line in sketch, so that at the outlet C it only partially fills the pipe.—A. H. MOUNTAIN.

[46931.]—**Cuts and Bruises.**—Would some reader kindly tell me what would be the best thing to keep in a workshop to apply to cuts from chisels, saws, splinters of iron and wood, &c.? Also, a few simple directions on the treatment of cuts, &c. Perhaps Dr. Edmunds could give a short paper on the subject?—AN AMATEUR M.

[46932.]—**Telegraphic Engineering.**—Could anyone give me any information about the Government Inland and Submarine Telegraphic Service, or tell me where I could obtain it? I have consulted the *Civil Service Gazette* and other works, but find no mention of it. I have also written to the secretary of the School of Submarine and Military Telegraphy, No. 12, Prince's-street, Hanover-square, and have received a prospectus of the school. But there are one or two points on which I have been unable to obtain information. These are principally the examinations, the mode of entering the service, and the limits of age.—JAMES SHONE.

[46933.]—**Photographing Monuments in Cemeteries.**—To MR. F. WETHERFIELD.—Can the burial board of a public cemetery or their servants legally prevent a person photographing tombs and monuments in the cemetery, and can the relatives of the deceased person to whom the grave belongs object to its being photographed?—AMATEUR PHOTOGRAPHER.

[46934.]—**Jewelling Watches.**—Will "A Fellow-Workman" kindly say how watches are jewelled?—HALL.

[46935.]—**Electric Bells and Lightning.**—I have an electric bell in communication with a friend's house, the wires for which stretch from window to window across two gardens. For greater convenience in fixing on a short distance, I have used two line-wires—doing away with the return by earth. Is any risk from lightning to be apprehended? The wires run from the top window of the house at an elevation of about 45ft. If resistance coils are necessary, how should they be placed in the circuit, and also, what would be the cost of construction?—PRAGMATICAL.

[46936.]—**Steam-Launch.**—I should be very grateful if some kind reader of this paper would help me out of my difficulty. I am building a steam-launch 18ft. long, 5ft. beam. What size engine, double cylinders, also, size of boiler will be required to run eight or nine miles per hour? Are dome boilers best? What advantage has a steel boiler over iron? Also, any other information on the subject, which may be interesting at the present season.—MOONLIGHT.

[46937.] — **Oaths in Courts of Justice.**—My views on this subject are almost identical with those held by the Society of Friends. Can I claim (as a right) to make an affirmation, either as a juryman or witness? Or is it in the power of the magistrate or judge to refuse to permit me to do so? I am a Congregationalist—not a member of the Church of England.—T. W. W.

[46938.]—**Photography.**—Many thanks to all who have so kindly answering my many queries. Will Mr. Parkinson give formula he used to develop the rapid plate he exposed for 33 secs. on a waterfall? With a 20 times plate and much shorter exposure, using a very restrained developer, I have never obtained a neg. without fog if the exposure has been much over the usual length for such places. I should have thought a waterfall a bad subject for a prolonged exposure, as it is not stationary.—F. C.

[46939.]—**Eames Locomotive.**—To "E. W."—Can "E. W." or "R. N. H." give sketch and dimensions of tender of the above locomotives? Are not engines with single driving-wheels an uncommon type in America? Also, particulars of the brake used upon this engine?—E. E. R. TRATMAN.

[46940.]—**Sidebotham's Axlebox.**—Could any of "ours" give a sketch and detailed description of the above as used on the Highland, West Lancashire, and also on the Egyptian State and other railways? I have a prospectus of the above, but the description is far from intelligible.—C.

[46941.]—**Soap-making.**—I have been trying to make pale household soap, and would like to know if there are any instruments for testing the strength of the leys (made from caustic soda), say, such as rectifiers of spirit used to tell the strength of spirit? And also the meaning of so many degrees "B.," as in Spon's "Workshop Receipts"?—SVENSKA.

[46942.]—**Resistance of Ring to Collapse.**—Let an iron ring 8in. diam. be suspended from a chain. From the same ring, and at a point diametrically opposite the first chain, a weight of 13 tons is suspended. What is (1) the position of greatest stress? (2) The amount of bending moment at such position? (3) How the above are determined? (4) Diam. of iron of which ring is made, supposing modulus of rupture is 54,000in.-pounds per sq. in.? It seems pretty evident that there are four points (the top, bottom, and points on the sides of ring midway between these) at which the bending moment is edual and at its maximum. It cannot be taken as a simple beam. Nos. 2 and 3 are the questions I wish more particularly to have answered.—GLATTON.

[46943.]—**Sprain.**—Will Dr. Edmunds kindly advise me as to the following?—When using the muscles of my left leg (for instance, when climbing a rope) I feel an acute pain in the inside (meaning right-hand side) of the centre of my foot, which continues as long as the muscles remain stretched; and when they are relaxed, it gradually dies away. There is no swelling or redness, but it feels as if a small bone, or something of that was out of place. I believe it is a common thing with athletes, so I have no doubt your answer will benefit a good many of "ours."—H. J. L.

[46944.]—**To Mr. Lancaster.**—I am in a difficulty with my Leclanché batteries; I cannot make a good connection with the carbons and wire. I have tried melting on a cap of lead, but a very poor current is the result. I have also tried a brass clip with the wire soldered on; but the clip soon oxidises. Will you kindly help me out of my difficulty? How are the connections made on the batteries sold in the shop? They seem to be a cap of lead.—G. I. C. E.

[46945.]—**Leclanche Battery.**—May I trouble Mr. Lancaster, or some other kind electrical correspondent, for a little information respecting the above? I have had a few cells which have been giving a good current about three years, but they are now getting much weaker (all connections are quite perfect). Some of the porous pots are much worn. Will it be well to have new pots and recharge them? And also, is it necessary to go to the expense of fresh carbon blocks? Will they not do again, and how long? Should pure sal-ammoniac be used?—W. J.

[46946.]—**Gold Fish.**—I have a tank which holds about five hogsheads in my garden, made for keeping gold fish in. It is supplied with water that runs off the house during rain; but I find that the soot from the chimneys blackens it so much, that I am afraid the fish will be killed. Could some reader suggest a plan to prevent the above? How would it be to use a kind of filter? And how could I make one to take a stream of water about 2in. diam.? Also, would a filter take any of the properties of the water away essential to the fish?—ROSS.

[46947.]—**Lesson in Assaying.**—I shall be greatly obliged if one of your readers can recommend me a good practical book on assaying, both by the scorification method, and the crucible method. Or perhaps some of your numerous contributors would kindly give a few short lessons on the subject similar to those on the use of the blowpipe, by Mr. C. J. Müller in Vols. XXX. and XXXI., which were extremely useful to myself and, I doubt not, to many others.—J. L. WHITAKER.

[46948.]—**Resistance of Electro-magnets.**—I understand that the resistance of the wire on an electro-magnet should be half that of the whole circuit, including line wire and battery. This, of course, is for a single magnet. When there are two or more in the same circuit, what is the best resistance to give the coils?—GLATTON.

[46949.]—**Sodium Salts.**—Is there such a compound as sodium and hydrogen tartrate ($NaHC_4H_4O_6$)? If so, is there another name for it? Will caustic soda do as reagent as well as caustic potash, and are the reactions the same—*e.g.*, for producing a ppt. with a zinc salt which ppt. is soluble in excess?—W. G. WOOLLCOMBE.

[46950.] — **Composition Gas-pipe.** — Of what metals, and in what proportion is compo. gas-tube made?—A. PARKER.

[46951.]—**Papyrograph.**—Some time ago I saw a rapid process described for copying a number of copies of manuscript by writing on ordinary paper, then placing the paper written on in a strong solution of resin (colophony) in turpentine, then place the resinous paper in a strong solution of caustic soda, withdraw, and wash well with cold water, when you will have a perfect stencil of the writing. If any of "ours" have succeeded by this process, and would give strength of solutions, &c. to be employed, I am certain it would interest many readers of the "E. M." besides—DABBLER.

[46952.]—**Reaction.**—The other day I had occasion to mix a saturated solution of brine (NaCl), and a saturated solution of carbonate of potassium (both commercial), and I was surprised to find that the mixture became cloudy with slight fluorescence, and after some time yielded a white flocculent precipitate. Will some kind reader oblige me with the reaction which takes place, and, if possible, set the equation out ?—Glass.

[46953.]—**Pearl Ashes.**—Will Mr. Allen or other of your kind chemical readers inform me of the most reliable method of analysing pearl ashes for carb. of potash (K_2CO_3), and give full directions ? As I want the results not to differ more than 0·5% in the same sample.—Glass.

[46954.]—**Dividing Apparatus.**—I want to use as a worm-wheel to make a dividing apparatus like that described by "J. K. P." on p. 277, Vol XII., an ordinary cog-wheel of 14 gauge, 120 or 180 teeth, as it would be much lighter than the 10 gauge-wheel used by Mr. Joyce. If I used such a wheel, would "J. K. P." kindly say what pitch and dia. should my tangent-screw have ? My leading screw has four threads to inch.—F. W. Mackenzie.

[46955.]—**Elementary Optics.**—In a telescope objective, can the spherical ab rration be corrected, as is the chromatic, or can it only be reduced ? If corrected, upon what principle ?—E. P.

[46956.]—**Chronometer and Watch Rating.**—Is there anyone among your readers who can tell us how the rate of a chronometer or watch can be ascertained to the ·1 of a second ?—Chronos.

[46957.]—**Battery.**—I have a Bunsen battery, which I want to make use of for plating and gilding purposes. Will any reader kindly tell me how to proceed—i.e., how to make solutions, &c. ? Any information will be gladly received by an—Amateur.

[46958.]—**Half-chronometer.**—Will any practical reader tell me if there is any difference between the escapement of the above and that of an ordinary lever with an overcoil spring ? A description will oblige—Chronos.

[46959.]—**Marine Steam-Boiler.**—I shall be glad if any kind reader can give me a description of the best boiler most suitable for a small yacht to burn charcoal, and to be made of copper, in order to generate steam quickly ?—Dynamatic.

[46960.]—**Model Electric Lamp.**—I have one of the above-named lamps, made by Mr. J. Bathurst, of the Strand, which burns Reynier's carbons, and shall be glad if any kind reader can inform me whether I can produce the light from other means than the acid battery ; and as I have a small steam-engine, I should like to make use of it to drive some dynamo or other electrical apparatus to produce the light, which I am of an opinion that there is some other kind of generator. The engine is as follows: 1½in. stroke by ¾in. bore, slide-valve inverted with an extra large diameter heavy flywheel of iron. The boiler is of a vertical type, 8in. by 4in. dia. ; the shell is made of 1-16in. gauge iron, with copper firebox and copper crown of 1-12in. thick, and one flue, water space all round firebox ¼in., and well riveted, with which a great speed could be obtained. Also, please say what pressure the boiler is likely to stand with safety ? and oblige—Dynamatic.

[46961.]—**Battery.**—To Mr. Tolman or Others.—I have made a battery of three cells, carbon and zinc in sal-ammoniac, plates 5in. by 2½in. I soaked the ends in paraffin all night, and the paraffin has crept up the plates. All connections are properly covered with paraffin wax. The battery will hardly ring when joined close up to the bell, and not at all through the bell circuit. I think it is the paraffin in the plates. How am I to remedy this, please ?—Bell.

[46962.]—**Stereoscopic Camera.**—Will Mr. Lancaster or some other reader kindly give me instructions how to make a steoroscopic camera ? Also, how to take views with same ?—Stereo.

[46963.]—**Astronomical.** — I have been reading "Astronomy Without Mathematics," and am puzzled with one or two statements. 1. It says (p. 45, sixth edition), speaking of the motion of the earth : "the addition of the rotation velocity at night, and the loss of it by day, about 1,000 miles an hour at the equator, is much too little to be perceived, and the change is also very gradual." Now seeing that it is always day somewhere on the earth, and always night, how is the above passage to be understood ? 2. On p. 125, "though the moon goes round the earth, it is no less true that the earth goes round the moon, only in an orbit as much smaller, as the earth is heavier—that is, 81·5 times." And on p. 522, "The earth revolves every month round the c.g. of the earth and moon, which is 2,895 miles from the earth's centre." I cannot understand the earth revolving round the moon, except in appearance to anyone stationed at the moon. Will someone kindly explain ?—Gimel.

[46964.]—**Soluble Oil.**—There is an article used by finishers called soluble oil, one variety of which seems to consist largely of glycerine ; the other is a kind of liquid soap, and smells of castor-oil. Can any of your readers give me any information as to how these are made ?—A Finisher.

[46965.]—**Pianoforte.**—Will any kind reader inform me the best way to prevent the rusting of wires, and to stop it ?—W. H.

[46966.]—**Balance-springs.**—To "A Fellow-Workman."—Sometimes when cleaning workmen's watches, I find spots of rust on the outside coil of balance-spring. What should be done with these to prevent the rust from spreading. I sincerely hope you will continue your articles on "Watch Cleaning and Repairing."—Revel.

[46967.]—**Coin Brooches.**—To "Alfojoe."—I want to make some coin brooches in various patterns. How are the coins to be held in position while soldering ? Binding-wire is out of the question, as the coins are so thin.—Revel.

[46968.]—**To Dr. Edmunds.**—I have a sister, aged 27, suffering from the following symptoms :—About 15 years ago she had a disease supposed to be nettle-rash, that came out out over her body, more particularly at the change of the weather, until the last five years, and was under doctors' hands ; but they did her no permanent good. Now and again a single blotch will come out, causing considerable heat in that spot, and giving a little relief for the time. At other times heat arises in the face, causing it to look a purple red, relieving dulness, &c. Costive at times ; nerve and brain affected, and blood seemingly stagnated.—J. Denvers.

[46969.]—**Railway Curves.**—Will any engineering correspondent, or preferably the able "M.I.C.E.," who dealt with letter 45268, Vol. XXXIV., week ending Nov. 25th, 1881, work an example out for me by the formulæ $a = c / \pi r . 908$, take radius of curve 40 chains, also 100ft. —J. Denvers.

[46970.]—**Grain Dresser.**—Would any reader give me a few hints on the construction of a grain dressing-fan ? A sketch would greatly oblige—G. G.

[46971.]—**Soluble Essence of Lemon and Cinnamon.**—Would any of "ours" give me the process whereby the oils of the above are rendered soluble in water ?—Chemist.

[46972.]—**Cheap Form of Voltaic Cell.**—I have constructed one of the above after the following manner —viz., a tin can capable of containing 3lb. of preserved fruit, porous pot 5in. high by 2½in. dia. (taken from an old form Leclanché cell), piece of new zinc 4½in by 5in. made into a cylinder ○, but the edges not touching each other, copper wire soldered thereto, and passed through a cork to allow of pot being made airtight, pot placed central in tin can, and space between filled with clean cast-iron borings, just made damp with purified caustic potash solution, supplied me by a chemist as suitable to supply the place of commercial potassium hydroxide. All joints are soldered ; but it fails to ring a bell formerly worked by four quart Leclanché cells. Will someone kindly say cause of failure and remedy ? Also, please say what steps to take with reference to the Leclanché, which have also failed to work ? Also, how can I tell if a battery is passing a current in the absence of any electrical appliances ?—R. A. G.

[46973.]—**Musical Shorthand.**—Will any reader of the "E. M." inform me if there be a book on writing music in shorthand ?—Phonographer.

[46974.]—**Horizontal Escapement.**—To "Thirds Practical Watchmaker."—Will you kindly tell me what the three dots are for near the balance in Swiss watches, and what you mean by the "draw" or lift in horizontal escap. ? I know it means two different things in lever escaps. I never knew that horizontal escap. had "draw." I always thought they had a "driving" action. Also, if he recommends anyone to press on watch wheels with pointed tweezer ? I use a cut peg. Will he give me a few hints ?—Working Blacksmith.

[46975.]—**To Dr. Edmunds.** — Having been troubled for the last six months with the gravel, I shall be thankful for information which, even if it does not cure, may relieve me. I am 61 years old. Corpulent ; in other respects enjoy good health, and an abstainer for three years.—A Welshman.

[46976.]—**Canary.**—Can any of your readers tell me the best remedy to employ for a canary suffering from asthma ? Every night the respiration of the little wee thing is visibly painful, and the bird gasps and opens and shuts its mouth, and apparently tries to cough. The sufferings are increased by being in a room where gas is burning. In the morning and during the day the bird is cheerful, and sings freely. Food at present : the usual rape and canary with a little maw seed occasionally, a little lettuce or watercress ; have found a little condensed milk a benefit, but not a cure. Will those having experience with birds give a little information ? as the one on whose part I venture to ask for a few crumbs of ease and comfort, is a general favourite.—R.

[46977.]—**Folding Canoe.**—Can any contributor kindly let me know the particulars for making a folding canoe ?—G. J. H.

[46978.]—**Canaries.**—I have had five nests of young canaries this year, about 15 birds. They live from six to ten days, and then die. Will any reader tell me what they think is the cause ? I think the old birds neglect feeding them. I also, like "Old Subscriber," would like a few hints about cayenne feeding.—Merton.

[46979.]—**Etching.**—Will someone oblige by giving some hints on etching on copper and steel plates ?—Rogator.

[46980.]—**Brakes.**—I should be obliged if any correspondent will tell me what brakes are about to be tried upon the Highland (North of Scotland), and Lynn and Fakenham Railways ? Also, should be glad of any details of trials said to be made by the East Lancashire Co. some years ago ? What is the Fay, Newall, and Eames brake, mentioned p. 109 ?—A Driver.

[46981.]—**Verge Turning Collet.**—Will "Fellow-Workman," "Alfojoe," or any other horological reader of the "E.M.," tell me how to make verge turning collet, with sketch of same ? Will it be proper to have it, when on verge, projecting a little beyond foot-pallet to keep pivot-file from coming in contact with pallet when reducing pivot ?—Poor Hand.

[46982.] — **Colouring Screw-heads — Clock cases.**—Will any reader describe the colouring or blueing pot for screw-heads, &c. ? Also, a few hints on the way of making Vienna or American clock-cases.—Steadfast.

[46983.]—**Concrete Bed for Engine.**—I am fixing a new horizontal engine, which will require a bed 3½ft. by 12ft. by 10ft. Would you advise me to make it of concrete ? If so, how should I prepare the concrete ?—Desoridi.

[46984.]—**Hardening Copper.**—Is there any way of hardening or "case hardening" copper ?—Jacques.

[46985.]—**Gilding the Edges of Mounts.**—I have had gilt paper recommended, with the back covered with common gum, and cut into narrow strips and put round the edges. I have tried this way, but I find it very difficult to make stick and lie down evenly. Will some kind reader of the "E. M." inform me which is the best way to gild the edges of mounts, and what is the best composition to put on the back of gilt paper to make it stick and lie down evenly ?—E. L.

[46986.]—**French Locomotives.**—To Mr. Gobert. —Many thanks to Mr. Gobert for his interesting and exhaustive answer to my query. If not troubling him too much, I should like to know whether the Crampton engines, formerly the standard Continental type, are now in general use ? And whether the sketches given in his letter represent the present standard type of French locomotives ? Also, are the inside or outside cylinder engines in most common use, and are single driver engines unused ? Could he also give me a sketch of one or two tenders of the above engines ?—E. E. R. Tratman.

[46987.]—**Tinning or Bronzing Small Malleable Castings.**—I have several hundred small malleable iron castings to tin, or apply a good bronze of a bright brass or copper colour. Can any of your readers direct me in the right channel ?—A. C. Meeker, 321, Larimer-street, Denver, Colo., U.S.A.

[46988.]—**Straightening Shaft.**—Will any of your mechanical readers say how a shaft can be straightened, 2½in. dia., while in its bearings ? and oblige—Wm. H.

[46989.]—**Stoppage in Urinal Pipe.**—Two urinals are used by about 40 persons. The down-pipe for 3ft. is straight down perpendicularly, then passes along the floor, and is 2in. clear in the bore. A small quantity of water is running day and night. Spirits of salts are used now and again to keep the pans in good colour, and once a week two buckets of hot water and soda are passed down. In spite of all this, in 12 months the down pipes close right up with a hard gritty matter. What can be done to stop this ?—J. E. Bird.

[46990.]—**Ship's Compasses.**—Will any friend state the most effective method of magnetising the bars of compasses that do not act ?—the appliances required, where they may be had, and how to use them, and oblige—Horo.

[46991.]—**Wages—Legal Query.**—A man enters employment as foreman engineer in shop, and to serve employer's interest, foregoes payment of wages weekly, works from time to time as required until amount due is about £25. Then applies for payment, and is flatly told that wages are only payable weekly, and unless so paid are not recoverable.—G. H.

[46992.]—**Organ Query.**—Will Mr. Dresser kindly tell me how to arrange a small organ (two manuals and pedal), so that I may build it without runners or castors, and yet be able to get at the key-action and windchest of the swell without taking the whole thing to pieces. Bellows and great soundboard are made, but building-frame not yet put together ; so a hint would be very useful indeed. What is the least space advisable, or allowable between top of swell keys and bottom of great windchest for proper working of backfalls and six rollers ? Also, how much space between under side of great keys and top of bellows (when full) is needed for a set of gt. to ped. backfalls ?—W. C.

[46993.]—**Consumption and Homœopathy.**—Could any of your correspondents inform me of a dispensary or hospital where consumption is treated by Lachnanthes, or is Lachesis the same ? If not, what would be the best homœopathic remedy to take ?—A Sufferer.

[46994.]—**Brass Door-plates.**—Will "Jack of All Trades" kindly inform me of the nature of the compositions, red and black, which are used in making and filling up letters in the above articles ? Is the composition run in hot, or is the plate alone heated, and then all faced off after the filling up ?—Alfojoe.

USEFUL AND SCIENTIFIC NOTES.

A paper was recently read before the South Staffordshire Institute of Mining Engineers, at Dudley, on "Lishman and Young's Patent Air Locomotive," by Mr. Henry Lawrence, of the Grange Ironworks, Durham. The engines, it was stated, were specially adapted for underground haulage, owing to their small size and the perfect control which the driver had over them. Incidentally Mr. Lawrence mentioned their use in fiery mines, and showed how a patent metal had to be used to prevent sparks from being emitted from the wheels when the engine surged at an incline. He submitted for the consideration of the members —(1) Whether sparks would fire gas in a pit, and (2) whether copper rammers were therefore safe, inasmuch as copper could give off sparks. The Government allowed copper stemmers and rammers, and yet these gave off fire upon being struck.

The *Lumiere Electrique* says the experiment has been made of lighting a Rhine steamboat with electric light, and it is proposed to organise a night service of boats lighted by Buergin machines and lamps, which are to be powerful enough to throw from the bows a light that will illuminate the immediate scenery.

Every Workman connected with the Building Trades requiring a situation should advertise in "THE BUILDING NEWS," published every FRIDAY, price Fourpence, at 31, Tavistock-street, Covent-garden London, W.C.

"THE BUILDING NEWS" is the Principal Journal, representing Architects and Builders, and has the largest circulation of any Professional Journal in the kingdom.

Every Workman should insist on seeing "THE BUILDING NEWS" every week at his Club or Coffee House. He will find more "Lists of Tenders" for new work in it every week than in any similar paper, and can thus judge where work is likely to be had. He is also specially invited to make use of "Intercommunication" if he wants to know anything about his trade ; to write to the Editor if he has any suggestions to make and to advertise in the paper when he wants work.

The charge for Advertisements for Situations is One Shilling for Twenty Words, and Sixpence for every Eight Words after.

CHESS.

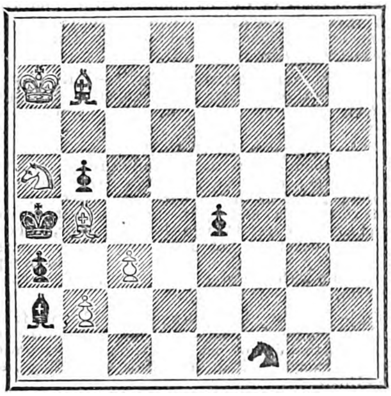
ALL Communications for this department must be addressed to the Chess Editor, at the office of the ENGLISH MECHANIC, 31, Tavistock-street, Covent-garden, W.C.

PROBLEM DCCXLVII.—By C. CALLANDER.

Black.

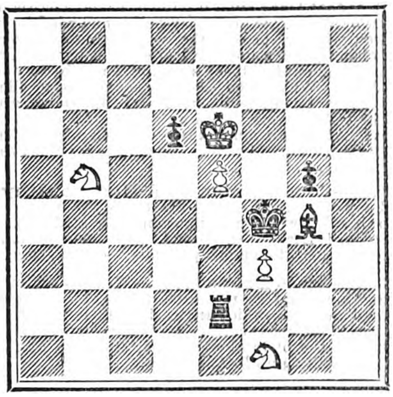


White.

White to play and mate in four moves.

PROBLEM DCCXLVIII.—By H. F. L. MEYER.

Black.



White.

White to play and mate in three moves.

SOLUTION TO 743.

	White.	*Black.*
	1. R takes Kt	1. K takes R (a)
	2. K to K 2	2. K moves
	3. Q mates accordingly	
(a)		1. K to Q Kt 6
	2. Q to Q Kt sq (ch)	2. K moves
	3. R or Q mates	

SOLUTION TO 744.

White.	*Black.*
1. B to Q Kt 7	1. Q takes Kt, R takes B, or P moves
2. Q to K R 7 (ch)	2. B takes Q mate
	1. Q takes R
2. Kt to K B 7 (ch)	2. B takes Kt mate

NOTICES TO CORRESPONDENTS.

SCHMUCKE.—Your solution of 743 is incorrect, for if 1. $\frac{}{\text{Kt. to Q B 6}}$ 2. $\frac{\text{Q to Q 7}}{\text{K to Kt 6}}$. In 744 you have overlooked that if 1. $\frac{}{\text{P-Q 3}}$ 2. $\frac{\text{Q-K R 7 (ch)}}{\text{R takes Q}}$ is not mate, as Kt can take R.

H. F. L. M.—Thanks for enclosures. We will endeavour to see about notice as soon as possible.

W. T. P.—The second game shall be inserted shortly.

H. E. KIDSON.—Thanks for the sui-mate.

Holloway's Ointment and Pills are remedies designedly placed within the reach of all sickly persons, because the treatment is easily applied, certain in its effects, and perfectly innocuous to the most delicate constitution. For all chest complaints, this Ointment rubbed briskly over the ribs night and morning gives ease, and prevents bronchitis, asthma, &c.

ANSWERS TO CORRESPONDENTS.

◆◆◆

⁂ *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or requies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

⁂ Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, May 17, and unacknowledged elsewhere:—

F. W. GREENE.—J. Mounsey.—R. Keith.—Fellow Workman.—J. Parkinson.—F. H. Wenham.—Glatton.—Fred. Walker.—Kautback.—Anxious One.—Ignorance.—Clyde.—F. White.—Volvox.—J. Henshall.—Perthshire Farmer.—J. B. S.—H. T. B.—Ready.—R. R.—J. H. Huxley.—J. R. Brown.

ENQUIRER. (In the absence of any special agreement, yours is a tenancy from year to year, and you are entitled to six months' notice from your landlord, terminating at the time of year at which you took the house.)—READER. (We cannot advise you, as you do not say which branch you propose to enter. We believe Cassell, Petter, and Galpin publish a guide to the Civil Service containing information likely to be of use to you.)—QUIZ. (An air-tight window is what you do *not* want. You require more ventilation in your window, and then the nuisance complained of will cease.)—ANTI HUMBUG. (Your proper course is to sue the company; but you will probably be throwing good money after bad. They are evidently quacks.)—THOMAS PARTRIDGE. (Small quantities could probably be supplied by any of the dealers in microscopic objects who advertise in our "Sale" columns.)—W. HAUGHTON. (We know nothing of the present whereabouts of the person mentioned. We have had similar complaints about him before, but in every case but one, the persons got their goods after more or less delay, or were satisfied by his explanations. We cannot be responsible for the bona fides of correspondents or advertisers, and we advise you and all other readers to adopt the same rules, with regard to business transactions, with contributors to these columns, that you would put in practice in dealing with any other tradesman, or, at any rate, if you see fit to depart therefrom, not to blame us for the result.)—J. C. A. (We do not know of any special works on the subject; but there are lengthy articles in such books as Payen's "Industrial Chemistry" and Ure's "Dictionary.")—ALFRED MEAGER. (Better put the question privately, as it is of no interest to any one but yourself.)—A LANCASHIRE LAD. (Both are correct.)—J. M. (There is no such thing, but you will probably find what you want in No. 801, p. 497. The simplest device is a cistern above the level of the tank. 2. No doubt some of our advertisers would put them in order for you.)—A NEW SUBSCRIBER, Sheffield. (No, a nickel-plating tank should be lined with pure sheet lead, the joints being burned, not soldered. 2. Would not do at all; the copper solution would attack the iron. 3. Look through recent back numbers, or write to the correspondent direct. He advertises castings.)—G. A. MOORE. (We are obliged for your letter, but it scarcely forms a reply of the kind asked for.)—AN AMATEUR M. (Make a size from best white gelatine.)—P. C. (You can introduce the mercury through a glass funnel properly shaped, and small enough to enter the tube.)—NOVICE. (No, certainly not. It is suitable for plating purposes, not for lighting.)—THOMAS H. ROBERTS. (The resistance in wires is directly as the length, and inversely as the sectional area. A thick wire, therefore, offers less resistance than a thin one. 2. Both actions take place, but under any circumstances lightning-rods should be pointed. See article last week.)—J. L. M. (Voss's induction electrical machine was fully described and illustrated on p. 335, No. 846. See also pp. 405, 429, 453, Nos. 849, 850, 851.)—THOS. RICHARDSON. (Messrs. Ritchie, of Edinburgh, we believe, publish a pamphlet descriptive of their system, which was illustrated and described in Nos. 464, 465. If you will look through the indices you will find references to various plans and systems of synchronising clocks.)—JAS. THOMSON. (We presume you mean the Berliner violin. See pp. 256, 303, 336, 355, 404, 475, 547, 568, last volume, especially p. 568, No. 882.)—R. BARRACLOUGH. (You do not give the cubic content of your house, nor the temperature you require to keep it at. The arrangement depicted "will do" for a greenhouse, but we should prefer hot-water pipes. How can we give any idea as to cost without knowing price of gas in your district and the temperature that it is desired to maintain. If you cannot refer to back volumes, procure a sixpenny book on heating greenhouses from the office of the *Journal of Horticulture*, Fleet-street, E.C.)—WIFE OF NEW SUBSCRIBER. (For description of the processes of painting on terra-cotta, see pp. 73, 141, Nos. 861, 864.)—W. G. WOOLCOMBE. (Yes, two names for same thing. 7. Solution of washing soda, potash, or ammonia, benzoline, bisulphide of carbon, turpentine, &c.)—ODINE. (Such a query must appear in the "Wanted" column.)—ARIA. (Such information is not available: it must be calculated. You may find something in papers read before the different engineering societies, and also in articles in our back volumes. See the indices of recent volumes.)—SEFTON. (It is simply impossible for any one to say "what is wrong" when you do not describe the arrangement. From what you say it would appear that the battery is not strong enough, but we have no idea where you place the carbon. 2. See recent numbers for replies to the second query.)—ALASKA. (Probably produced by the friction of the particles of steam, but we are in doubt as to what you mean.)—A GLASGOW READER. (Use solution of indiarubber, made by dissolving in bisulphide of carbon or mineral naphtha.)—ELECTRICIAN. (If you will look through the last ten volumes you can take your choice of a great variety of telephones. The ohm is the unit of resistance, and for all practical purposes may be taken as the resistance of one foot of copper-wire 3·117 mils. thick. The zinc is the positive element, and the wire from the carbon the positive pole.)—A. W. REED. (In the first number of this volume, p. 5.)—CALEDONIAN. (Every portion of the "bends" must be above the level of the pipe where it returns the water to the boiler, for if any part is below, water will accumulate. The whole system of pipes being above the level of the inlet to the boiler, the pressure will be equal, and the water finds its way back by gravity.)—J. ELYOT. (Any ordinary closed stove, with a pipe leading into chimney.)—H. D. (Tinplate will do, but pewter lasts longer. Salt and ice will do for freezing mixture, or you can use one of those given on p. 546, No. 646.)—NEW BEGINNER. (You should look through the indices. There are many in back numbers. Perhaps that on p. 404, No. 875, will suit, or one on p. 496, No. 879.)—W. P. (See the index to Vol. XXXIII., under head Hard Soldering, &c. Both questions frequently answered lately. For whitening, heat to a good red, and boil in a mixture of sulphuric acid 1, water 40.)—W. H. (See pp. 469, 493, Vol. XIII., and pp. 425, 567, 592, Vol. XXXII. Vulcanite is a preparation of sulphur and indiarubber, which becomes hard when subjected to heat and pressure.)—CHURCHMAN. (It would occupy too much space to explain the differences in construction. They have been adopted with the view of obtaining the best results. No, to the other questions. For the chair-covers, see p. 194, No. 840.)—VILLIGE BLACKSMITH. (Your communication is incomprehensible.)—G. M. B. (Sprague's "Electricity," published by Spons; Thompson's "Electricity and Magnetism," Macmillans. 2. We do not know of any works on the other subjects.)—GRAVER. (You should fill up with asphaltum varnish or with copal and lampblack worked thick. We know of no book specially devoted to the subject.)—LONG TOM. (An ordinary forge will do; the dimensions are immaterial. See pp. 73, 95, last volume.)—J. T. C. (Give up drinking and smoke less, and consult a medical man *at once*, or very probably you will not have need to do so.)—A MOTHER. (Try the application of pernitrate of iron. There is no *quick* cure. 2. The application of a little vaseline will soon remove the roughness complained of.)—J. W. (You must be a very recent or very irregular reader if you have seen no account of the Crystal Palace Electrical Exhibition in these pages. See pp. 509 and 609 of last vol., and p. 23 of this. Many others are as desirous as yourself of obtaining a small cheap and effective dynamo-machine. The difficulty is the combination of these requisites.)—E. B. L. (Possibly the waterproof blacking given on p. 69, Vol. XXX., would suit you, or here is another, which, however, we have not tried: Mix intimately together three or four pounds lampblack and one half-pound of burnt bones with five pounds glycerine and five pounds syrup. Then gently warm 2½ ounces of guttapercha in an iron or copper kettle until it flows easily; then add 10 ounces of olive oil, and when completely dissolved, one ounce of stearine. This solution, while still warm, is poured into the former and well mixed. Then add five ounces gum senegal dissolved in 1½ pound of water and ½ ounce of lavender or other oil to scent it. For use it is diluted with three or four parts of water. It is said to give a fine polish, to be free from acid, and that the glycerine keeps the leather soft and pliable.)

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post-free to any part of the United Kingdom. For the United States, 13s., or 3 dols. 25c. gold, to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 3d. each to cover extra postage.

Messrs. JAMES W. QUEEN and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post-free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. XXIV., XXVI., XXVII., XXVIII., XXIX., XXX., XXXI., XXXII., and XXXIII., bound in cloth, 7s. each.
[Vol. XXXIV. Now ready.]

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in March and September, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d each, through any bookseller or newsagent, or 2½d. each, post-free from the office (except index numbers, which are 3d. each, or post-free, 3½d.)

Indexes for each half-yearly volume up to Vol. X. (except Vols. II., III., IV., V., and X.) inclusive, 2d. each. Post free 2½d. each. Indexes to subsequent vols., 3d. each, or post-free, 3½d. Cases for binding, 1s. 6d. each.

⁂ Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The regulations of the post-office prevent their transmission through the Post.

The English Mechanic

AND

WORLD OF SCIENCE AND ART.

FRIDAY, MAY 26, 1882.

ON WIRE CHUCKS AND SMALL SCREWS FOR METAL-WORK.

By F. H. WENHAM.

THERE are now several workshops established in this country, devoted entirely to the construction of small screws of every size and description, made either of brass or steel, for watch, clock, and philosophical work, and therefore manufacturers in these lines seldom find it worth while to make for themselves, as they are obtained at a very low price from those who have the proper machinery, and make a speciality of the business.

It sometimes, however, happens that the amateur constructor requires a number of particular screws, all of one pattern, and would prefer to make them for himself. My object in writing this article is to offer some information that may expedite their construction by means of the ordinary foot-lathe.

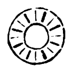

FIG. 6.

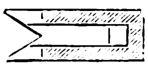

FIG. 8.

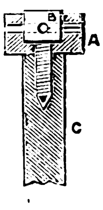

FIG. 7

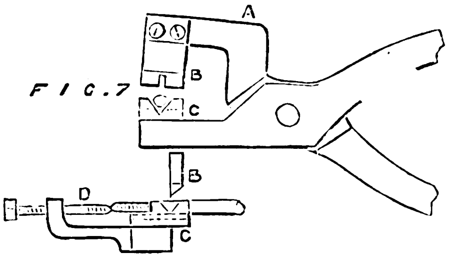

FIG. 9

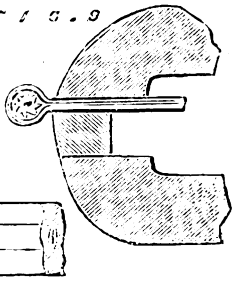

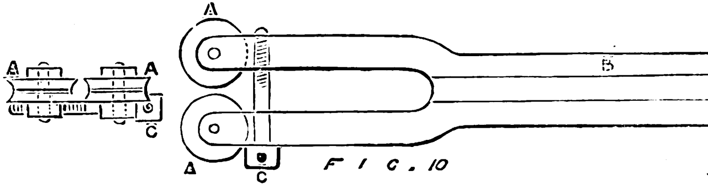

FIG. 10

The first part of the question relates to the chucks for holding the wire. The old-fashioned "die chuck" consisting of a pair of dies sliding in a dovetail block, and brought together by two opposite screws, is well known: this is strong, simple, and enduring, but rather limited in its range for different sizes of wire, so that several chucks are required. The American scroll and other wire chucks are more universal, but too refined for the rough and constant use of a busy shop, and when they do give way, no amount of patching will renew their strength; in fact, effective repair is almost impossible. I am cognisant of one large workshop that a few years back was liberally provided with these chucks of various sizes, not one of which is now in use: they have all broken down.

I visited a manufactory in Paris where they made nothing else but screws for metal-work, and I there noticed a form of wire chuck in use which seemed both strong and enduring, and as it may not be generally known to the readers of this journal, I give a description. Figs. 1, 2, and 3, are a front view, section, and plan. A is the body of the chuck made of cast-iron, and screwed to fit the mandrel; a transverse dovetail groove is cut on the face, into which is fitted the sliding steel-block, B; a hole is cut clear through this of the form shown in the front view, and at the back of the slide a square-sided groove is planed out to meet the through hole. This admits the parallel tail-piece of the steel angle-jaw, C, the short end of which is made flush with the face of the chuck. The notched apex of the chuck is hardened and tempered, as is also the lower portion of the sliding block. All these pieces should be nicely fitted without shake, and made so that the opening and sliding jaw falls true in the centre line. The work is clipped by the screw D, tapped through the sliding block B, and bearing on the back of the jaw C. The chuck as shown (half size) will take in a ⅝in. rod down to a 1-16in. wire. Of course, if the chuck is made true, the wire is always clipped true across the centre in one line; to bring it true crossways, the slide-block B is shifted to the point required, and clamped fast by the side-screw E. The adjustment for one size, therefore, always remains exactly in the centre. The grip action comes close to the face of the chuck; all the slide bearings are broad, and consequently the chuck is strong and stands wear well.

Small screws are most frequently made by shifting a short piece of wire forward each time in the chuck, and regularly turning them up one by one; but unless the mandrel is bored throughout (which every mandrel should be), the process is a wasteful one, besides taking up much time.

The following method of working up long pieces of wire into screws is preferable, as by it they can be made very expeditiously. The length of wire is held fast at the mandrel end by a wire chuck. A brass plug *a* is fitted into the sliding socket B of the shifting centre. Into this brass is driven centrally a hardened steel tubular cutter of the form Fig. 4. The hole in this cutter is drilled out to the same diameter as the barrel of the intended screw, and the projecting end of the cutter is filed into radial notches (Fig. 5), with sharp edges—this is for square-headed screws; but if the screws are to be countersunk, or have angular heads, the end of the cutter is to be filed across with a small triangular or "three-square" file in two directions, at right angles (Fig. 6); this will carry four cutting edges from the circumference down to the bore, and form the chamfer required on the underside of the head of the screw. The bore of the cutter should be deeper than the longest screw to be made, as the proper length can then be obtained by dropping in short plugs of steel wire, more or less according to the length required for the work.

The mode of procedure is as follows:—Bring the cutter up to the chamfered end of the wire by sliding the loose head along the bed of the lathe by hand-pressure. A few turns will shave off the metal till the point of the wire butts upon the stop-piece in the bore of the cutter. Slide back the head, stop the lathe, and turn the reduced end of the wire into a screw-plate held in the hand. When screwed up sufficiently, run the plate off by reversing the lathe. The next thing to be done is to cut off the piece behind the head to the exact length of the screw. For this purpose the following form of cutting nippers is needed. A (Fig. 7) is the end of the instrument, representing a stout pair of pliers (a pair of leather punching pliers may be converted into this tool). On the side of the upper jaw is screwed a hard plate of steel B, chamfered at an angle of about 60° at its lower edge. C is a block of steel attached to the lower jaw of the pliers, having a V-groove cut across it transversely. This block is notched across where the upper cutting plate falls, so that its edge may reach near the bottom of the V-groove. When this instrument is nipped upon a rotating wire a piece will be cut off with a flat top, leaving a chamfered end on the stock wire exactly true with the outside, so that when it is again entered into the tubular cutter the barrel of the screw will be cut concentric with the exterior. The edge of the cutting nippers will do its work if left plain; but it is better to make a saw notch in it exactly in the centre of the V-groove.

The length of the screw cut off, inclusive of the head, is determined by a set or stop screw, tapped through a spring nut at the end of the V block. It will be seen that by this method the blanks may be made very rapidly. The longest part of the time is taken up by the screwing. This might be expedited by using clam dies set in the end of a pair of nippers to be opened as soon as the screw is run up to a sufficient length. The lathe need not then be stopped during the process of screw-making.

A common way of making the notches in the heads of these screws is to drill a hole through a plate of brass or steel the size of the barrel of the screw, and then drill another into this to let in the head, which should sink below the top of the plate. A saw-cut is taken diametrically across, deep enough to limit the bottom of the cut in the screw-head. The screw is dropped in, and a few strokes of a fine-tooth saw is given down the cut in the plate till the teeth come to the bottom; it is better to make the saw-cut across the piece of metal before drilling it through, as then a small drill fitting the cut is sure to carry the hole midway in the centre, in which the larger or gauge-drills will follow.

If the screws are required to be capstan-headed, such as are much used in philosophical work, the cross holes in the head should be made with the following tool (Fig. 8). A is a hardened circular steel block, with a central cavity, B, to admit the head and shank of the screw. Two cross holes are drilled diametrically through the block; the projecting end of the screw passes through, and is held tight up in place by means of a tapped piece of brass rod, C, below, which serves as a handle. The use of the instrument is this: the screw thus firmly secured is drilled through the head at right angles, by passing a drill running in the lathe into the hole on one side of the block, which it nearly fits, and forcing it up by the centre set in the opposite end of the hole; it is best to carry the drill only half-way through the head, and finish by reversing the handle, as there is then less chance of injuring the drill or work.

In the absence of the foregoing arrangement, another method may be mentioned for working up a piece of wire into screws without any trouble about centring. In place of the iron T-rest, insert a turned cylinder of hard wood in the socket; file a V-notch across the top of this wood; secure the end of a wire, the diameter of the head of the required screw, on to the mandrel, by screwing it into a piece of metal, or otherwise, and lay the other end of the wire into the V-notch, bringing up the centre as a pointer, to show that the wire runs in the axis; if not, raise the wood in the socket, and shift this crossways till it does, then clamp fast; hold the wire down hard into the groove by means of a flat piece of wood with a hole in it, for the wire to pass through. This, of course, is held down close to the V-cylinder on the side next to the mandrel. A graver is used overhand for forming the barrel, trimming the head, and cutting off the screw after the thread is cut, the top of the wood itself serving as rest. This simple cylinder of wood is most useful for pointing wires, turning the ends, or sinking the centres for drilling up. This kind of work is generally too small for the cone-plate as usually supplied with every complete lathe, but it may often happen that the V-groove is not sufficiently rigid, or the form of the work will not allow it to be used, such as in forming a point or pivot, or in drilling up a piece of pinion wire. In this case, take a narrow strip of sheet-brass, bend it round the pinion wire, and pinch it close in at the neck; clamp the end down over the top of the T-rest by means of a cramp or hand-vice, as shown by the sketch, Fig. 9; leave as much of the end of the wire projecting as may be required to work upon, using the ordinary graver as a turning tool. If, however, the wire is to be drilled up, it need not project.

Oftentimes vast numbers of wires require to be screwed up a considerable distance, for the construction of some instruments, such as piano-work: it is important to effect this rapidly without any strain that will cause the wire to bend or twist. The following form of dies will effect this at one fixed cut, however deep the thread or coarse the pitch may be. A A, Fig. 10, are two circular pieces of steel similar to a pair of milling wheels, set so as to rotate freely in the ends of a forked steel holder B; this is split up and slightly elastic, so that the wheels can be brought nearer together by means of the set-screw C. The cutting teeth of the wheels are formed by running a tap or hob in the lathe, clamping the stem of the instrument in the slide-rest, and bringing this up so that the hob gradually enters between the wheels; these, of course, rotate, and are brought together by means of the set-screw till a full thread is obtained; the wheels are then taken out by driving out the hardened pin centres; they are set on an arbor, and a groove turned in each at the bottom of the hollow, and finally hardened and tempered.

The use of this strange form of diestock is as follows: it is packed and set fast in the slide-rest, so that the bore and partition of the wheels fall exactly in the centre. A piece of wire, either long or short, is held by a wire chuck or otherwise; the free end is entered between the dies; these at once commence to rotate in opposite directions, and being well fed with oil, begin to cut a screw at the end. But this will go no further till the slide-rest is advanced, which may be done as slowly as proper, and as far as the screw required. When finished, turn the rest quickly back, and the wheel dies roll clear off the wire. The lathe is not stopped during the cutting of the thread, and however deep this may be, the work need not be strained, as of course the cut is a very gradual one, depending upon the rate at which the slide-rest is advanced.

As it may not always be possible to rotate long wires, the wheel dies should in this case be set on a block or chuck running with the mandrel; the ends of the long wires are then passed through a clip socket, fixed in the slide-rest, and advanced forward to to the length of screw required, which may then be released and instantly drawn out.

ASTRONOMICAL BIBLIOGRAPHY.*

AN astonishing monument of the most extraordinary industry and patient research lies before us in the shape of the Second Volume, only just completed, of the magnum opus of MM. Houzeau and Lancaster. The design of the Belgian Astronomer Royal and of his Librarian embraces a complete list of all extant Astronomical Works, of Memoirs on Astronomical subjects which have appeared in the *Transactions* of learned societies, reviews, journals, &c., &c.; and of all observations of which any record exists, and of the Observatories in which they have been made. Commencing with their Second Volume, our authors have furnished us in its 2225 pages (!) with a practically exhaustive list of everything having reference to Astronomy which has been published in the form of essays or papers (included, that is to say, in other works) for the last 440 years. It is needless to point out to the student of Astronomy the great value and importance of such a work as this. To whatever branch of the science he may be devoting himself, he will find in MM. Houzeau and Lancaster's wonderful Thesaurus the fullest reference to everything that has previously been accomplished. He is, for example, pursuing some investigation into the Motion of the Solar System in Space; he turns to pp. 675 et seq. of the "Bibliographie," and there finds no less than 57 references to memoirs on this subject, with the most ample details as to the dates, the publications in, and the pages on, which they have appeared, together with the authors' names, &c. Or he is engaged in the study of the surface of the planet Jupiter; and here again, our authors supply him (on p. 1362 et seq.) with 25 closely-printed columns containing a similar catalogue of descriptive papers on this particular subject, beginning with one by Kircher, in 1646, and concluding with Mr. Dennett's letter (18474) on page 37 of our own XXXIIIrd Volume. A supplementary list, we may note, on pp. 1736 and 1737, brings this down to the date of the latest monograph issued from the well-known Observatory of Dr. Von Konkoly, at O'Gyalla, in Hungary. In cognate fashion will be found the fullest and most accurate lists of all that has been published concerning everything (at once the most recondite and most familiar) pertaining to the study of Astronomy. The temperature of space; a resisting medium; cosmogony; the Lunar theory; shooting stars, meteorites and aërolites; spectral photography; scintillation; the optical effects of diffraction; the Zodiacal light; the figure and rotation of the planets; the stellar universe; and the Calendar are a few—a very few indeed—of the subjects on which such information is supplied. We cannot conclude our brief notice of this noble work without the expression of our gratification at finding the ENGLISH MECHANIC so largely and frequently quoted in its pages. In a paragraph in their introduction, devoted especially to thanking those to whom M. Houzeau and his confrère are indebted for materials, we find mention of the fact that the Public Library of Antwerp placed its set of this Journal at their disposal. We can only express our hope and belief that the future Astronomical contributions to our columns may render our volumes, in time to come, as worthy of a place in the Bibliothèque of the ancient Flemish city, as they have been held to be in the past.

CART AND WHEEL-MAKING.—XVI.

(*Continued from page* 187.)

By J. CHARLES KING.

THE narrowest lines of relief are called "fine-lines," and require experience and judgment in placing them appropriately to the other lines of relief, either in the centre of the work, or on the mouldings, or on the edges, or near the edges of other lines. These lines are mostly those which terminate in scrolls or flourishes, when used. The "picker-out," or "fine-liner," whichever designation may be used for this workman, is the head workman, par excellence, if not in responsibility, in a paint-loft.

Good sight, firm hand, and sensitive touch are not the only requisites for this workman, but a knowledge of the harmony of colours and their manipulation from pigments into paints is indispensable. The band lines are painted with a swan's quill pencil, stripes and lines with sable or camel's hair pencils of suitable sizes. These pencils have the hairs from 1in. to 2in. long, and are held with thumb and finger of either hand, according to the run of the work to be done, the middle, third, or fourth finger serving to guide and regulate the distance of the lines from the outline edges of the work, whether of body or carriage. The dexterity of the carriage-painter in laying on these lines is surprising, and only to be acquired by much practice. A first-class carriage, with much fine-lining or picking-out about it, is estimated to have more than a mile's length of lines painted on it. The eye is directed always to the heel of the picking out pencil; there, the pressure, or slight defection sideways of the pencil by the thumb and finger determines the course of the line and its thickness. The guide fingers have sometimes to pass over inequalities, or spaces with nothing for their rest or guide.

From practical observation I have found the eyes have a power of *divided observation*, one looking at the *intended course of a line, the other at the line just completed.* For some fancy scroll-work a rest-stick may be used, though it is not often. For curved lines—away from any edge to guide the fingers—a guiding edge may be formed of a piece of $\frac{1}{4}$in. bent brass wire, which may be altered to any requisite curve, and allowed to rest lightly on the moulding while used. A few words upon the difference in the hair of brushes and pencils may be of interest and service to a workman. Although the microscope with its wonderful power was unknown to the ancients, they knew the distinction between hair and wool, and their suitable application. We have no record of ancient brushes, but ample traces of their use in the painted views of scenes and events, &c., in Egypt, India, and China, whose people gathered the grains of gold in their auriferous streams by means of a wool-fleece that caught the metal, but which allowed the grains of sand to be washed away by the flow of water. A camel's, tiger's, or dog's skin would have been useless. Thus the story of Jason and the "golden fleece" was but one of many simple yet tangible records of the processes of art and industry concealed beneath the embellishment of old Grecian fiction. It is inaccurate to say that the gold clings to the fleece—it is the fleece clings to the gold, as is obvious upon viewing the difference in the formation of wool and hair by the microscope. This difference determines the utility of hair for paint-brushes. The bristle of the hog, like the hair of the Caucasian type of man, consists of overlapping scales. These are termed imbrications, from *imber*, a shower, and *imbrex*, a tile. The imbrications are closely fitting scales in the bristle, which become finer and closer near the point.

---

*Bibliographie Générale de l'Astronomie, ou Catalogue méthodique des Ouvrages, des Memoires, et des Observations astronomiques publié depuis l'origine de l'imprimerie jusqu'en 1880. Par J. C. HOUZEAU et A. LANCASTER. Tome second : Memoires et Notices. Bruxelles : Xavier Havermans. 1882.

Those of sable-hair are long, pointed, overlapping scales, scarcely projecting from the surface at the point of the hair. The camel's hair is again different, but by the peculiar set of the imbrications admirably suited to hold and release colour.

Badger-hair more nearly approaches the human hair in appearance. Siberian ox-hair is nearer like the bristle. The imbrications on wool, or the hair of the Negro type of man, project from the stem like the sprouting leaves up the stem of a palm-tree. Such wool or hair will readily cling to the rough surface of grains of gold, and would hold paint in the same way, but would not allow it to flow from it freely like hair or bristle does.

Bristles have a natural taper-point, mostly split into three: these points are ground off when made into brushes. The brushes should be tied up with these taper-points gradually overlapping each other for some distance from the point of the brush, as well as being ground mechanically to a level surface of hair. If brushes were made scientifically they would give greater satisfaction. Sable-hair is considered best for straight lines, and camel's-hair pencils for curved lines. The sable-hair is slender near the root, covered with long, pointed imbrications or overlapping scales, about ten of which form a complete whorl or ring. The fibrous portion is moderately thick, inclosing a double row of roundish cells. The camel's-hair has imbrications that project but little from the surface, and a different internal construction. These hairs, while taking up paint readily, hold and part with it easily. Wool or grass fibre do not take up paint easily; but when charged with paint part with it with difficulty, by the reaction, under pressure, of the projecting imbrications; for this very reason, making this wool or grass preculiarly well suited for clinging together for weaving or felting. One simple test for brushes and pencils is to dip them in oil-colour, and then rinse the colour out with turpentine. If much of the colour still clings to the brush or pencil, it is not well adapted for the flow of paint. Before treating of varnish, it may be as well to explain how some painters avoid having to face-off much of the surfaces of the three final coats of colour, except to give it what is called an egg-shell dulness of surface, yet positive smoothness without polish, and yet use very little pumice-stone dust: it is simply because they insured the surface being smooth by the colour being freed from clots of oil, varnish, or turps, fine hairs, or dust, by straining their colour through fine wire sieves. This is particularly necessary in the use of colour in which varnish is to be mixed to make glaze-colour, also in all the mixed colours that precede glazing, also with lakes, ultramarine, mauve, or any brilliant colour without much body or solidity is painted. Glazing with one colour on another produces beautiful and delicate bloom of tints, slightly analogous to the differing tints of colour in the warp and weft of silk, producing "shot-silk." A learner must practise much before he can succeed in producing a good effect, even on a small surface, without dense, cloudy, or streaky places. Such glazing, with the same colour over the previous coats, must be done with care, and when two coats are laid on, the *first coat* is mostly left without being faced-off, for fear the thin surface of colour should be cut through, and show the former coat. The facing-off is mostly done to the *second coat* of colour; but with properly filtered colour, the first coat may be faced-off very lightly, with advantage. In varnishing a glaze-colour, in most cases, pick-out on the glaze, when picking-out has to be done. All colour, even the filling-up, should be strained; the preparing colour through wire sieves of a mesh of 60 wires to the inch, and the fancy colour through sieves of a mesh of 80 wires to the inch, according to the class of work to be done, or the amount of varnish in the fancy colour which is used, either for quickness of drying for facing-off, or for glazing. If there is any difficulty about getting the wire gauze, "foundation-muslin" is exactly adapted for the job, and serves as well for ensuring purity of texture in the fluid-colour, which must, if laid-on and laid-off as already directed, insure a good painted surface for varnish to cover, and show well upon, when hard. It is singular that the carriage-makers, who take such laudable pride in their work, and succeed in producing painting which has renown all over the world, should attain the same result by different processes, and by the use of different appliances. Thus, in one shop paint-mills are used, but not sieves; in another sieves have never been heard of, or mills never tried; in another, perhaps, tried and thrown away, as they would get foul, and choked-up with dried colour. This points to the necessity of standard works of reference—technical, not merely scientific—such being published for the use of masters and men, with descriptions of the appliances and modes of operation, of which long and varied experience in the craft has proved the value; and, where it is possible, to have these appliances on view, at the Coachmakers' Hall or any suitable place within reach of workmen, always supposing the officials of such expositions have the technical knowledge to understand the use of these appliances, and are able to explain them.

The fact that the paint sieves *do get foul*, is an admission of uncleanliness of the users. Such men let their varnish brushes get "lousy," as the term is for dirty varnish-brushes. Of course a sieve would need cleansing as soon as done with, and if of brass wire, the wire part should be kept standing in a dish of clean water; if of muslin, it has to be washed with turpentine, brushed quite clean, and hung up to dry thoroughly, ready for instant use. It takes time to work the colour through the sieve; but the gain in easy flatting, or facing-off, and in the finish of a job, amply compensates for the trouble.

A sieve is not at present a stock tool; each painter makes his own at a trifling cost. When its value is better known, doubtless a small filtering-sieve similar to "Stapfer's paint, varnish, and oil-filtering machine" will become general, on accout of its simplicity, and ease of cleansing the sieves, and changing the discs of one sized mesh for another; also for pressing the paint quickly through the sieves without the risk of straining the texture of the wire or muslin used.

In facing-off a surface to prepare it to receive another coat of paint or varnish, be sure not only of having a *pail of clean water, but a clean pail* for the water. Water, however clean, may be soiled by a dirty pail, and thus cause scratches or soil the surface of the paint or varnish. In facing-off a surface with finely sifted pumice-stone dust, a piece of sponge is better than cloth for the mouldings, as by its softness it enters the corners, without pressing too hard on the edges of angles, or prominent parts of the mouldings, which with cloth are apt to be rubbed through one or more coats of paint. A paint-shop should be as clean as a dairy, and plenty of fresh water is needed to insure work being well and quickly done, more especially in washing off newly-varnished carriages, to get them ready for another coat of varnish, or for use quickly, if the carriage be wanted out in a hurry.

It may appear a contradiction of terms for a foreman to say to a painter, "You will never get that varnish hard and dry in time, unless you wet it more, and use plenty of water to the job"; yet it is so, and *fresh water* must be used. The same water used over and over again is not sufficiently pure, for this reason—paint and varnish dry and harden by the absorption of oxygen and the action of the light. Water contains from 13 to 14 per cent. more oxygen than the air; by flowing water over paint or varnish the oxygen becomes absorbed to a considerable extent each time of contact of the particles; thus is done quickly and fairly, the drying which the air would do slowly, but surely.

Varnishing is less a craft mystery or highly critical process than most of the foregoing processes of painting, unless it be that of glazing with one colour over another. The good or evil of painting is all done before the varnish has to be laid on; if good, the varnish-makers' wares have a good advertisement; if bad, the varnish-maker has the blame, due in most cases to the incompetence of the workman, of his ignorance in the application of the previous coats of filling-up and paint alluded to in the early portion of these remarks.

Varnishing, like the other processes, requires the keen eye and firm touch which has acquired dexterity in the use of the brush and tool with either hand. It need hardly be said that the tendency of varnish to flow downward necessitates the care in beginning at the top and laying on lightly at the bottom edges of the panels, while, if too much varnish is used, it gets into the "quirks" and corners, and will daub them up and produce a shrivel of the overflowing varnish. A small pointed tool, without any varnish, held in the resting hand, serves to clear away the excess at once.

Light and air promote rapid drying, so as to admit of the varnish being faced-off within a day or two. Fine pumice-stone dust, that has been carefully sifted, and water is used to level any slight crudities that may mar the surface. A piece of sponge is best for mouldings, and cotton cloth for panels, the same as recommended for the facing-off the fancy colour. If, by chance, the varnish be rubbed through into the colour anywhere, the workman who does it is a bungler or a tippler, and will never make a good painter.

As soon as dry, another coat of varnish may be put on; this, when dry, to be faced-off the same as the first coat, unless in haste to get the work out; then the facing-off may be left undone, and the third coat of varnish can be put on with care over the other, just as it is dry enough not to feel "tacky" to the back of the hand. The fingers should never be used to try if a panel is dry or not.

One wash-off with very clean water, using a new paint brush and clean sponge and leather, after the varnish will bear it, helps to harden the surface, and prevent a carriage spotting so readily when first used and mud may have dried on the panels. Successful varnishing depends upon cleanliness and good brushes, as well as upon the weather favouring rapid drying.

A well-worn and oval-shaped bristle brush is good for all purposes; but a finishing coat of varnish had better be put on with a badger's-hair brush if the bristle brush is not in first-rate condition. The same rules apply to "tools" of various sizes. The best manner of keeping these brushes and tools in order is to suspend them by a piece of wire passing through holes in the handles, so as to have them hanging in the varnish in cans by means of a hole in a cardboard cover to the can, through which the brush-handle projects. The varnish should reach up to the tying-up of the brush-hairs.

The same rules of painting apply to japan, which is but prepared black varnish, to be used over parts that are black. The objects obtained by its use are the same as any other prepared paint: a uniform density of colour, economy, and speed in drying; as it is specially manufactured with driers, which rapidly absorb oxygen, and cause the hardening of the liquid particles of japan, leaving a lustrous surface, which may be made to take the place of the colourless varnish or not, as the work in hand demands.

Japan requires either gradual drying in an equal temperature, without sun glare or draughts; or it must be, for some purposes, "ovened," or baked quickly while the japan is still almost flowing. Japan, like varnish, should always be tested by painting on a piece of glass, and leaving to dry, washing several times and exposing to sunlight, draughts, or frost; you will then, with the naked eye, be able to see if it reveals any fine cracks, or changes colour, or loses lustre; if it does not it may be safely used.

But the varnishes and Japans of English makers have so high a standard of excellence that it is only in case of failure or doubt that recourse need be had to this ready test.

(*To be continued.*)

ASTRONOMICAL NOTES FOR JUNE, 1882.

The Sun.

Day of Month.	Souths.	At Greenwich Mean Noon.		
		Right Ascension.	Declination. North.	Sidereal Time.
	h. m. s. a.m	h. m. s.	° ′ ″	h. m. s.

6	11 58 21·63 ,,	4 57 33	22 40 36	4 59 11·01
11	11 59 19·09 ,,	5 18 13	23 6 20	5 18 53·79
16	0 0 22·14 p.m.	5 38 59	23 21 54	5 38 36·58
21	0 1 27·42 ,,	5 59 47	23 27 10	5 58 19·37
26	0 2 31·63 ,,	6 20 34	23 22 7	6 18 2·15

The method of finding the Sidereal Time at Mean Noon for any other station will be found on p. 390 of Vol. XXXIV.

At 1 p.m. on June 21st the Sun is said, technically, to enter Cancer, and summer is then supposed to commence. This is the longest day, the Sun in London remaining 16 hours and 34 minutes above the horizon, and, of course, only 7h. 26m. below it. At this date, and for a day or two before and after it, the Meridian may be determined with considerable accuracy by the method of equal altitudes. During the month of June there is no real night in any part of the British Islands. Large and complicated groups of spots, faculæ, and prominences continue to appear on the Sun's disc.

The Moon

Is Full at 8h. 33·2m. p.m. on June 1st, and enters her Last Quarter at 5h. 9·4m. in the afternoon of the 8th. She will be New at 6h. 33·1m. p.m. on the 15th, and enter her First Quarter at 6h. 1·3m. p.m. on the 23rd.

Day of Month.	Moon's Age at Noon.	Souths.
	Days.	h. m.
1	15·2	12 6·2 p.m.
6	20·2	3 51·5 a.m.
11	25·2	8 8·7 ,,
16	0·7	0 39·3 p.m.
21	5·7	4 30·3 ,,
26	10·7	8 8·0 ,,

The Moon will be in conjunction with Saturn at 6 a.m. on the 13th; with Jupiter at 8 p.m. on the 14th; with Mercury at 2 a.m. on the 17th; with Venus at 10 a.m. on the 18th; and with Mars at 6 p.m. on the 20th.

Mercury

Attains his greatest elongation east (23° 27′) at 10 p.m. on June 1st, and comes into inferior conjunction with the Sun at 6 a.m. on the 28th, between which dates he will obviously be an Evening Star, becoming subsequently a morning one. At the beginning of the month he does not set until about two hours after the Sun, and may be found with the naked eye at dusk glittering near the N.W. horizon. He is, further, as well situated as he possibly can be for the observer with the telescope. His angular diameter increases from 8″ on June 1st to 12″ by the 26th, insensibly diminishing afterwards.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	6 19·2	25 3·2	1 39·5 p.m.
6	6 37·0	24 2·6	1 37·5 ,,
11	6 46·9	22 45·9	1 27·8 ,,
16	6 48·7	21 24·3	1 9·9 ,,
21	6 42·7	20 9·0	0 44·3 ,,
26	6 31·5	19 11·1	0 13·4 ,,

From which it will be seen that Mercury describes a pendulum-like path, which is wholly confined to the constellation Gemini.

Venus

Is an Evening Star during the whole of June, and is well placed for the observer. She is now very markedly gibbous, but is scarcely yet a very interesting telescopic object. Her angular diameter increases from 11·2″ at the beginning of the month to 12·6″ by the end of it.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	6 28·0	24 41·5	1 48·2 p.m.
6	6 54·5	24 23·7	1 55·1 ,,
11	7 20·9	23 48·3	2 1·7 ,,
16	7 46·8	22 55·9	2 7·9 ,,
21	8 12·3	21 47·4	2 13·6 ,,
26	8 37·3	20 24·1	2 18·9 ,,

As indicated by the above Ephemeris, Venus will, during June, cross nearly the entire width of Gemini into Cancer. On the 9th and 10th she will be rather more than 1° North of δ Geminorum, while on the 24th she will be in the same low-power telescopic field of view as η Cancri. Two days later she will be south of γ Cancri.

Mars.

Is now too near the Sun to be fairly seen; while

Jupiter and Saturn

are actually immersed in his rays.

Uranus,

To be seen at all, must now be looked for the moment it is sufficiently dark. Our Ephemeris of him will be discontinued after this month until 1883.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	11 4·0	6 49·9	6 23·5 p.m.
6	11 4·2	6 48·4	6 4·0 ,,
11	11 4·5	6 46·4	5 44·7 ,,
16	11 4·9	6 43·8	5 25·4 ,,
21	11 5·3	6 40·8	5 6·1 ,,
26	11 5·8	6 37·4	4 47·0 ,,

Uranus will thus travel slowly towards σ Leonis again.

Neptune

Will not return until the autumn.

Shooting Stars

Are rare in June, but may be looked for on the 6th and the 20th.

Occultations of (and a near approach to) Fixed Stars by the Moon.

WATCH-CLEANING AND REPAIRING.

By "A Fellow-Workman."

(*Continued from page* 210.)

Horizontal Watch.

When I say, "Horizontal watch," I mean a "Geneve," which is really a horizontal movement; but what is known to the trade as a "horizontal watch," is similar to a verge movement, only the escapement is different, it having a 4th wheel in place of contrate, and the 5th wheel being a *brass* escape-wheel, it looks very much as though a verge watch had been converted into a horizontal; but it is not so. I believe it was the first introduction of the horizontal movement into this country; but as they are very rare, and are really a mixture of verge and Geneve, I do not think it necessary to say any more about them.

Fig. 51 represents the *back* or *top* view of a "bar Geneve." The dotted lines show a ¾-plate. A is barrel bridge, B barrel, which is called a "going barrel," in consequence of the teeth being on the barrel, which does away with fusee and chain; C click, D ratchet cover, under which is the ratchet, E is click screw, F centre-wheel, G is set-square and arbor, H centre bridge, I 3rd wheel, J 3rd bar, K 4th, or seconds-wheel, L 4th bar, M escape or steel wheel, N banking-pin, O balance, P are dots, which act as a guide for putting watch in beat, Q is hairspring stud, R regulator, S jewel cover, T tension or curb-pins in end of regulator, U cock-bar, V screw for holding movement in case, W steady-pins for same purpose, X hairspring, Y escape bar.

FIG. 51

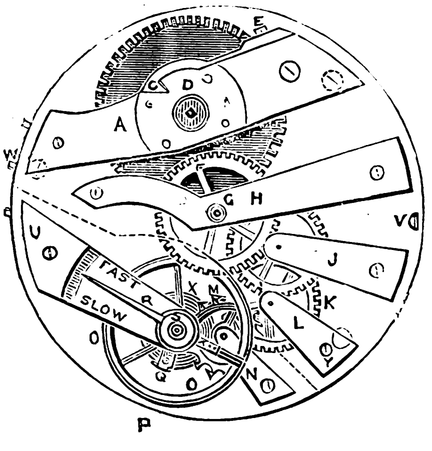

Fig. 52: A is looking plate, B barrel cover, C is dot as a guide for putting on barrel cover, D hole for dial, E hour-wheel, which works on cannon-pinion, F is motion-wheel, G seconds-

hand, H hour-hand, I minute-hand, J bottom bar.

Barrel.—We will take A, B, C, D, and E together, as they are all in one piece. There are two different barrels, one as shown, Fig. 53, with the lid or cover at the bottom, and the other with the cover at the top; but there are several different kinds of clicks. Fig. 53 is the most difficult to repair, being solid, with the exception of piece B, which is screwed on. Fig. 53: A barrel, B body of arbor, C arbor, D bridge, E click-cover, F locking plate, G ratchet. In repairing the barrel your chief point is to work from the top, *i.e.*, so long as you get the "wheel" or going part of your barrel true, the other part must follow. Suppose we say you have got to put two new holes to the barrel: you can see that the top of the barrel rubs against the centre wheel, is loose on its arbor, &c. Jobbers who have not a mandrel would generally punch the holes round; but this is not a proper way to do it, neither does it at all times end satisfactorily; but anyone who has a set of bench turns can easily convert it into a mandrel; so next week I will give full instructions for making a good substitute for a mandrel.

FIG: 52.

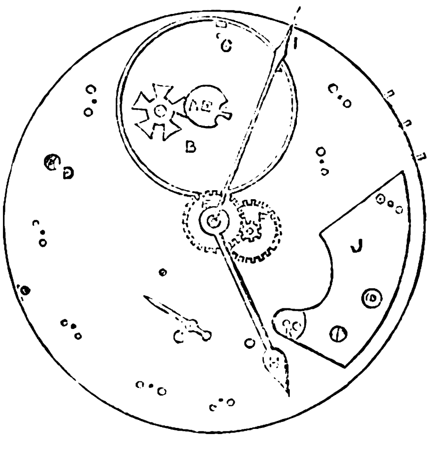

FIG 53

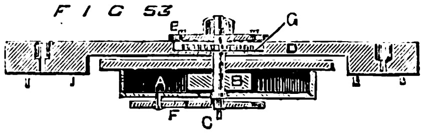
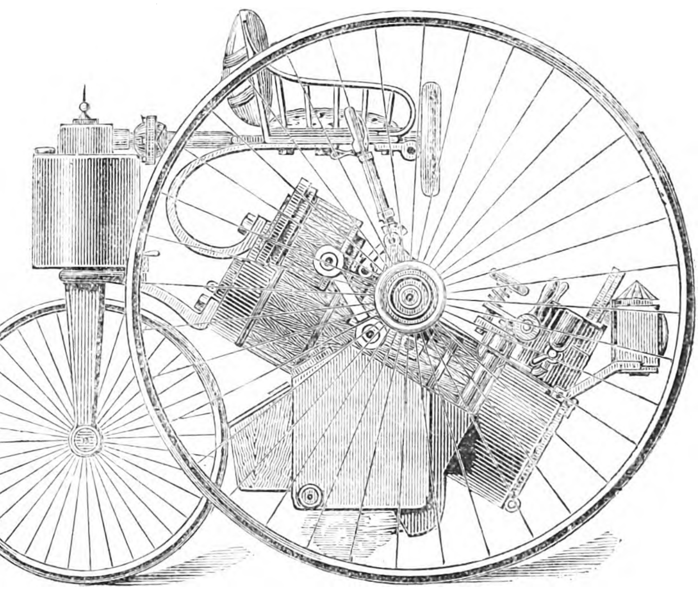


A STEAM-TRICYCLE.*

In the construction of a steam-carriage there are various things needed to make a successful machine, and it is difficult in practice to obtain good results. The greatest obstacle to success was overcome by the application of the rubber tire, in 1870, which made a practicable machine of the steam-carriage. All jars or vibrations are taken up by the rubber tire, and prevented from being transmitted to the machine. Small obstacles such as stones, etc., bed themselves in the tire, and little effort is required to force the carriage over them. Lightness is another important requisite. This can be obtained by the use of steel in the boiler, using the boiler for the frame, and the use of high speed three cylinder engines. The lighest fuel that can be carried is petroleum. It occupies less space than coal, is only about one-half the weight, and its heating capacity is greater, and it is easier handled. The boiler should be close to the ground, so that the machine will be steady from its centre of gravity being low. The wheels should be large, as large wheels pass over obstacles easier than small ones. In firing with oil it is easy to make an automatic arrangement to control the fire, so that the engineer can give his attention to steering the machine. I inclose a sketch of a proposed steam-carriage, which, as will be seen, consists of a steel boiler, suitably lagged with wood. The boiler is hung to the main axle by bearings. The boiler is an inclined tubular. It takes the place of framing for the engine, seat, etc., and is connected to the hind steering wheel by a steel brace. The water-tank and tool-box are hung underneath. The water is fed to the boiler by an inspirator, which is operated by the left hand of the rider. By casting his eye down, the rider can see the water-gauge. The steam-gauge is placed on the dasher in plain sight of the rider.

In the night time the light is reflected back from the lantern through a tube which illumines the glass dial of the steam-guage. A whistle is also in front and is operated by the foot of the rider. The fire is controlled by either the foot or hand of the rider. On the right of the seat is the starting bar, which also controls the amount of steam entering the engine. On the left is the hand steering wheel. This wheel works a worm and worm gear on the single wheel behind. The engine works a train of gearing which is rendered noiseless by the use of a rawhide gear. In climbing hills, to obtain the necessary power a clutch motion changes the movement into a slow speed for the carriage, the engine making the same number of revolutions.

The fire is made from a jet of air and oil, blown into a chamber of fire-clay by a jet of steam, regulated by the steam pressure of the boiler. The oil is in the holder over the steering wheel. The exhaust is rendered noisless by passing through a perforated pipe, and is blown out underneath the carriage. The supply of water and oil will last four hours, the machine making an average of twelve miles an hour. The oil and water are then easily replaced, as they can be got anywhere.



The front plate of the boiler turns down, so that the fire can be started on the usual plan (a cap taken off at the back allowing the smoke to ascend). As soon as steam is up the front plate is shut and the oil-and-air feed started. Nearly all the weight is borne on the large wheels, which have rubber tires, protected by a chain of sheet steel. The wheels are constructed similar to a bicycle wheel.

The engine is reversed by the starting bar. The safety valve is in front. The proportions to which the machine is built could be varied to suit the wishes of the builder. Say, for instance: Driving wheel, 5ft.; steering wheel, 2ft. 6in.; width of rubber tire 4in.

Boiler of steel, with 66 copper tubes ½in. diameter, 30in. long; shell 9½. diameter, ⅛in. thick; weight 100lb.; engine, 1½ horse-power. Water tanks to hold one cubic foot of water; the whole weight, about 550lb.

This design of boiler and engine could be much reduced in proportion; less weight of oil and water could be carried, and the whole vehicle made much lighter; but I think it better to make too large than too small. A proportion of 1 horse-power engine, 1¼ft. boiler, with two hours' supply of oil and water, might do.

ELEMENTARY LESSONS IN DRY-PLATE PHOTOGRAPHY.—X.*

Defects and Remedies.

At the end of the last chapter we described the conditions which gave rise to the occasional necessity for intensifying a negative. A good intensifier will increase the density of every part of a negative proportionately.

We may say at once that there is no thoroughly satisfactory intensifier for gelatine negatives, and that such a thing is a great desideratum; but we shall give a formula which has at any rate the advantage of simplicity, and which will be found to give fairly good results. It is one of the "mercury" intensifiers. It has two drawbacks. First, the results are not always permanent. Second, there is great difficulty in regulating the amount of intensification given by it. The first objection is much lessened, however, from the fact—not, we believe, generally known—that when a mercury intensified negative fades, it can generally be brought back to its original condition by performing again the process of intensification. We shall suppose that a negative on printing is found to give a poor-looking print, lacking contrast. Let the following solution be prepared:—

Bichloride of mercury	1 ounce
Water	10 ounces

The whole of the bichloride of mercury will not dissolve, but the residue may be left in the bottle, and as the solution gets low through necessary waste, water may be added.

Let the negative be thoroughly washed. Let it be placed in a dish, and let the mercury solution be poured over it. It will gradually become whitened or bleached. When the film is bleached throughout—as indicated by its being white at the back—let the solution be poured back into the bottle, and let the negative be most thoroughly washed. On the thoroughness this of washing seems to depend to a great degree the permanency of the results.

The negative has now to be treated with ammonia solution, which will blacken it, but the strength of the ammonia solution must be varied according to the amount of density required. Thus, if the print got from the negative previous to treating with mercury was very nearly up to the mark, a very weak solution of ammonia must be used; one or two drops to the ounce of water will be enough. This solution is poured over the negative, and it will be seen gradually to darken. When all action ceases, the process is complete. The negative will now be of a curious orange tinge by transmitted light. If, on the other hand, the negative was one giving a very shadowy print, a solution of ammonia of one to twenty may be used. On this being poured over the plate, darkening will take place almost instantly, and the result will be a fine black-coloured negative.

Too great density of image is a fault sometimes met with. It is always due to error of judgment in development. It may be corrected by performing the first part of the process for intensification. This method is objectionable, however, as the results may not be permanent. A better plan is to immerse the negative, after fixing and washing, in a solution of one part of eau de javelle to three or four of water. After the desired amount of reduction has taken place, the plate should be again fixed and washed.

Spots of various kinds are liable to be found in the finished negative. They are of various forms, and are produced in various ways. Minute transparent spots or pinholes are caused by dust on the plate during exposure. The plate should be brushed with a broad camel's-hair brush before it is placed in the slide. Small transparent spots with irregular outlines are due to defect in the manufacture of the plate, and cannot be well corrected by after manipulation. Small transparent perfectly circular spots, with well-defined outlines, are due to air-bubbles in the developer, and are only produced when too small a quantity of developer is used. Air-bubbles do not, as is commonly supposed, form on the surface of the plate under the surface of the developer; they form on the surface of the developer, and, if there is too little solution, come in contact with the surface of the plate, and there adhere. Opaque spots are always due to defects in the plates, and cannot be corrected by after manipulation.

---

* By J. H. Davis in the *American Machinist*.

* Condensed from the *Photographic News*.

A yellow stain, or rather a yellow veil, in the shadows of a negative is often found after pyrogallic development, especially if the process has been very prolonged, or if much ammonia has been used. Such stains should never occur if our instructions are carefully followed, but if it does it may be removed by placing the negative, after fixing and washing, in the following solution :—

Saturated solution of alum	10 ounces
Hydrochloric acid	¼ ounce

Mr. Herbert Berkeley has recently introduced a new developer, which totally prevents any yellow stains from occurring, and which deserves strong recommendation. The pyrogallic stock solution is mixed with four grains of neutral sulphite of soda to each grain of pyrogallic. The whole is rendered slightly acid with citric acid, for it must be understood that so-called "neutral" sulphite of soda is really alkaline. Care must be taken to use the *sulphite*, not the *sulphate*.

A white powdery deposit is sometimes found on the surface of the negative after drying, especially after ferrous oxalate development. It is, in such a case, caused by lime in the washing water. It may be removed by dipping the negative in a 1 per cent. solution of hydrochloric acid. If the solution of alum used before fixing be acid, and the negative be not sufficiently washed between the alum and the fixing-bath, a deposit of sulphur will form in a fine powder. This may be removed by gently rubbing the face of the negative with a plug of cotton-wool, while water is running on it from the tap.

Irregular action of the developer, causing zig-zag lines across the plate, may occur if the developer has not been made to flow over the plate in one wave at first.

Halation is caused chiefly by reflection from the back of the plate. It makes itself evident only when the subject includes very strong contrasts; for example, when an interior with windows open to the sky is photographed. It shows itself in the form of a halo round the highest lights, and produces a very unpleasant effect, sometimes known as blurring. It occurs only to a small extent with plates that are very thickly coated. In the case of an attempt being made to photograph a very trying subject, such as the interior mentioned, it is well to "back" the plate; this is, to paint or otherwise cover it at the back with some substance which will absorb light. The following is a good method to adopt. Procure a piece of black carbon tissue, cut out a piece slightly smaller than the size of the plate to be used (there should be about ⅛ of an inch margin all round) moisten the black surface of the carbon tissue with glycerine, allow all that will to drain off, and press the tissue against the back of the glass. It will adhere, and may be removed just before development.

ELECTRICAL ACCUMULATORS, OR SECONDARY BATTERIES.*

By PROF. OLIVER J. LODGE, D.Sc.

THE distinction between a primary and a secondary battery is in no sense an important one when we are considering either as the producer of a current; and we may have in our minds an old Volta cell, or a Smee, Grove, or Daniell, just as satisfactorily as a Planté or a Faure, while we consider the ensuing few theoretical remarks.

I shall use the term "radicle" in preference to "element," as being more general. Radicles may be elementary, but they may also be compound. The atom of hydrogen, of oxygen, or of lead, is a radicle, but so is the group SO_4 or NO_3. A radicle is any group of atoms that can combine, or be removed from combination, with another group. Chemists have long been accustomed to divide radicles into electro-positive and electro-negative, or "basylous" and "chlorous," though they have been slow to recognise the full physical meaning of this distinction. They have also classified them into monad, diad, triad, radicles, and the like; and without entering into the disputed question of whether atomicities are fixed or variable, it is absolutely certain that in a definite compound, and when released from definite compounds, certain radicles are monad, diad, or triad, as the case may be.

It is, moreover, known that radicles can exist temporarily in the free state, when they are said to be dissociated; and that many liquids—not to speak of gases—contain a number of such dissociated molecules, the number depending on the temperature as well as on the nature of the liquid, and being on the average pretty constant—that is, they are equally distributed through the whole liquid, and if some are by any means removed, more will at once be formed to keep up the average. Not that any one radicle need remain long dissociated—there is, no doubt, a continual interchange—but the average number dissociated is definite under definite physical conditions.

Now there is a large class of liquids whose dissociated radicles are all charged with electricity—half of them with positive, and these are they which chemists call electro-positive or basylous radicles—half of them with negative, called therefore electro-negative or chlorous. Moreover, it was shown by Faraday that the charge possessed by every monad radicle, of what kind soever, is precisely the same in quantity, though it may differ in sign; and that diads have twice, triads thrice, this atomic charge, and so on. The existence of these charges are certain from the facts of electro-chemistry, and the electrical charge appears to be the essential condition for even the momentary existence of a free radicle. It further appears that when two opposite radicles combine their charges are either lost or are masked by proximity; and that before two radicles of the same kind can unite into a molecule their charges must be given up to some third body. A liquid which possesses such dissociated and oppositely charged radicles, sauntering about in it, is *ipso facto* susceptible of being decomposed by electrical means, and is called an electrolyte. Liquids which have no such charge and dissociated molecules are not electrolytes, and will not conduct electricity. Electrolytes conduct electricity by a bodily transfer in opposite directions of the oppositely charged radicles; they conduct it, in fact, as a convection current, or rather perhaps of two equal opposite convection currents, one of the positive radicles the other of the negative. The resistance of the liquid depends upon the slow shearing asunder of these two sets of radicles by a process closely analogous to diffusion, for it is possibly only assisted or directed by electricity in the immediate—molecular—vicinity of the electrodes.

What are these electrodes? They are conductors introduced into the liquid, with the property of exerting upon the charged radicles in their immediate neighbourhood unequal, or else opposite, forces. Thus, suppose they are two plates of platinum connected with a battery, so that one plate is always +, the other always −; and suppose for simplicity that the dissociated radicles are hydrogen—electro-positive, and oxygen—electro-negative, respectively. Oxygen atoms close to the positive electrode are attracted by it; they deliver up their charges to it, and uniting into molecules, rise as gas. Their places are taken by others from the slightly more remote region, and so on, a virtual procession of oxygen atoms continually taking place towards the positive plate, each carrying its charge with it. The same thing happens on the hydrogen side, only that twice as many dydrogen atoms take part in the action, the charge of each being half that of an oxygen atom.

This, then, appears to be the state of things in ordinary electro-chemical decomposition; only the radicles liberated on the surface of the electrode will combine with it, if in any way possible, instead of merely combining with each other and becoming free. Thus the hydrogen alloys itself as well as it can with the platinum; and the oxygen, if it finds any copper or other less noble metal on the surface of the electrode, will readily combine with it, the ordinary chemical affinities being enhanced by the electrical attractions.

But now, instead of two oppositely charged plates of the same material, let us immerse in the liquid a plate of zinc and a plate of copper, or any two metals which have a different affinity for oxygen. The oxygen atoms are now attracted to the zinc just as they were to the positive plate, but apparently by a chemical, not an electrical, force. It may be possible ultimately to reduce chemical forces to electrical ones, or *vice versa*; but at present it seems necessary to draw a distinction between them. This attraction for the oxygen is, as before, only to be supposed to be effective within far less than a microscopic distance of the plate. The replenishment of the oxygen into this region is wholly carried on by diffusion and fresh dissociation. The copper on the other side pulls the oxygen too, but less powerfully. Nothing more than slight motion and very slow combination, however, is found to go on so long as the two plates are kept separate, provided both are pure and homogeneous; but the tending of the negatively charged oxygen towards the zinc makes it transfer negative electricity to the copper as soon as they are connected by a wire.

The copper so connected, being now negatively charged, actually repels the oxygen atoms, and is protected from their attack, while it attracts the hydrogen. We now therefore have the continuous opposite processions again, the oxygen atoms combining with the zinc, and neutralising by their charges positive electricity at its surface, in other words, partially giving up negative electricity to it; the hydrogen atoms going to the copper, hydrogenising it to some extent, but soon giving up their positive charges to it, uniting with each other and escaping from the liquid. A constant current must therefore be flowing along the connecting wire, of negative electricity from the zinc to the copper, of positive from the copper to the zinc.

Next, suppose two plates of the same metal, say both platinum or both lead, not connected with any battery, but with their surfaces in different chemical conditions—say one coated with hydrogen, the other with oxygen. Plainly the same kind of action can go on. The oxygenised plate will be attracting the hydrogen like the copper, or like the negatively charged plate connected with the pole of a battery; the hydrogenised plate will behave like the zinc or the positively charged plate. The positive current will flow along the connecting wire from the oxidised plate to the hydrogen-coated one.

We have thus a battery which will maintain a current so long as the plates continue coated or combined with the two gases; but the action of the current is obviously to destroy these gases and restore the plates to a condition of equality. A battery may be made, then, either of two different metals, one of which attracts oxygen more than the other—this case we will not now further consider —or else of two pieces of the same metal, one more oxidised than the other or one more hydrogenised than the other; or, still better, one oxidised and the other hydrogenised. Take, for instance, two plates of lead and immerse them in dilute sulphuric acid; let one be bright and metallic, the other rusted over with a coat of oxide of lead. As soon as metallic communication is made between the two plates, a positive current of electricity continually flows along it from the oxidised plate to the other, the bright plate becoming gradually oxidised and the other becoming gradually reduced. If the plate has been oxidised by exposure to hot air, or by ordinary chemical means, such a battery would be called a primary one; if the coat of oxide has been produced by passing through the cell an electric current from some independent source, then the battery is called a secondary one.

DIFFERENCES BETWEEN POSITIVE AND NEGATIVE ELECTRIC DISCHARGES.

WHILE, according to former observations of Herren Wächter and Reitlinger, the glowing electrode particles which form the electric spark are exclusively detached and carried off by escape of positive electricity from the electrodes, the experiments of Plücker, Gassiot, Hittorf, and others, appear to prove that, under certain conditions, a projection of particles takes place exclusively at the negative electrode. The question thus arose how these observations were to be brought into harmony, or what differences exist between the electro-positive and electro-negative projection of particles. Herr Wächter has recently given his attention to the subject, and his experiments yield the result that the projection of particles detached from the positive electrode (anode particles), differ from that of particles detached from the negative electrode (cathode particles), in the following points:—

1. The projection of anode particles occurs in atmospheric air at a pressure of 4500 to 10mm. of mercury; the projection of cathode particles is only observed at a pressure of 63 to 0 005mm.

2 The quantity of electrode particles detached in equal times, and under otherwise similar conditions, *decreases* at the anode with diminishing air-pressure, but *increases* at the cathode.

3. The anode-particles are, under like conditions, carried considerably further than the cathode-particles (at 63mm. pressure about 3,400 times as far).

4. The anode-particles go out uninfluenced by air-pressure, always from a comparatively very small surface. The cathode particles, on the other hand, are, with decreasing air-pressure, projected from ever-greater surfaces. (The size of the latter may even attain 10,000 times that of the surface whence the anode-particles are projected.)

5. The anode-particles always go out only at a particular part of the anode—*viz.*, at that situated nearest the cathode, whereas the cathode-particles appear, according to the density of the gas, on the whole surface of the cathode.

6. The emission of the anode particles is favoured by a bent or pointed form of the electrode; that of the cathode-particles by a clean, that is, unoxidised surface.

7. The direction of motion of the anode-particles is determined by the position of the cathode relatively to the anode, as the anode-particles move in the direction of the electric current, in the path of least conductive resistance to the cathode. The direction of motion of the cathode-particles is, in all circumstances, at right angles to the cathode-surface, and is not influenced by the position of the anode and the direction of the electric current.

8. The anode-particles can move in all con-

---

* Condensed slightly from the *Engineer*.

ceivable curved paths, but the cathode-particles can only move in straight paths.

9. The anode-particles are deflected by the magnet like diamagnetic substances; the cathode-particles like paramagnetic.

10. The anode-particles are carried over both in the luminous and in the non-luminous state; the cathode-particles only in the non-luminous state.

11. The anode-particles have a measurable size, and are probably detached mechanically by separate impulses; the cathode-particles are immeasurably small, and seem to come off by a process of vaporisation.

12. The heating of the electrode acts in a distinctly favourable way on the projection of cathode-particles; but this cannot be said of anode-particles.

13. The cathode-particles are the means of passage of the electric current from the electrode to the gas-molecules; but this is not the case with the anode-particles.

14. For detachment of the anode-particles, a greater electric tension previous to discharge is necessary (according to the experiments of Wiedemann and Ruhlmann), than for detachment of cathode-particles. The emission of the former, therefore, takes place, other circumstances similar, at greater intervals than the emission of the latter.

These facts, in Herr Wächter's opinion, indicate a difference between positive and negative electricity, which is not to be regarded as an opposition of plus and minus of two similar conditions of matter, but rather as a *qualitative* difference of the two kinds of electricity.

SCIENTIFIC SOCIETIES.

ROYAL MICROSCOPICAL SOCIETY.

THE eighth meeting of the session of the above society was held on the 10th inst., at King's College, Strand, the chair being taken (in the absence of the President) by James Glaisher, Esq., F.R.S.

The minutes of the meeting of 12th April last were read and confirmed, and were signed by the Chairman.

The list of donations (exclusive of exchanges and reprints) received since the last meeting was submitted, and the thanks of the Society given to the donors.

Mr. Crisp read letters from Prof. C. Robin and Dr. L. Dippel in acknowledgment of their election as Honorary Fellows.

Mr. Dowdeswell read a paper "On Davaine's Septicemia."

The Chairman said he was very glad that they had had a paper on so important a subject. Observations upon *bacteria* were daily acquiring more and more value, from their supposed connection with various kinds of disease. He hoped that Mr. Dowdeswell would continue his observations upon the subject, and that he would be able to explain the great discrepancies which he had observed to exist between the size of the specimens he had described and those which had been referred to by other observers.

The Chairman referred to a letter received from Mr. Ralph, the President of the Victoria (Australia) Microscopical Society, in which he mentioned that he expected to be present that evening. At the last moment, however, he had been prevented from coming.

The Chairman said that he was sure they would all hope that Mr. Ralph would be in England at their next meeting, so that they might welcome him both as one of their ex-officio Fellows and also as the representative of almost the only Colonial microscopical society.

Mr. Burnett's note on a new form of rotating live-box was read, and the apparatus exhibited.

Mr. Sigsworth exhibited a spring paper-clip which he had found very useful in fastening card cells upon slides and much more convenient for the purpose than the so-called "American" clips.

Dr. Van Heurck's views on the use of the incandescent electric light for microscopy were briefly referred to by Mr. Crisp, who explained, by means of black-board drawings, two cases in which, in consequence of its superior intensity, the electric light might be made use of to extend somewhat the resolving power of an objective. Dr. Van Heurck had recently obtained an improved form of battery which superseded the one he originally described. He found the Swan form of lamp to be the most suitable for microscopical work.

Prof. Abbe's paper "On the Relation of Aperture and Power in the Microscope," part I., was read by Mr. Crisp, who referred to it as being one of the most valuable and useful papers that had ever been brought before the Society, dealing as it did not only with the theoretical part of the subject but establishing also a rational standard for the practical construction of objectives.

We give an abstract of Prof. Abbe's paper as follows:—

Part I. of the paper contains a general consideration of the relative values of wide and narrow apertures, in regard to which Prof. Abbe lays down the following propositions:—

(1) Wide apertures are necessary when *high amplification* is required; low or moderate apertures when low or moderate amplifications are sufficient, or cannot be over-stepped.

(2) Wide apertures are necessary with *objectives* of short focal length; low and moderate apertures with those of low and moderate power.

(3) Wide apertures, together with high powers, should be used for those preparations only which do not require perceptible depth of vision, that is, for exceedingly flat or thin objects, and for transparent objects which can be studied by optical sections; moderate and low apertures when a wide range of penetration cannot be dispensed with.

(4) Never use wider apertures than are necessary for the effectiveness of the power, because excess of aperture is always waste of time and labour.

(5) Scientific work with the microscope will always require not only high-power objectives of the widest obtainable apertures, but also carefully-finished lower powers of small and very moderate apertures.

Amongst other points dealt with by the author, he calls attention to the uselessness of objectives of 1-50in., with which no more can be seen than with an objective of half the power, or even less; also to the positive damage connected with the use of unnecessarily-wide apertures, they being prejudicial to the ease and convenience of microscopical work in two essential respects: first, they necessitate a progressive reduction of the working distance of the objective, which decreases from 0·7 of the focal length for an aperture of 30° to 0·1 for an aperture of 116°; and, secondly, the sensibility of the objectives for slight deviations from the conditions of perfect correction is greatly increased; so that, whilst with 30° differences in the cover-glass are practically inappreciable, with a dry lens of 100°, a change of thickness of 0·02mm. only introduces perceptible aberrations and a visible loss of definition; to avoid which a change of the correction-collar would be required for almost every change of focus in the inspection of successive layers, unless the preparation is exceedingly thin

He also calls attention to the misunderstanding of the principles involved in the construction of objectives, which has given rise to the notion that a wide-angle objective can also be made to do duty as a narrow-angle one by such arrangements as the Davis "aperture shutter," or diaphragm All such contrivances are entirely illusory, and have for their result to produce a bad low-angle objective instead of a good wide-angle one. If a low-angle objective is required, it must be *originally* constructed for that purpose, and cannot be converted out of a wide-angle one in the way suggested.

[We are informed by the secretary that in the second part of the paper, which will be read at the next meeting, and then, we hope, more fully reported, Prof. Abbe deals more in detail with the proper ratio which must be maintained between aperture and power, giving tables showing the maximum apertures which can be effectively used with given powers, and conversely. He first considers what relation the *total amplification* of the microscope (that is, both objective and eyepiece) should bear to the aperture—a point which is determined by defining the visual angle required for distinct recognition of an object, and the smallest dimensions of microscopical detail which a given aperture will delineate. Having determined the relation of the total amplification to aperture, he next considers how this total must be apportioned between the objective and the eyepiece, and as the result of the discussion, arrives at conclusions in regard to the power of eyepiece that can be usefully employed for the best definition, which are not a little at variance with popular views on the subject.]

The Chairman considered that Prof. Abbe's paper was indeed a most useful one, and that it would be greatly appreciated by practical opticians.

Mr. Beck said that he considered it was an exceedingly valuable paper, and one that would enlighten a great many persons as to the relative value of aperture and magnifying power in regard to which great confusion had existed. There were people who thought that if they could get a 1in. objective with an aperture of 120°, they could resolve difficult diatom tests. He had heard it claimed that such glasses had been made, but although he had ordered one he had not yet been able to get it, and hopes that might have been raised by these announcements would be damped by the contents of Prof. Abbe's paper. He was very glad that it had been written, because it had been his impression for some time that Prof. Abbe had been working exclusively in the direction of wide apertures.

Mr. Ingpen was surprised to hear Prof. Abbe, of all persons, charged with an exclusive approval of large apertures, for if anyone looked at Zeiss's catalogue, they would see at once that all the dry lenses were of remarkably small angles, nothing exceeding 110°.

Mr. Crisp said that the most opposite notions had been held as to Prof. Abbe's views on wide or narrow apertures. Some years ago it was stated, at one of the Society's meetings, that he advocated only narrow apertures, and some correspondence took place in regard to it in the *Monthly Microscopical Journal*. Again, later, it was insisted that Prof. Abbe considered all but wide apertures useless to the microscopist. The fact was that Prof. Abbe had, since the date of his earlier observations on aperture, advocated the maintenance of a proper ratio between aperture and power—wide aperture for high powers, and small apertures for low powers—and had always insisted on the great importance of perfecting the construction of moderate apertures.

The confusion had arisen from the fact of Prof. Abbe having shown, in connection with his theory of microscopical vision, that wide apertures, and wide apertures only, gave true images of minute objects; but it did not, of course, follow from that that wide apertures were to be universally used, with low powers and with objects, if unsuitable either from their requiring depth of vision, or for other reasons.

Mr. J. Mayall, jun., exhibited Ross's "Hospital Microscope." The speciality is the fine adjustment, which is of so simple a construction that Messrs. Ross are enabled to issue the microscope at a less cost than any previous form issued by them.

Dr. Maddox read a paper "On Some Micro-organisms from Ice Water and Hail," illustrated by a number of photo-micrographs.

The Chairman inquired how Dr. Maddox accounted for the existence of the organisms which he had described. Did they come from the atmosphere?

Dr. Maddox thought that with regard to those from the ice of the water-butt, they probably were in the rain-water before it froze, and they alone survived; those found in the water from melted hail most likely came down from the atmosphere with the hail.

After a few remarks on Dr. Maddox's paper by Mr. Beck, the Chairman adjourned the meeting to June 14.

THE METEOROLOGICAL SOCIETY.

THE usual monthly meeting of this Society was held on Wednesday week at the Institution of Civil Engineers, Mr. J. K. Laughton, F.R.A.S., President, in the chair. Miss W. L. Hall, Mr. E. J. Pearson, Dr. J. R. Somerville, and Mr. W. J. V. Vandenbergh were elected Fellows of the Society.

The following papers were read:—"On the Diurnal Variation of Wind and Weather in their relation to Isobaric lines," by the Hon. Ralph Abercromby, F.R.S. By constructing synoptic charts at different hours of the same day, and by comparing the wind and weather records at the different hours, and examining their relation to mean curves of diurnal variation, the author shows that the mean diurnal increase of the wind's velocity is explained by the fact that for the same gradient there is more wind by day than there is by night. The mean diurnal velocity of the wind is explained by the fact that in cyclones the wind is a little more incurved, and in anti-cyclones a little more outcurved by night than by day. The mean diurnal increase of the frequency of rain during the day hours is explained by the fact that in any given cyclone the area of rain is larger by day than by night. The diurnal changes of every element are superimposed on the larger general changes, and are independent of each other. Great stress is laid on this point, both as explaining and classifying many meteorological questions and as simplifying the problem of weather forecasting. The author gives a simple hypothesis, from which it appears that the diurnal veering and increase of rain follow as a natural consequence of the diurnal increase of velocity. A paper on "Mechanical Conditions of Storms, Hurricanes, and Cyclones," by W. F. Stanley, F.M.S., was also read.

Catalogue of American Tools, &c.—Messrs. Churchill, of 28, Wilson-street, Finsbury, have issued a new catalogue of American tools, machinery, &c., containing about 100 pages of illustrations and descriptive matter. It is the largest and most complete list of the kind issued in Europe, and will be found useful by amateurs who are not acquainted with the many appliances now provided for the mechanic. Besides tools, the catalogue contains a number of fretwork designs, clocks, and clock movements, and altogether affords ample reason why Messrs. Churchill should have found it necessary to erect larger premises in Cross-street, to which they will remove in the course of two or three months.

THE production of Bessemer steel ingots in the United Kingdom during 1881 was 1,441,719 tons, being an increase of 397,337 tons on the quantity produced in the preceding year.

SCIENTIFIC NEWS.

FROM Dun Echt Circular, No. 51, we learn that Dr. Oppenheim has completed the following elements of Comet Wells from observations at Harvard College on March 19, the mean of three observations at Dresden and Leipsic on April 15, and the Kiel observations of May 12: T = June 10·56221, Berlin M.T. $\pi - \Omega$ 209° 0′ 31·2″, Ω 204° 54′ 54″, i 73° 47′ 29·4″ log. q 8·783216. His ephemeris for May 27 (Berlin mean time) and following days reads as follows:—

	R.A.			N. Dec.	
	h.	m.	s.	°	′
May 27	3	57	21	56	13·3
28	4	3	24	54	25·7
29	4	8	54	52	35·2
30	4	13	58	50	41·6
31	4	18	36	48	45·0
June 1	4	22	53	46	45·2
2	4	26	53	44	41·3
3	4	30	40	42	32·9

At the last date the comet will have a brightness of 113, March 19 being taken as the unit-date, but on June 11 it will be 1565. Mr. Hind has also calculated an orbit, and an ephemeris which, for Greenwich mean time on May 27, is R.A. 3h. 57m. 39s., N. Dec. 56° 8·1.

Dr. Wentworth Erck, lecturing last week at the Royal Dublin Society, said the distance of the comet from the surface of the sun at perihelion will not exceed five millions of miles. At this period it is calculated, having regard solely to the distance of the comet from the Sun and from the Earth, that the brightness of the comet will be 3,600 times greater than at the time of its discovery, when it was equal to an eighth magnitude star; but some time before and after perihelion the comet will be lost in the rays of the Sun, and the great amount of twilight at this season of the year will probably prevent the tail from ever becoming a very conspicuous object. But the calculation of brightness, based upon the mere distance of the comet from the Sun and from the Earth, though perfectly correct in the case of a constant reflecting surface, by no means holds good in the case of a comet whose dimensions and internal constitution undergo the most violent transformations in passing from the cold of space to a temperature far higher than we can have experience of. In point of fact the brightness is found to increase in a greater ratio than that due to diminished distances. The rule, however, seems not to be of universal application, and to fail in the case of the present comet.

Judging by the telegrams from Egypt, the eclipse expeditions have been successful beyond their expectations, for the French astronomers believe they have detected a lunar atmosphere, a fine comet was discovered close to the sun, a series of good photographs of the corona was obtained, and for the first time the spectrum of the corona was successfully photographed. Dr. Piazzi Smyth writes from the Royal Observatory, Edinburgh, that the observers on the Calton Hill speak of the so-called sunspots being in greater size, force, and energy of movement and change than they have been seen for the last eleven years.

In the course of some investigations of electrical phenomena Mr. Willoughby Smith has made a remarkable discovery—one that may possibly have an important bearing on telephony. The name given to the apparatus, as at present used, is the inductophone, which partly explains the character of the phenomena. In the electrical circuit, Mr. Smith has a large tuning fork with springs for making and breaking contact, and a large flat coil or disc of rather thin silk-covered wire. This coil produces a large field of electrical lines of force, constantly changing owing to the make and break arrangement of the tuning-fork. If a telephone is brought into this electrical field, but without having any metallic or other visible connection with the circuit, it faithfully reproduces the musical sound of the tuning-fork. A telephone is not necessary,—the diaphragm of one is sufficient, or even a bar of iron. Further, the receiver may be placed at any distance apparently, within, say, a house, for so long as the diaphragm is properly situated as regards the lines of force, it reproduces the sounds though brick walls and many yards of air intervene. When the plane of the diaphragm is placed at right angles to the plane of the coil, both being on the same axial line, no sound is heard; but when the diaphragm is placed so that the lines of force can, so to speak, impinge upon it, the sounds are reproduced, although the diaphragm may be turned to almost any angle.

During the recent telephone case it was stated that the electrical resistance of gas carbon does not vary under pressure. Mr. W. F. Nosworthy has repeated his experiments, and has found that the resistance of gas carbon is sensibly reduced by compression, so that the statement above referred to holds true only in such conditions as "compression" produced by sound-waves.

The largest locomotive in the world is now on the Pennsylvania Railroad, having been recently built at the company's works, Altoona. The engine weighs 120,400 pounds, and is what is called a double-ender. The driving-wheels are 5ft., and the truck wheels 33in. in diameter. On her trip from Altoona to Philadelphia, a mile was run in 59 seconds. A special train, consisting of three cars and engine, made the following certified times recently on the West Jersey railway:—16½ miles in 14 minutes, 61·1 miles in 60 minutes, and 76·1 miles in 76 minutes. Mr. Barnet Le Van read a paper before the Franklin Institute, in which he contended that 90 miles an hour is not only safe, but perfectly feasible.

Dr. J. Barrois will be the director of the new zoological laboratory the French Government are to establish at Villefranche-sur-Mer.

Sulphurous fumigation is adopted by the Abyssinian elephant-hunters when they descend to the malarial lowlands, and M. D'Abbadie suggests that European explorers might find a similar immunity from fever if they followed the same practice.

The Exhibition of Electric Lighting at the Crystal Palace, will cease on Saturday, June 3, so those who have not already seen it, should remember that the opportunity will end with next week.

Mr. H. H. Warner, of Rochester, New York, has again offered a prize of two hundred dollars for each discovery of a new comet made in North America or the United Kingdom; also a prize of the same amount for the discovery of a meteoric stone, found in the countries above named, which, in the opinion of Professor H. A. Ward, Principal Dawson, and Mr. J. L. Smith, contains fossil remains of animal or vegetable life. A sum of fifty dollars is offered for a specimen of any meteoric stone seen to fall in the United States during 1882. The discovery of the comet must be made known by telegraph to Dr. Lewis Swift, director of the Warner Observatory, Rochester, N.Y.; and specimens of the meteoric stones, not less than 2oz. in weight, must be sent to him by mail with full particulars.

The influence of thunderstorms on the magnetic needle is generally too instantaneous and too weak to deflect it, even when most delicately suspended. That such storms do affect magnetised bodies, however, has been proved by M de Lalagade thus: At the end of a long magnetised bar he arranged a thin iron membrane, mounted as in the telephone. At each flash of lightning, a small but distinct dry sound was heard in the membrane. A more sensitive apparatus was obtained by arranging, horizontally on a tower, twelve magnetised steel bars, each about 6ft. long, and covered at the end, in a fifth of the length, with twelve coils of fine wire. The ends of the wires were brought to two conductors, which were connected with a pair of telephones. Not only was a dry sound heard at each flash, but before each flash there was a slight buzzing (*bruissement*). The author suggests that an apparatus like the second described might be advantageously used in the simultaneous observations to be made in Polar regions.

The way in which M. Mascart, at the College of France, obtains records of magnetic perturbations is as follows. Three bar magnets, for the declination, the horizontal component, and the vertical component respectively, one furnished with mirrors which receive three rays of light from the same gas-lamp, and the three reflected rays fall on one sensitised place moved by clockwork. The clockwork has an electric contact, which every hour sends a momentary current into three coils (one near each apparatus), producing an interruption, and indicating the hour.

The Congress of the French Association for the Advancement of Science meets at La Rochelle this year on Aug. 24. A list of grants by the Association to savants for special researches will be found in *La Nature*, May 6.

Some observations of the effects of cold on birds in the valley of the Marne during the winter of 1879-80 have been lately published by M. Lescuyer, and M. Milne-Edwards, remarking on the importance of such an inquiry, has added some notes of his own, made in Paris. It seems that exotic birds, such as peacocks, silver and golden pheasants, suffered little from cold, though they had little shelter, some perching at night on trees or on the iron bars of inclosures. On the other hand, fowls in well-sheltered inclosures died in great numbers. A still more singular fact is the resistance of Australian cockatoos to cold. Several of these birds remained from October to March in the open air in a large cage, which is occupied in summer by monkeys; there was no shelter, except a building on the north side, yet all the birds had continued good health. Their feet were often on iron bars, the temperature of which was so low that water froze immediately when poured on the metal; several nights the cold was more than 25° below zero C. The black swans of Australia and the coscoroba of South America did not suffer, and in spring they set about constructing their nests; though frequently, in the winter mornings the keepers had to detach them from the ground to which their feathers had been frozen. The cassowaries of Australia were often, during the night, entirely covered with snow; but in the morning they shook their wings and seemed none the worse. In a word, the cold was more hurtful to many indigenous birds, than to species imported from hot climates but of more robust constitution.

In Colorado, it is said, there is a ten-acre field which is really a subterranean lake covered with soil about eighteen inches deep. On the soil corn is cultivated, producing 30 bushels to the acre. If a hole be dug to the depth of a spade handle, it fills with water, and fishes four or five inches long may be caught in it; these have neither scales nor eyes, and are perch-like in shape. The ground is a black marl. In all probability vegetable matter at one time began to accumulate on the open water, and has increased from time to time to the present thickness of productive soil. The cultivation has to be done by hand, the crust not being strong enough to bear the weight of a horse. A person rising on his heel and coming down suddenly can see the growing corn shake all round him. Anyone having sufficient strength to drive a rail through the crust, will find, on releasing it, that it will disappear altogether.

To burn petroleum economically, Herr Deutsch adds 4gr. oil of turpentine and 2gr. camphor, per litre. The wick is covered with dissolved tallow, to prevent passages of gas out or in. The inventor maintains that petroleum so used will burn six or seven hours longer, and with a brighter light, than an equal quantity in the ordinary way.

An interesting new process has been invented by M. Puech, of Mazamet (in France), whereby the wool of sheepskins is transformed into a kind of velvet. Hitherto, sheepskins, tanned with the wool on them, have only been used for mats, the lining of coats, &c., and the adherent wool, not subjected to treatment, is curled or compressed. Now, as the numberless fibres are placed, naturally, in a most regular way, very suitable for production of velvet, M. Puech conceived the idea of cleansing both skin and wool from impurities, and making all the woolly hairs stand independently. After long efforts, he has succeeded in producing this wool-velvet on natural skins. There are 10 principal operations, the first four being concerned with cleaning the skin on the woolly side, the fifth to the ninth with tanning and preparation of the skin, so that a full adherence of the wool to the skin is insured. Lastly, the skin is treated with certain machines, which make a kind of velvet of the wool. (Fuller details will be found in the *D. A. Pol. Zeitung*.)

The following arrangement has been proposed by M. Ledieu for a simple and cheap *pyroscope*, or "preventer" of fire (as he calls it). A cylinder of strong insulating matter is interposed in a circuit. It is filled with a liquid which resists electrolysation, and has good conductivity, increasing considerably with the temperature. (Absolute alcohol is found to serve very well.) At either end, a tight packing is penetrated by a platinum rheophore, connected with the end of the divided circuit. The effect of increased temperature on the liquid is indicated by a galvanometer, the needle of which, at a certain point, sets a bell ringing.

The Royal Library in Brussels, following the example of our British Museum, is to be lit with the electric light. In the National Library of Paris the light is not yet adopted, as the present reading-room is merely provisional.

A curious experiment, illustrating the pressures on the walls of a vessel that contains water, is described by a writer in *La Nature*. To a water-tap you attach a pretty flexible tube of caoutchouc, the lower end of which has a small piece of glass tube bent at an angle. On opening the tap, the action of the water on the tube displaces it, but, owing to the elasticity of the caoutchouc, the direction of this force changes very rapidly, and the tube performs the most varied and strange movements, now like those of a swan, now like those of a snake. With a very thin tube the glass tube may be dispensed with, provided the pressure of water is sufficient, and the movements are very complicated.

A water-bath is kept at constant level by Herr Schimmel, of Elberfeld, by the following simple contrivance: In the water dips a bent tube communicating laterally with the lower part of a stoppered vessel of water on the stand above. The tube has a lateral aperture, which from time to time gets uncovered as the water is vaporised, and the level goes down. whereupon a little air enters the vessel, and a little water enters the bath, restoring the level.

LETTERS TO THE EDITOR.

[*We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the Editor *of the* English Mechanic, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. Passmore Edwards.

⁂ *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

COMET 1882 a (WELLS).

[20065.]—In my letter last week I find that through forgetting the extent of the field of my comet eyepiece (which in my large instrument has only half the extent, that was in the 7½in.), I had erroneously estimated the tail at 100′ instead of about 55′.

I had a fine view of the comet last night (13h.—14h.); the nucleus was very small and sharp, having the appearance of a brilliant point of light, seen through a nearly opaque opal glass, so as to give it a strong red tint, contrasting curiously to the bluish white of the coma, as also to the light of a star near. The idea conveyed to the mind was certainly that the coma was partially opaque and shining by reflected light from the Sun.

Herbert Ingall.

Champion Hill, May 17th.

[20066.]—Comet a has been observed here on the following nights, with a 3in. aperture and power 80:—

May 17th, 10 15 p.m. to 11.15 p.m.—Nucleus not decided, but similar to a bright star out of focus. No particular change during the observation, but apparently a great amount of luminous vapour surrounding the nucleus, and gradually growing fainter towards the extremity of the tail.

May 18th, 10 p.m. to 10.45 p.m.—Nucleus now decided, and slightly brighter. The tail shorter and narrower. Occasionally, a glimpse of a faint star was had through the tail. The observation generally was not so imposing as previous one.

May 19th.—Not visible; very cloudy.

May 20th, 10 p.m. to 10.45 p.m.—Apparently very little change, either in brightness or in size. The nucleus seemed a little brighter than on previous night, and the tail shorter. There was a small star in the *n.f.* field, towards which the comet seemed to be rapidly approaching; but a dense cloud intervened, which prevented continued observation. During this observation, the tail could not be traced as far by the aid of averted vision as on May 18th. **A. Manock.**

High-street, Doncaster, May 21.

[20067.]—This comet has been frequently observed here since the beginning of April. On April 6th, as seen in my 10in. reflector, the tail was 13′ long, and the nucleus about equal to a star of mag. 7½. This was at 11h., when the moon was above the horizon in E.S.E.

On May 6th, at 10h., the tail was estimated at 40′ long, and the nucleus brighter than a 6th mag. star. The comet was just barely visible to the naked eye.

On May 18th, 19th, and 20th, it had become far more conspicuous. To the unaided vision it looked like a hazy 5th mag. star, with a tail nearly a degree long. Viewed in the telescope at 11h. 30s., on the latter night the tail was traceable over fully 1° 25′, though the sky was not very clear.

As a telescopic object this comet has been extremely interesting, and will continue to be so; but, considered as an object for popular observation, it will prove disappointing, for it will altogether fail to present that magnificent appearance which has been predicted for it. Though it is now brightening very fast, it is approaching the sun so rapidly, and is becoming every night more under the overpowering effects of twilight and moonlight, that it is very questionable whether this comet will ever become a large and attractive object to the naked eye. In this respect it will certainly not be comparable to B 1881, and will probably fall short of Schäberle's comet also.

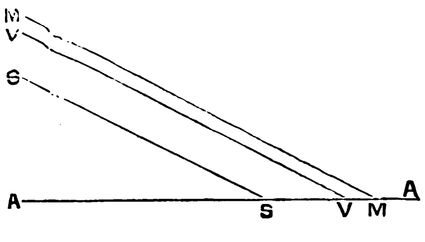
The announcement that a fine comet was discovered near the sun by the eclipse observers in Egypt on the morning of May 17th is important. The probabilities are that this comet is one of great inclination, and has approached the sun, without being observed, from the southern hemisphere, for in view of the vigorous search for comets pursued in America and elsewhere it is difficult to understand how this new visitor could have eluded detection, if visible before perihelion, in northern latitudes. The telegrams announce it as a striking object perceptible to the naked eye. Its position relatively to the sun was determined by photographs; but nothing could be ascertained (owing to the very brief interval during which it could be seen) as to its direction or rate of motion. The rediscovery of this body is, therefore, most important, and observers will do well to scan the whole northern horizon during the next week or two with this purpose in view. Any small telescope, having a large field, can be effectively employed in this work, the comet being a brilliant one, and, should it make its appearance above our horizon, will doubtless be visible to the naked eye.

W. F. Denning.

Bristol, May 21st.

THE PLANET MERCURY.

[20068.]—Comparatively speaking, few persons have ever seen the planet Mercury. It is at present, and will be during this month, in positions most favourable for observation. It can now be seen with the aid of a small pocket telescope, and it will improve for a fortnight. Those who possess equatorials have no difficulty, but many, like myself, are not so fortunately mounted, and have to do the best they can with their alt-azimuth. On the evening of the 16th being very clear in the west, I got my first view of Mercury, and annex a method, by which any one with a small telescope may do so also.



Draw a line A A, and from it upwards, slanting to the left, draw other three lines S S, V V, and M M. A A represents the horizon S S the path of the sun. V V that of Venus, and M M that of Mercury.

Watch the sun, as he apparently comes down the line S S, and note the point on the horizon where he sets. The path of Venus represented by the line V V is parallel to and a little (4°) to the north of S S, while that of Mercury M M is a little more than this (1° 2′).

At the present time Venus can easily be seen after the sun has set. Mercury sets before Venus, and must be looked for to the north of the path of Venus (on the line M M) down towards the horizon. On the 31st of this month, they both reach the horizon within one minute of each other—viz., 10h. 8m. and 10h. 9m. respectively. Venus sets 10° farther north than the sun, measured along the horizon, while Mercury sets 1° farther north than Venus. **L. T. Fleming.**

Berwick-on-Tweed, May 19th.

ASTRONOMICAL EYEPIECES.

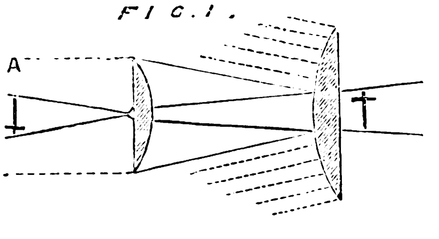
[20069.]—I am glad "Ascalon" has called attention to the very unsatisfactory manner in which the subject of telescope eyepieces is generally treated. Certainly, in this respect, writers of astronomical works have much to answer for, and though, according to Mr. Proctor, the subject may be one of admitted difficulty, this should hardly form a sufficient reason why the diagrams and descriptions should almost invariably be at cross-purposes with each other.

To give one example out of many. The reader of such works will very likely be told that "to magnify an object" means really nothing more than to practically decrease the distance between it and the eye. And that the reason this cannot be done without the aid of a convex lens, is because the rays would not enter the eye sufficiently parallel to produce distinct vision. So far, this is quite clear, and easy of comprehension; but, as if to further elucidate the theory, the attention of the student is next directed to the rays that emerge from the eye-lens of an eyepiece, and which, in the diagrams, are made so convergent that they cross immediately in front of it. This constitutes dilemma number one, for here are two distinct statements, each the opposite of the other, and it is easy to conceive how perplexed a student must be in endeavouring to reconcile them. Further reference to the text will not help him, unless, perhaps, to make it clear that there are gaps in the evidence which the author himself was glad to fill up with a few platitudes concerning the action of prisms and lenses on rays of different angles.

In all telescope eyepieces there are two sets of rays to be dealt with. 1st. The cone of direct rays from the object-glass, which, by the way, is the only one represented in text-book diagrams. 2nd. The rays diverging from the image, and which alone can be utilised for vision. It does not seem to strike these writers—if one may judge by the careful way they delineate the cone-rays—that after the image has been projected, it matters little or nothing whether the cone that conveyed it is refracted sooner or later to a focus, or whether it is stopped off altogether.

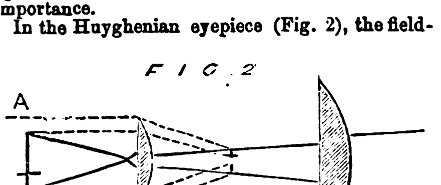
In the positive or Ramsden eyepiece the image is formed immediately in front of the field lens, and hence considerably within its principal focus. The emergent rays, therefore, though not visible, must be extremely divergent (see dotted lines, Fig. 1.) This, no doubt, causes a portion of the light to be wasted, but the loss is more than compensated for, since the spherical aberration is lessened in an equal degree, and results in the agreeably flat field so peculiar to this eyepiece. The action of focussing an eyepiece of this character consists in regulating the distance of the field-lens from the image, and by so doing, closing or opening the paths of the rays until they are sufficiently parallel to suit the eye of the observer. The position of the apex of the cone itself not being of the slightest importance.

FIG. 1.



In the Huyghenian eyepiece (Fig. 2), the field-lens is pushed in until it has passed the image; consequently, both it and the cone are converged simultaneously, the former being formed just at

FIG. 2



the principal focus of the eye-lens, and within the boundary of the cone, whilst the cone itself is continued, as in the Ramsden eyepiece, to an apex, and is not appreciated by the eye. A re-inverted, or erect image may, however, be rendered visible by holding a screen to receive the rays after they have crossed (as at Figs. 1 and 2). They may also be refracted to the visual angle by interposing a plano-convex lens between them and the eye.

Combination, or, as they are termed, pancreatic eyepieces, are usually made on Huyghens' principle, but with an eyepiece of this description the lenses can never be placed closer together than the focus of the eye-lens, since it is evident that the magnified image can be seen distinctly from no other position; consequently, if the lenses are closed beyond this limit the image must be viewed from outside the field-lens, and this would change its character into a modified form of the Ramsden eyepiece.

Aldebaran.

REFLECTORS v. REFRACTORS — DOUBLE-STAR WORK PERFORMED BY AN 18¼in. SILVERED GLASS "CALVER" REFLECTOR: Σ 3121, κ LEONIS, ω LEONIS, φ URSÆ, γ LEONIS, 145 (B) LEONIS, ξ URSÆ, ι LEONIS, Σ 1555, γ VIRGINIS, 35 COMÆ BER., 31 VIRGINIS, 42 COMÆ BER., 25 CANUM VEN.—NEW DOUBLE STARS—DIFFICULTY OF DOUBLE-STAR MEASUREMENT.

[20070.]—The object to which I have chiefly devoted my 18¼in. silvered-glass "Calver" Reflector is the measurement of close binary stars. I have done this not only on account of the interest and importance of this branch of astronomy, but also for the purpose of contributing somewhat to the much-debated question of Reflectors v. Refractors. It is frequently stated that reflectors are unsuited to this class of work for want of adequate defining power, and no less an authority than Mr. Burnham seems to be of this opinion. I wished, therefore, to test the question with a really fine mirror, and as Mr. Calver has furnished me with one of unsurpassed excellence, I have had the opportunity of doing so. After two years' experience with this instrument, I have ventured to form the opinion that Mr. Calver's mirror will perform work which would go hard to rival that of the great Chicago refractor, were the two instruments placed side by side, and tried by the same person on the same objects. I do not mean to say that in my hands, and in this climate, my instrument can rival Mr. Burnham's work with the Chicago refractor, for I do not think that the atmospheric conditions are, in England, ever so favourable as to render such work possible with any instrument, refractor or reflector. Nor, perhaps, shall I be far wrong in supposing that no other eye than Mr. Burnham's could have performed it even in Chicago;—but, place the two instruments side by side, an observer unaccustomed to either, would not perhaps find so very much difference in their performance.

However, as the above test is impossible, I will, with your permission, from time to time, lay before your readers such measurements of binary and other stars as I am able to make. The instrument is, as I have said, an 18¼in. silvered-glass reflector, the mirror having been figured by Calver. It is mounted on a Berthon "saddle-back" stand, and driven by clockwork. The observatory is a "Romsey," with a transit-room attached. The micrometer is an excellent one, by "Cooke," of York, and I can use either bright wire or bright field illumination. The whole of the apparatus belonged formerly to the Rev. Henry Cooper Key. I may also premise that I never give a measure of a star without I am certain that I have divided it, and that I endeavour as far as possible to divest my mind of previous knowledge before taking the measures.

Commencing with the IXth hour of R.A., I have the following measures:—

Σ 3121. R.A. 9·10, Mags. 7·5, 7·8
P = 33·5° D = 0·51″ Ep. 1881·23
P = 214·0° D = 0·51″ Ep. 1881·25

(1) *κ Leonis.* R.A. 9·17, Mags. 4·9, 10·7
P = 207° D = 2·89″ Ep. 1881·15

ω Leonis. R.A. 9·22, Mags. 6·2, 7
P = 88·3° D = 0·52″ Ep. 1881·23
P = 82·0° D = 0·31″ Ep. 1882·36

φ Ursæ Maj. R.A. 9·44, Mags. 5, 5·6

I fancied this star to be dumpy in direction 90° and 270°, but cannot be sure.

Ep. 1882·36

γ Leonis. R.A. 10·13, Mags. 2, 3·5
P = 111·0° D = 3·1″ Ep. 1881·13
P = 114·3° D = 3·5″ Ep. 1882·36

(2) 145 (B) *Leonis.* R.A. 10·14, Mags. A 7·8, B 8·3, C 9·3
AB. P = 281·5° D = 0·4″ } Ep. 1881·23
AC. P = 12·0° D = 7·7″ }
AB. P = 274·0° D = 0·4″ Ep. 1882·26

ξ Ursæ Maj. R.A. 11·11, Mags. 4, 5
P = 88·6° D = 1·8″ Ep. 1881·39
P = 76·0° D = 1·4″ Ep. 1882·36

ι Leonis. R.A. 11·17, Mags. 3·9, 7·1
P = 66·0° D = 1·82″ Ep. 1881·24
P = 63·0° D = 2·58″ Ep. 1882·36

This is a double star of exceptional beauty.

(4) Σ 1555. R.A. 11·30. Mags. A 6·4, B 6·8, C (?)
AB. P = 162·0° D = 0·52″ } Ep. 1881·24
AC. P = 148·0° D = 20·51″ }
AB. P = 160·0° D = 0·72″ } Ep. 1882·27
AC. P = 145·0° D = 21·03″ }

(5) *γ Virginis.* R.A. 12·35. Mags. 3, 3.
P = 156·3° D = 5·1″ Ep. 1881·39
P = 158·0° D = 4·8″ Ep. 1882·36

(6) 35 *Comæ Ber.* R.A. 12·47. Mags. 5, 7·8.
AB. P = 62·4° D = 1·0″ Ep. 1881·40
AB. P = 60·0° D = 0·9″ Ep. 1882·36

(7) 31 *Virginis.* R.A. 12·35. Mags. 6, 12.
P = 30·0° D = 4·3″ Ep. 1881·24

(8) 42 *Comæ Ber.* R.A. 13·4 Mags. 6, 6.
P = 13·5° D = 0·53″ Ep. 1881·41
P = 20·0° D = 0·4″ Ep. 1882·36

(9) 25 *Canum Ven.* R.A. 13·32. Mags. 5, 7·6.
Comes not seen. Ep. 1881·39
P = 152·0° D = 0·35″ 1882·26
P = 162·0° D = 0·31″ 1882·36

1. Very easy: a beautiful pair, 4·9 golden, 10·7 blue.

2. Beautifully separated: two lovely little discs.

3. H_2, quoted by Gledhill in his invaluable "Handbook of Double Stars," says of this famous binary:—"A double star, in which the two stars are nearly equal, connected undoubtedly in a binary system by their mutual gravitation, and revolving round their common centre of gravity, with a motion so rapid as to admit of being traced and measured from *month to month* must be allowed to be a phenomenon of no common interest, and deserving every attention both from the practical and theoretical astronomer." Period about 60 years.

4. Gledhill, in the "Handbook," says that of A C no other measures but Smyth's are known, which are: P = 145.0°. D = 17·0″. Ep. 1834·31. C, however, is egregiously palpable.

5. A splendid pair of suns: single in 1836.

6. Difficult: requires a fine night to see close and small companion.

7. One of β's discoveries: 12m.; bears illumination well.

8. Σ., the discoverer, quoted by Gledhill, says, "This star is worthy of all attention, for there is a suspicion that its period is smaller than that of ξ Ursæ Maj." Period about 25 years.

9. This star is very difficult, and cannot be seen unless def. is very good.

The following are, I believe, new doubles discovered by me:

Nova. R.A. 9·27. Dec. 15·0. Mags. 9, 14.
P = 108°. D = 8·2″ Ep. 1881·25.

Colours: White, bluish-white.

Nova. R.A. 18·3. Dec. 9·20. Mags. 8·5, 10.
P = 305·0°. D = 2·0″. Ep. 1881·38.

This is a new double. β kindly measured it as follows:—

P = 306·5°. D = 2·75″
Nova. R.A. 15·39. Dec. 31·52. Mags. 8·5, 14.
P = 121·0° D = 3·1″ Ep. 1881·40.
Nova. R.A. 17·57. Dec. 33·14. Mags. 5, 12.
P = 108·0° D = 15·0″ Ep. 1881·40.
Nova. R.A. 16·59. Dec. 19·46. Mags. 7·5, 10.
P = 224·0° D = 1·2″ Ep. 1881·41.
β measured this as follows:—
P = 225·0° D = 1·81″
Nova. R.A. 12·53. Dec. 19·0. Mags. 10, 10.
P = 105·0° D = 1·2″ Ep. 1882·34.

The magnitudes of the new stars are estimations: for those of the other pairs I am indebted to the "Handbook of Double Stars," by Messrs. Crossley, Gledhill, and Wilson, a work which is quite indispensable to all double-star observers.

Those of your readers who have ever been themselves engaged in the work of double-star measurement, will know its extreme delicacy and difficulty; and unfortunately the atmospheric conditions required for very close doubles are such as are found here only on an exceedingly limited number of nights in the year.

Jevon J. Muschamp Perry.

St. Paul's Vicarage Observatory, Alnwick.

WENHAM'S NEW MICROSCOPE.

[20071.]—Letters signed by Mr. Wenham and Mr. Moss give "an unqualified denial" to the obvious fact that the stands recently patented by these gentlemen are unacknowledged appropriations of the principle enunciated by Dr. Edmunds at the Royal Microscopical Society. Mr. Wenham attempts also to minimise the value of the principle. Mr. Moss, on the other hand, asserts that his stand "was devised long before Dr. Edmunds's words were uttered, and primarily for a purpose in the perfecting of microscopical vision which, judging from my letter, I have as yet failed to grasp."

Messrs. Ross and Co. also write, but carefully abstain from touching questions of fact. There remain, therefore, only the three allegations to answer.

I. If Mr. Moss ever had in view any object other than the appropriation of the principle enunciated by Dr. Edmunds, he has forgotten to claim that object in the specifications of his patent.

II. The statement:—"There can be but little claim to invention in this idea, and it might readily occur to any one looking at the illustration of the Wale microscope then published," comes very badly from Mr. Wenham, about an idea which he rushed down to the Patent Office to appropriate. I quite admit that any fool can see the principle at once, *after it has been pointed out*, though it is not every fool who would attempt to appropriate, by means of small mechanical contrivances for applying it, a leading principle in microscopical construction which had been enunciated *pro bono publico* at a scientific society, and amply published in its journal. But the answer to Mr. Wenham is this:—Mr. Wale never saw it, Dr. Carpenter never saw it, no other Fellow of the Society saw it; Mr. Moss, who was there in person, and "Messrs. Ross and Co.," who were there in proxy, never saw it, nor, after the principle had been enunciated by Dr. Edmunds, did either of these astute gentlemen rise to say that it had ever before been suggested. Mr. Swift, at the close of the meeting, asked Dr. Edmunds for permission to adopt the construction in his students' microscopes—a permission which was then given, together with further explanations on the various ways in which the principle could be applied. While this explanation was going on, Mr. Moss was sufficiently interested in the matter to stand by and carefully listen among other gentlemen who were there.

The pages of the *Journal* of the Royal Microscopical Society for the previous years show scores of drawings of stands, in no one of which had this principle ever been shadowed out. An inspection of the stands now in the window of Messrs. Ross and Co.'s warehouse will further demonstrate that their newest stands show no trace of this principle, but are all swung on the same absurd eccentric arrangement as for a whole generation made our revolving stages only a ridiculous complication. Had Messrs. Ross and Co. ever yet realised the importance of this new principle of construction which they seem to have had some share in the attempt to appropriate, it could not be imagined that they would have continued to accumulate on hand such a stock of those really awful and ridiculous swinging substage stands—a stock which will have to be either remelted or sold off by Dutch auction, as was recently done with a cartful of other stands. So much for the originality of the principle. As to its value,—not yet admitted by either of the gentlemen who have attempted to appropriate it—I venture to predict that it will govern the construction of all future microscopes as completely as the concentric principle now governs the construction of revolving stages.

III. The value of the "unqualified denial" which is given by Mr. Wenham and by Mr. Moss will be shown by comparing the dates and the specifications of these gentlemen's patents, each of which may be got from the Patent Office by sending 6½d. in stamps.

1. In the discussion upon Dr. Carpenter's demonstration of the Wale microscope,—

"Dr. Edmunds pointed out that this most useful microscope-stand would be vastly improved if only the arc upon which the body turns were so constructed that the centre of the circle of which the arc forms part were made to coincide in position with the centre of the stage. The object would then undergo no movement of translation, either in rotating the stage or in turning the tube from the vertical to the horizontal. In rotating the stage, the object would turn upon the optic axis; in moving the tube into various degrees of obliquity, from 0° to 90°, the object would rotate upon its horizontal axis. The result would be that, with a thin stage and a hemispherical lens in immersion contact with the under-surface of the slide, all the complicated swinging substages and other contrivances now upon the table might be swept away, and every angle of illumination could be got by merely inclining the body of the microscope upon its sustaining arc. There would only be needed a lamp on a level with the object, with a condenser at its focal distance standing upon the table in line between the lamp and the object."

In this paragraph there is enunciated, amply and unequivocally, the concentric principle—*i.e.*, that of making the object the centre about which the optic-plane revolves, as well as the centre about which the stage-plane revolves. The optic-plane being vertical, and the stage-plane at right-angles thereto, it follows that the optic-plane will always turn upon that point in a horizontal line in the stage-plane at which the object is located, while the stage-plane will turn reciprocally upon that point of the optic axis at which the object is located. In microscopes previously constructed, the optic plane rotates, not upon a point in the optic axis, but upon the point at which the optic tube is pivoted—i.e., from 3in. to 5in. behind the optic axis, and, therefore, on inclining the microscope body, the object is displaced or translated along an arc of from 3in. to 5in. radius, instead of remaining in its place as a general centre to the microscope, so as to be susceptible of exactly those refined orientations in reference to a fixed light which are needed in order to command all its optical reactions.

2. The above cited remarks having been made on Nov. 10, 1880, were published in the *Journal* of the Royal Microscopical Society on Dec. 13; and on Dec. 22, just nine days later, Mr. John Matthew Moss left at the Patent Office a provisional specification, the following being the text of his claim:—

"This invention relates to improvements in microscopes, and consists of a method of mounting the body or portion carrying the lenses on a stand so constructed as to be capable of presenting the instrument together with the object in every possible position with regard to an illuminating ray proceeding in a fixed direction, so that every possible variety of illumination—from direct front light to the last degree of obliquity at which a ray of light will enter a surface of glass—can be obtained without the interposition of any substage or subsidiary apparatus whatever, without once losing sight of the object or the light. To effect this, I mount the body together with the stage upon an arm capable of rotation in a vertical plane, the centre of which rotation is exactly in a horizontal line with the object when the latter is in the focus of the objective. In other words, the line of rotation of the body and stage is exactly in the focal plane of the objective.

"The cradle or other joint upon which the instrument turns to effect this is attached by means of a pillar or pair of pillars to a horizontal rotating plate, the centre of rotation of which is exactly beneath and in a line with the optical axis of the microscope when the instrument is in a vertical position.

"I thus obtain two motions, one in altitude the other in azimuth, so related to each other as to be capable, when used separately or in combination, of presenting the object together with the body in any position towards a ray of light proceeding from a fixed point or in a fixed direction. This ray I obtain by means either of a lamp mirror, &c."

There follows a claim for improvements in the stage invented by Tolles, and in the specification itself, filed on June 22, 1881, Mr. Moss thus formulates his claim (lines 11-15, p. 4):—

"I declare that what I claim as the invention, to be protected by the hereinbefore-recited letters patent, is,—

"1st. Mounting the body of the microscope together with the stage upon a stand so constructed as to permit of their rotation about two axes, so arranged with regard to each other and to the other parts of the instrument that the body and stage may be presented at any angle to a fixed ray of light, substantially as herein specified and illustrated in the drawings.

"2nd. In a mechanical stage the combination of two pinions on the same vertical axis with two racks at right angles to one another operating independently or in combination to impart motion in any direction to the slide, substantially as specified. In witness, &c."

Now, setting aside the claim for improvements in Tolles' mechanical stage with which we now have nothing to do, and ignoring the fact that Mr. Moss imagines that there is a limit to "the obliquity at which a ray of light will enter a surface of glass"—a statement which throws much light upon his knowledge of optics—his patent amounts to absolutely nothing but an attempt to appropriate the important principle laid down by Dr. Edmunds, and he attempts to do this by means of the invention of a lateral pivot for the "horizontal axis" defined by Dr. Edmunds. The "drawings" consist precisely of the one figure already given in the *Journal* of the Royal M.S. and in the ENGLISH MECHANIC. In the formal specification, filed six months after the original one, Mr. Moss solemnly reproduces his delusion with regard to "the last degree of obliquity at which a ray of light will enter a surface of glass." Of course, every tyro in optical science knows that there is no such limit. So much for Mr. Moss and his assertion of having compassed some other "purpose in the perfecting of microscopic vision which I have as yet failed to grasp."

3. Mr. Wenham did not leave his provisional specification till Jan. 12, 1881, some two months after the meeting at which the principle had been enunciated by Dr. Edmunds. Mr. Wenham's provisional specification runs thus:—

"The first improvement relates to the stand for carrying the limb body of the microscope. The stand consists of a segment of a circle or sector extending behind the limb and beneath the stage. The centre is from a point in the axial line of the microscope body, slightly above the stage, and in the plane occupied by an ordinary slide thereon, so that when the microscope is inclined by a rack or pinion movement, or otherwise to or from the observer, the object in focus is at the centre of rotation. The sector passes between guides or jaws upon a base with an arrangement for fixing the instrument at any inclination. The microscope is attached to the sector by an axis, so that it can be inclined on either side; the centre line of this axis also intersects that of the body in the plane of the object on the stage. The base turns on a foot-plate, the axis of which is also in a perpendicular line intersecting the object. The edge of this foot-plate may be divided into degrees for measuring apertures, and indicating angles of illumination. When the microscope is inclined backwards by the sector movement or turned sideways on the back axis, or rotated on the base footplate, these movements, used either separately or combined in all directions, admit a ray of light from a fixed source to reach the object, as all the movements radiate from this as a centre."

"The second improvement is for an application of anti-friction rollers for the fine focussing movement of microscopes, &c., &c."

"The third improvement is for a simplified form of thin mechanical stage, &c., &c."

With neither of the latter claims have we anything to do; but I may remark that Mr. Wenham's stage claim is to me indistinguishable from that of Mr. Moss's; both also seem to me to be little more than appropriations of the Tolles stage by means of the Tyrrel milled heads, so long used horizontally by Powell and Lealand. With regard to Mr. Wenham's new stand, it is simply an appropriation of the principle of co-ordinate axes and reciprocal rotations enunciated by Dr. Edmunds. It is quite true that the base is very large and heavy, and that, as Mr. Wenham claims, this base brings the centre of gravity very low. But this only secures the stand against being overturned; it does not give stability to the parts that are jointed on above. The additions in Mr. Wenham's stage are not new, and are, in my opinion, useless and expensive complications. So much for the "unqualified denials" of Mr. Moss and Mr. Wenham.

Another F.R.M.S.

[20072.]—So far as regards the backward inclination of this microscope in an arc whose centre is the object on the stage, I beg to say the principle cannot be the discovery of Dr. Edmunds because of some words spoken by him in November, 1880. My reason for this assertion is a very plain one: When I was in New York, about four years ago, I saw a good deal of Mr. George Wale, the designer of the "Wale" microscope. The possibility of making his sliding limb move concentrically with the object—the very point mentioned in the quotation of Dr. Edmunds's criticism of Wale's microscope, cited by "Another F.R.M.S." on page 217—was the first scheme tried by Mr. Wale, and he gave it up because he found he could not succeed with it without producing an unsightly limb.

Mr. Wenham appears to have overcome the difficulty by making his sector *not* the limb itself, but an exterior carrier for the limb.

I do not see any resemblance between this arrangement and that actually adopted by Mr. Wale, nor do I see the slightest justification in the claim made on behalf of Dr. Edmunds.

Yet Another F.R.M.S.

[20073.]—As I understand "Another F.R.M.S.," the claim he sets up on behalf of Dr. Edmunds to be the originator of the main principle of Wenham's new microscope is based on a suggestion made by Dr. Edmunds, on Nov. 10, 1880, for improving Wale's microscope.

The main principle of Wenham's new microscope is, that all the movements radiate from the object as a centre.

The suggestion made by Dr. Edmunds was, that Wale's stand would be improved by striking the radius of the sliding limb from the object as a centre. The reason he gave for the suggestion was the sufficiently obvious one,—that, with the limb so altered, "every angle of illumination could be got by merely inclining the body of the microscope upon its sustaining arc."

Dr. Edmunds made this suggestion as though he were the first to have thought of it. But, unfortunately for his originality, a curious coincidence occurred with reference to this very subject. Mr. Wenham worked out the idea on the drawing-board some two years before, when Wale's stand was first figured in the *American Journal of Microscopy*, and abandoned it as unsatisfactory.

Strangely, too, within a day or two after the meeting of the Royal Microscopical Society on November 10, 1880, when Dr. Edmunds first made his suggestion, he communicated his idea to Mr. Swift, the well-known optician; Wale's microscope was placed in Mr. Swift's hands, expressly that he might have a fair opportunity of improving upon it. The result was *nil*,—Dr. Edmunds's plan was found to be a failure. In proof of this, I adduce the fact that, in the microscope issued by Mr. Swift, based on Wale's, the sliding limb is not modified, as Dr. Edmunds recommended, but is an exact copy of Wale's. Clearly, then, when Dr. Edmunds himself deliberately undertook the alteration of Wale's microscope, in the direction he had recommended, unforeseen difficulties cropped up with which he was unable to cope, and hence his suggestion was abandoned—precisely as Mr. Wenham's attempt in the same direction had been abandoned some two years before! And yet this criticism on Wale's microscope, this suggestion which Mr. Edmunds himself failed to embody, and which Mr. Wenham had tried two years before, is adduced by "Another F.R.M.S." as "the source of the inspiration from which Mr. Wenham drew his design"!

"F.R.M.S." has pointed out some of the devices by Grubb, Nachet, Tolles, and Zentmayer, in which the problem of oblique illumination, by means of movements radiating from the object as a centre, has been dealt with more or less effectually. And it is abundantly evident that Wenham's new microscope must be regarded as the natural outcome from these devices.

That "Another F.R.M.S." should claim "for Dr. Edmunds, and for him alone," "the merit of this important principle of construction," which he elsewhere terms "the great new principle of microscopic construction," shows simply that he is unfamiliar with the progressive genesis of the microscope.

The plain fact is, the principle embodied in Wenham's new microscope cannot justly be claimed for any single individual; it has been gradually developing from the quite early days of the microscope—more rapidly from the date of Grubb's invention of the substage-arc, and still more rapidly since Zentmayer's swinging tail-piece was exhibited at the Philadelphia Exhibition in 1876.

Akakia.

MICROSCOPE POWER.

[20074.]—IN the R.M.S. *Journal* there is now presented, in tabular form, the assumed magnifying power of eyepieces of the principal London makers with the magnifying power of various objectives *alone*, of different focal lengths, on a 10in. tube; and the united magnifying power of each objective combined with each eyepiece. The table is, perhaps, more useful in suggesting how the amateur may conveniently specify, for ready reference, the capabilities of his "battery," than in affording definite information; and I venture to offer for your columns a partial statement, founded upon this example, of the details of magnifying power provided by an ordinary well-furnished instrument of full size.

The *Journal* article, in which this information was first introduced, expresses surprise that the combined magnifying powers of eyepieces and objectives, as published by their makers, should in some instances give actually different values for the magnifying effect of the same eyepiece. There can be no doubt of the fact, paradoxical as it may seem, if the comparisons be made with objectives of widely different focal length, using the same eyepiece, and the draw-tube closed, in each case. The reason appears to be, that the length of the draw-tube practically varies, according to the length of the objective itself, and the distance at which it stands from an object in focus. And, of course, as the length of the draw-tube varies, so does the magnifying power of the objective. For example, suppose the magnifying power of a 1½in. o.g., at a distance of 12in. from object to image, to be 7·5 times; and of a ¼in. o.g., under like conditions, to be 100 times. Suppose also that the magnifying power of an A eyepiece has been determined independently to be five times exactly. The eyepiece, being of low power, enters some 2in. into the draw-tube. The image from the objective must be formed in the focus of the eye-lens of the eyepiece, and that point happens to be 0·9in. below the top of the draw-tube when the eyepiece is pushed home. Also, in the example supposed (which is derived from experiment), the top of the draw-tube—*i.e.*, the milled edge against which the rim of the eyepiece abuts, is 11·9in., from the object when in focus with the draw-tube closed. Moreover, the effect of an alteration of 1in. in the length of the draw-tube, is a change in the magnifying power of the 1½in. objective of 0·7 times. Consequently, as the image is formed 11in. instead of 12in. from the object, the actual magnifying power of the objective is reduced to 6·8 times. If now, the combined image, as seen in the eyepiece, be projected by the camera-lucida at 10in., the total power will prove to be about 34 times—which is the product of the two magnifying powers taken separately; and if this be divided by 7·5, neglecting the change which has been virtually made in the length of the draw-tube, the power of the eyepiece comes out 4·53 times instead of 5.

Similarly, with the ⅛ objective, the distance from the object in focus to the top of the draw-tube is 11·2in., and the magnifying power of the objective, alone, is altered seven times by a change of an inch in the length of the draw-tube. Using the same eyepiece as before, that length (from object to image) is 10·3in., instead of 12in.—being reduced 0·8in. by the shorter length of the objective, and its nearer approach to the stage; and, 0·9in., as before, by the formation of the image in the middle of the eyepiece below the top of the draw-tube. Consequently, the actual magnifying power of the objective is now only 88·1 times; and a projection at 10in. of the combined image will show a total amplification of about 440 times: this, divided by 100, gives 4·44 for the effect of the eyepiece; another value again. It is, therefore, obvious that, when measures are taken with a closed draw-tube, whose virtual length will vary with different objectives, the effect due to the same eyepiece may apparently differ, because the effect due to the objectives individually has been calculated at the same fixed distance.

That distance in the article referred to is taken at 10in. But the large stands, now so general, do not permit this comparatively short length of tube for the interval between the conjugate foci at which the object and image are placed. A more convenient assumption is 12in., and for very low powers, such as a 4in., a distance of 14 may be necessary.

It would be unreasonable to ask you to print particulars of a full series of objectives; the details of a few will suffice.

OBJECTIVES.

Focal length in inches.			Aperture.		For ·005 cover-glass.			Magnifying power.		
Nominal.	Actual (no adj.) (*a*)	Less for 10 div. adj. (*b*)	In air. (*c*)	Numerical. (*d*)	Best adj. (*e*)	Working distance. (*f*)	Diam. field. (*g*)	At 12in. (no adj.) (*h*)	Difference per in. of d. t. (*k*)	Add for 10 div. adj. (*l*)
3in.	2·25	—	12°	·11	—	2·01	·36	3 46	0·5	—
$\frac{2}{3}$	·669	—	32°	·27	—	0·26	·077	15·9	1·4	—

Magnifying power (*p*) ..	5	7·8	12·4	16·7	23·3	8·	14·

Draw-tube closed.			Combined magnifying power of objectives and eyepieces.						
O.G.	Distance to top of d. t. (*q*)	Power of o.g. alone. (*r*)	A	B	C	D	E	K_1	K_2
3in.	13 3in.	4·11	18 3	31·3	51·6	70·3	99·2	29·7	55·4
$\frac{2}{3}$	11·4	14 78	67·6	113	185	251	354	109	201
$\frac{1}{4}$	11·05	42 05	193	322	529	715	1006	312	572
$\frac{1}{8}$	11·2	94·4	440	725	1178	1600	2218	710	1292

(*a*) This value was determined, (i.) by Mr. Cross's well-known formula $f = \frac{n\,l}{(1 + n)^2}$: where n is the ratio of image to object, and l the distance in inches between them. A convenient method of obtainining n is with a ruled stage micrometer, and Jackson's eyepiece micrometer; the actual distances of their respective divisions being first carefully ascertained. It is important that nothing besides the objective should intervene between the scales, and therefore the "field-glass" must be temporarily removed if a Huyghenian eyepiece be employed. The true focal length of each objective was also tested (ii.) by using it as an eyepiece upon a telescope of known (147·7in.) focal length, and calculating the magnifying power, after adjustment to stellar focus, with the aid of a double-image dynameter. For all but extreme cases, such as 1-20in. and a 4in. objective, with which the difficulty of measurement is considerable, the agreement was all that could be desired.

(*b*) The above values were taken with the lenses of the objective "open"—i.e., at "uncovered." A movement of the adjusting collar, to correct the o.g. for covered objects, approximates its lenses, thus shortening their combined equivalent focal length, and increasing the magnifying power of the objective. This column shows the effect in diminution of focal length of one whole turn, or 10 divisions, of the adjustment collar; and the effect of more or less "adjustment" may be taken proportionately: though certainly there are some objectives to be met with, in which the collar can be moved through several divisions before and after a corresponding effect is produced by correcting the mutual position of the lenses.

(*c*) This was found by admitting parallel solar rays to the back of the objective placed horizontally, receiving the emergent cone of light upon a vertical screen, measuring the height and base of the cone and calculating its angle.

(*d*) This is a matter of faith rather than sight. The figures in the column are the readings for each objective on a glass semicircular disc known as the Apertometer of Prof. Abbe. The apparatus has been described in the "E. M."; and also, with copious discussion of the "Aperture Question," in recent volumes of the R. M. S. *Journal*. I may mention here an experiment which is somewhat perplexing. Suppose an oil-immersion o.g. is tested by the apparatus, and in the first instance focussed *dry*, and the reading taken; then let a drop of pure water be interposed, the readings instantly increase considerably, and the field becomes brighter. Next, let the water be completely removed, and oil of cedar substituted; the readings generally increase again, to some extent, but not much; and oil-immersion o.g. are to be met with, and good ones too, which show no increase of aperture whatever, by this apparatus, with oil as compared with water. Of course this digression is not meant to imply that oil lenses can be *used* either dry or with water.

(*e*) It is convenient to register the amount of collar-adjustment with which an objective is found to perform most successfully over a given thickness of cover-glass. At the same time, unless this thickness be previously marked upon a slide, it is not easy to ascertain it precisely. Directions have been given to measure the apparent thickness by the "fine movement," first focussing the object, and afterwards dust upon the cover-glass, so as to determine the real thickness by calculation. But the result so obtained will depend upon the index of refraction assumed for the glass; and this assumption may be largely erroneous.

(*f*) This is readily measured by the fine movement, aided, for low-power o.g., by a scale and vernier on the principal limb and racked slide of the microscope—if that convenience should exist.

(*g*) The actual diameter of field shown at one view, by the lowest eyepiece; the objective being uncorrected; i.e., having its adjustment-collar at zero.

(*h*) The most intelligible way of considering magnifying power is to separate it into its component parts—so much due to the objective, and so much to the eyepiece. The latter will evidently magnify an image the same number of times wherever it happens to meet with it, in focus; whereas the size of the image formed by the objective will depend upon the distance from the object at which the image is formed and viewed. Throughout the present examination, the stage-micrometer and the eyepiece-micrometer were kept precisely 12in. apart, giving a uniform comparison for all the objectives. Those possessing adjustment divisions were used with the collar at zero; and a ruled glass stage-micrometer, which had been detached from its slide, was inverted and focussed as an "uncovered" object. The figures in this column denote the number of times the object was thus magnified by each o.g.

(*k*) An increase in the length of draw-tube leads to a corresponding increase in magnifying power. The additional number of times per inch of tube, here specified, may be considered constant for such distances from the object as are practicable—viz., about 11in. to 15in., with the instrument employed.

(*l*) As remarked under note (*b*), the magnifying power of an objective is also increased by adding to the divisions of its adjustment collar, and this column shows the additional number of times due to the first 10 divisions of adjustment.

(*m*) The eyepieces, A to E, are Huyghenian; K_1 and K_2 are of the Kellner form, giving plenty of light and a large field.

(*n*) Their focal length was obtained by combining them successively with a hom. imm. objective of nearly 1-14in. measured focal length; and in each case the draw-tube was so adjusted that the eye-lens of the eyepiece should receive the image transmitted by the o.g. at the same distance of 12in. from the stage micrometer. The stand carrying the tube in a horizontal position, the image from the eyepiece was projected by the camera-lucida on a rule placed horizontally 10in. below the axis of the microscope, and the position of the rule was tested with a thin plumb-line for each eyepiece. This gave the total magnifying power in the usual way, and the power due to the objective alone at the prescribed distance having been previously determined, a process of simple division gave the magnifying power due to the eyepiece alone, when the combined image was projected at 10in. Lastly, dividing this number 10 by the power thus found for each eyepiece, the quotient was the focal length of each. And the value thus obtained agreed, to the first place of decimals, with that derived from the telescope, applying the eyepieces to the latter as described in note (*a*).

(*o*) The measurements of tube-length have been taken uniformly to the top of the draw-tube. But that point did not coincide with the focus of the eyelens of the eyepiece; generally this focus was below the tube-top, thus virtually shortening its length; though in the "deeper" eyepiece, this focus is outside the draw-tube. Consequently, a correction becomes necessary in determining, by calculation and without experiment in every case, the total power employed.

(*p*) See note (*n*) above.

(*q*) When the draw-tube is closed, and an object in focus on the stage, these are the least distances, for the several o.g., at which an image can be formed at the top of the draw-tube. Collar adjustment, zero.

(*r*) This shows the corresponding magnifying power, due to these altered distances, slightly different for each objective, as compared with those given in column (*h*) for the uniform distance of 12in.

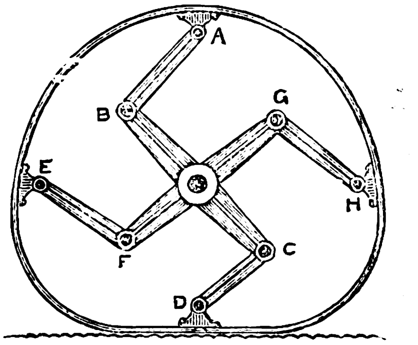
And finally, the table of combined magnifying power shows at a glance the total amplification derived from each objective (without adjustment) when associated with any eyepiece (the draw-tube being closed.) When the draw-tube is not closed, and when divisions have been taken on the objective-collar, corrections are necessary. For example, the power of a 4-10in. o.g. alone, at its nearest distance of 11·2in., with closed draw-tube, is 26·95 times; the increase for 1in. of draw-tube is 2·5 times, and for 10 divisions of adjustment 0·75 times. It was used at a distance of 11·7in., with 8 divisions of adjustment, and with the B eyepiece, required the power. The nett increase of draw-tube is 0·3in., eqvivalent to 0·83 times; and the increase due to 8 divisions of collar is 0·6 times; adding these to the 26·95, we have 28·38 for the o.g alone, and multiplying that by 7·8 (the power of the eyepiece), the combined power proved to be 221, and it was exactly verified by projection.

Antares.

P.S.—Can you persuade "F.R.M.S." to give us a paper explaining how the conditions of a slide can best be distinguished—viz., whether the object is on the slide or on the cover; whether it is mounted "dry" or in balsam, or other medium; and what would probably be the best method of illumination in each case?

THE PARADOX WHEEL.

[20075.]—So called from its appearance; for seeing that all the internal parts *a b c d*, and *e f g h* are pivots which support the whole of the internal parts, and that the cross in the centre is also free on the axle after the manner of a pair of scissors, a collapse appears inevitable; whereas the axle continues as firmly in the centre as in the ordinary wheel with fixed spokes, and the elastic tire gives way, and flattens on the ground with the same freedom as if the load were merely placed on the top of the elastic tire: and (as I shall show) gives us a base equal to the sleepers which (on a railway) support proportionately a locomotive engine. See Fig. 1. This wheel might also be named the leg wheel, or the walking wheel, from its appearance.



By publishing this invention, I am showing to our readers my "trump card"; for so important is a means of reducing the horse-power required for traction on a common road to the same low amount (for the same load) as is required on a railway, that its general adoption would amount to a revolution in locomotion on common roads.

I am aware that others have tried to effect the same object; but one mistake has been, to make the internal part of a wheel elastic; whereby the load only descends nearer to the ground, instead of the tire becoming uniformly flat next the ground, as is the case in this invention. In other designs, the two wheels on each side have not been independent of each other, whereby guiding has been prevented.

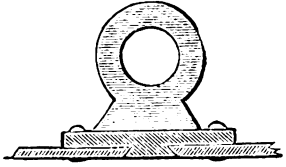
In order to show that my object has been attained, I will explain why it is, that so great a proportionate tractive power is required on the common road.

The common wheel acts somewhat after the manner of a cheese-cutter, and grinds to powder annually millions of tons of road metal, and also falls into, and has to be dragged out of, every rut, little and big: this amounts to a lot of uphill work, and accounts for the extra power required. By the adoption of my invention, these evils are avoided; as there is always a base or foundation sufficient to make the tractive power no more than that of a railway on the same gradients—mind, I say, on the *same* gradients; which we know are more favourable on a railway.

To compare: Let us suppose a cart has 5ft. wheels, and the tire to flatten ⅛th or about 2ft.; width, say, 4in.; total surface bearing 1ft. 4in.; and, say, total weight, 1½tons. Now, a locomotive engine will weigh about 24 times this, which, × 1ft. 4in. = 32ft. super. for sleepers, which, divided by, say, 5 sleepers, gives each 8ft. 7in. long by 9in. wide, which is not far from the truth.

The tires should be one piece of spring steel, tempered clock-spring, of width and thickness as engineering data may dictate. The ends of the tire may be riveted to the bearing, same as the other three, but the ends must be shut into the dovetail, cast as part of *one* of the four bearings, which is shown at bottom of Fig. 2. The other parts of the tire should be *malleable* cast iron.

FIG. 2



Other advantages resulting are, that carriage-springs are needless, the tires being themselves the springs; and all noise, jolting, and vibrations, are done away with, so that the motion will be as easy as can well be imagined.

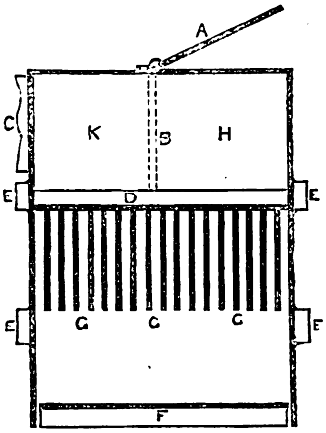
About nine years ago I had a model pair of these wheels made, 21in. diam., which were put by, waiting for a change in those blessed Patent Laws existing in this heavenly-governed country; but now I shall expect to have joined the great majority before this desirable change takes place.

To conclude, I will (from an inventor's point of view) speculate on the results of the delay. Millions laid out in tramways, millions of tons of road metal powdered, to be replaced by new, to "rattle our bones over the stones," thousands of men and horses for this work, millions of horses for general traffic, where less than half so many would suffice. I could go on thus yet further, but must leave the rest for the imagination of the reader, including the cost, only remarking, in conclusion, that, by the adoption of this invention, the unfortunate Upper Ten may save the new carriage-tax.

Barry-road, S.E. **J. H. Huxley.**

DOMESTIC SMOKE-CONSUMING STOVE.

[20076.]—The fire is contained behind and above bars G. Above is chamber divided into two parts H and K, by vertical partition B. A door (A) admits coal, which is heated in H, and whose more volatile constituents have to pass through or over incandescent coal, and are burnt before reaching the chamber K, and passing out by the chimney C. By raking along the opening (D) with a poker, burning coal in chamber H may be moved along to make room for fresh fuel.



Doors are hinged to E, E, E, E, which fold across the front bars, to give an increased draught when necessary. An ashpan (F) is placed below. Unimportant details and ornamental ironwork not shown. This stove combines the advantages of an open fire and consumption of smoke without great complication of parts. It may be made any size.

W. A. Lee.

NEW ELECTRO-MAGNETIC CLOCK.

[20077.]—Among the various methods which have been adopted in the application of electro-magnetism as a motor for clocks, I believe that little or nothing has been accomplished in applying it to the upper part of the pendulum; and certainly no method as shown by this invention, where as will be seen (in Figs. 1 and 2) the pivot of the pendulum is also the armature of the electro-magnet.

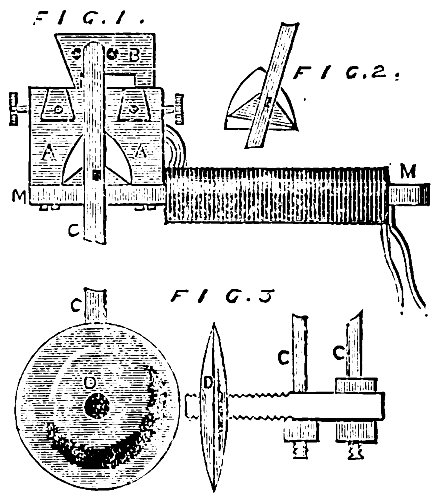


FIG. 1. FIG. 2. FIG. 3

I have only figured enough to show one method of applying the principle here introduced; leaving out the train and its attachment to the new apparatus, merely observing that the pendulum is connected with the escapement rod in the usual way; and whereas in this case (instead of the train moving the pendulum) the pendulum moves the train, it is necessary to reverse the escapement action; and further that that part of the train only is required, from the escapement to the hour and minute wheels inclusive.

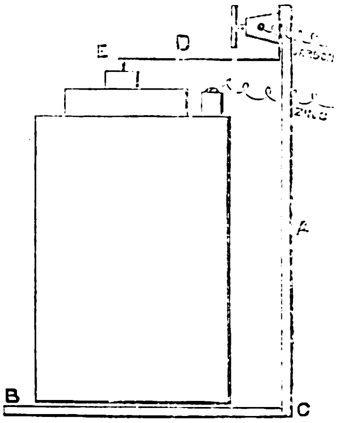
Insomuch as this method utilises the greatest force the magnet is capable of exerting on the armature, it is perfect; and I doubt not that it will be found that a very weak current will suffice, such as a small earth battery, or the gas and water pipe and earth, &c. &c.

In Fig. 1, A A is a piece of ivory screwed to one leg of magnet having a gothic arch, at the top of which are dovetailed two pieces of brass, having binding screws for the wires. The pendulum rods are fixed at the ends of a triangular prism of iron, seen resting at the bottom of the arch; which rods embrace loosely *one* leg of the *e* magnet M. Above the ivory arch is a brass bridge, B, actuated by rods of pendulum, which by reason of space between the pins (shown) allow this bridge to make connection of circuit during the return of the pendulum to its perpendicular position *only*, at which time current ceases; and allows freedom to complete its arc, and return by a *nearly* complete arc before the current is on again. Fig. 2 gives an idea of the position of the iron prism at the end of the arc, where the surfaces are seen apart. Fig. 3 shows my substitute for the gridiron pendulum, namely, a rod of iron and of brass, *c c*, which, expanding at different ratios, allows the bob when properly adjusted on the screw to remain unaffected by temperature: the nuts make the ordinary adjustment for length. I should have said that the prism armature is on both legs of *h s* magnet. The wires for battery connection and also to the binding screws are also shown. D is the pendulum bob.

Barry-road, S.E. **J. H. Huxley.**

LECLANCHE BATTERY CONNECTIONS.

[20078.]—As I have more than once seen complaints against the lead caps on the above batteries, and have had much trouble myself that way, I thought perhaps the following may be some use to amateurs who construct their own, as it makes a most efficient connection without the trouble of melting and using lead. A and B, two pieces of boards screwed together at C. B forms a stand of sufficient length to carry the number of cells required. A, upright piece forming back, same length as B, which may rest as a bracket against a wall, also to carry carbon and zinc terminals. D, piece of brass spring about ½in. wide, 1-16 thick, bent at right angles and clamped to A by a strong binding-screw.



At the other end of the spring is soldered a small piece of platinum wire E, about ¼in. long and 1-16 diameter, so as to press down on the carbon block. Let the spring be covered with sealing-wax varnish to prevent corrosion. The above drawing shows one cell, but when more are used, the wire from zinc rod goes to binding-screw of carbon-spring.

W. J.

A CHEAP FORM OF BUNSEN BATTERY.

[20079.]—To make this, obtain two dozen salt jars for the outer containing vessels; these can be obtained from any marine store for about 1s. 6d. They hold a quart, and are about 5in. by 3½in. external.

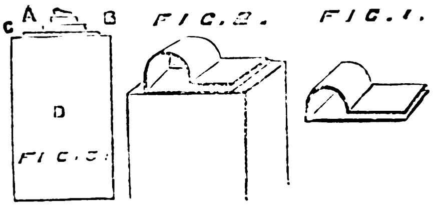


FIG. 3. FIG. 2. FIG. 1.

The porous cells should be 5 by 2, two dozen of these will cost 6s. The carbon blocks to go in them must be 6in. long by 1in. square. The same number of these will cost 9s. Now get ½lb. of paraffin wax (1s.), and melt it in an old pot. Then soak the tops of the carbons in it for about an inch up, then take them out, and with the blowpipe drive the wax back ⅛in. from the top. Then deposit on the tops a coat of copper, put on slowly to insure hardness.

When they have all been coppered, bend two dozen strips of stout copper sheeting ½in. wide into shape, and exactly twice the size shown in Fig. 1. Then solder one on the coppered top of each carbon, as shown in Fig. 2. Then brush over the coppered tops a coat of sealing-wax varnish, except in between the jaws of the clamp, which, of course, must be clean, so as to make good connection. Now you have your negative elements complete, place them in the porous cells, and these in the salt jars.

When a number of cells are used, the carbon connection described above gives much greater satisfaction than the usual clamp, because the copper surface in contact with the carbon is so much greater, and also because the paraffin wax prevents the acid creeping up and destroying the connection by forming a non-conducting salt of copper.

For the positive element, if not very particular about first cost, use a rolled zinc cylinder 2½in. in diameter by 5in. high, with 6in. of 16 copper-wire soldered on to it, bearing at the end a little slip of copper sheet for connecting it with the carbon of next cell.

If the battery is not going to be used very often, three zinc plates, each 1in. by 5in., at equal distances round the porous cell, the three connected by a wire with the connecting-slip, may be used; they will give nearly as much power, but will require renewing very much oftener.

The zincs should be amalgamated once every three times they are used. The price of zinc plates cut to size is from 4d. to 6d. per pound.

The charge for this battery is nitric acid, saturated with bichromate of potash, for the porous cell, and dilute sulphuric acid for the outer cell. I use it, as a rule, directly after mixing, and find that I get the same power with very much less acid.

If the plates are used, the battery will not cost more than £1 5s. or £2, using cylinders, and it will give a good little arc light of about 200 candle-power for 4 hours, at a cost of 3d. an hour if the acid is bought by the carboy, or 7d. an hour if bought in Winchester quarts.

If all is not quite plain, or if instructions are wished for coppering or making sealing-wax varnish, let me know, and I will send. Fig. 1, copper clamp (half exact size); Fig. 2, top of carbon, with copper clamp; Fig. 3, cell complete; *a*, carbon; *b*, porous cell; *c*, zinc; *d*, salt-jar.

H. T. B.

REFRIGERATION — DYNAMOS — CARBON RESISTANCES.

[20080.]—In letter 20055, J. H. Huxley describes an apparatus for refrigeration, which, though simple, would, I fear, be ineffective. In the first place, the reason why snow lies perpetually on the tops of mountains has little to do with pressure, but is caused by the fact that dry air cannot absorb heat; thus the rays of the sun do not heat the air, whilst when they fall upon the snow the heat is reflected and scarcely any is absorbed. But there is plenty of heat since water may be boiled in a blackened test tube (the blackening causes it to absorb heat) without the aid of lenses, but by the direct rays of the sun. In J. Huxley's apparatus I can find only one possible source of cold. When the pump is worked, the air inside is caused to expand, it is true, but since it *does no work in expanding*, no heat will be lost, and thus no cold produced. Now for the possible source of cold. Suppose we have damp meat, &c., or even a vessel of water, the removal of pressure will promote evaporation, and thus produce cold; but in this case the moisture must be removed, or only at first will the effect be produced.

"E." contributes valuable information on dynamos, though if he will excuse criticism, I think he would have added to its value if he explained more fully the reasons why certain proportions between the resistance of magnets, coils, &c., are best.

I recently saw a query in this paper about carbon for resistances, which, as it has not been answered elsewhere, I will attempt to answer. First, I do not think carbon resistances good for any even fairly accurate work. If, however, they are to be used, I would say that the great difficulty is obtaining satisfactory contact between carbon and leading wires. Perhaps the best way is to make (or get) rods of carbon of the required sizes, and deposit copper on the ends by a battery, then wash very thoroughly, dry, and solder on the wires. On no account be tempted to use rods of a mixture of carbon and sulphur, for though a high resistance is easily obtained, they are extremely sensitive to temperature. I would also suggest to any one who wishes and has the time, to try whether the resistance of such rods is not altered, even by the *passage of a current*, say from 1 Daniell cell. I believe recently I detected an alteration, but have not had time to pursue it. In next week's number (if possible) I will describe a method of making a reliable set of resistance coils, at a very cheap rate.

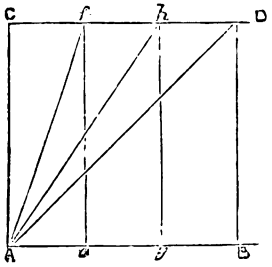
LL. B. A.

NOTES ON DYNAMO-MACHINES.—III.

[20081.]—24. The armature, brushes, field-magnets, and lamps in the ordinary dynamo form one continuous circuit. When the E. M. F. of machine is spoken of, the total E. M. F. is meant, and not merely the difference of potentials between terminals of machine. To find the total E. M. F., add to the difference of potentials between terminals the product of $C \times r$ where C = current and r = resistance of armature and field-magnets. If d = difference of potentials between terminals the E. M. F. of machine $= d + (C \times r)$.

25. The relations between the resistance, E. M. F., and current at different speeds can be graphically represented by diagrams. Take, first, the simpler case of a magneto-machine, and, in drawing a diagram representing these relations for a fixed speed, let distances on the horizontal line A B. (Fig. 1) represent current in ampères to any convenient scale, and on the line A C represent to the same scale the E. M. F. in volts. Since, in the magneto, the E. M. F. is constant for a constant speed, if a horizontal line be drawn from C to D, distances *ef*, *g h* will represent the E. M. F. for any current and any resistance. Join A*f* by a line: the total resistance in circuit to get a current equal to $Ae = fe / Ae = \tan fAe$. In the same way the tans of *h* A *g* and D A B give the resistance in the circuit for currents equal to A*g* and A B respectively.

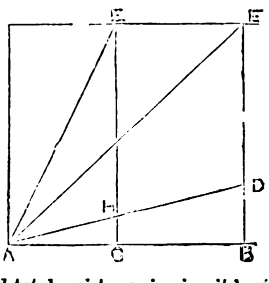
FIG. 1



26. If the speed of the magneto be increased we know that E.M.F. is increased in the same proportion; hence a new diagram can be drawn for the increased speed without troubling to find out by experiment with the machine. The ordinates A C, *ef*, &c., have to be lengthened or shortened in proportion, as speed is increased or diminished.

27. In Fig. 2 let internal resistance of the magneto-machine be represented by tan of D A B, and total resistance in circuit by tan F A B. Vary the resistance in circuit, so that current is diminished from A B to A G. The internal resistance, of course, remains unchanged. In the first case, when current A B is flowing, E. M. F. spent usefully in overcoming the resistance outside terminals is, to E. M. F. wasted in heating the machine, as F D is to D B. In the second case, with smaller current equal to A G, the proportion of work to waste is E H to H G. Thus, as the total resistance is increased and the current diminished, the percentage of waste is lessened.

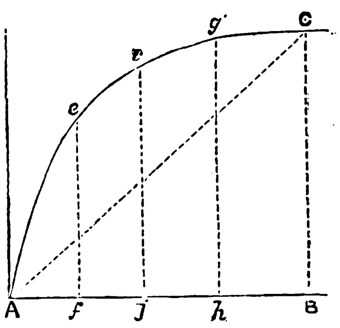
FIG. 2.



28. In a dynamo-machine, where the field magnets are in circuit with the lamps, the E. M. F. line will rise in a curve, as represented in Fig. 4. For any constant speed, let distances on the horizontal line A B represent, on any convenient scale, the current in ampères and ordinates *e f*, *g h*, &c., on the same scale the E.M.F., when correspondingly different currents, as indicated by the distances on the line A B, are flowing through the machine. These ordinates must represent total E.M.F., and their magnitude for different currents must be measured by careful experiment, in order that the curve may be plotted out accurately.

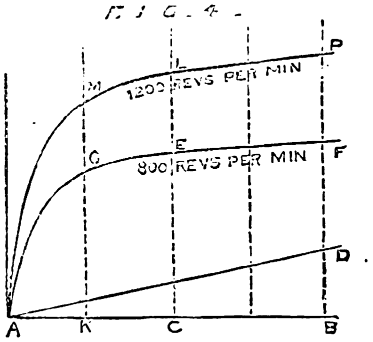
29. If B C be taken as the E.M.F. when the current equals A B, then tan C A B will give the total resistance in circuit necessary that this relation holds good, and the same for all the other ordinates. We see by this curve the characteristic action of the dynamo. The E.M.F. rises very rapidly at first, the strength of the magnetic field being approximately proportional to the current. Soon, however, the curve begins to flatten, owing to the partial saturation of the field-magnets. The line further on becomes nearly parallel with the horizontal line A B, the magnets being now completely-saturated. When this state of things is reached, higher and higher currents will only increase the strength of the field, inasmuch as the coils on the field-magnet act as a solenoid. With large currents we approach the condition of things in a magneto machine, the E.M.F. remaining constant.

FIG. 3.



30. Let A G F in Fig. 4 be the characteristic curve for a Gramme machine at 800 revs. per min., and let internal resistance of machine be equal to the tan of the angle D A B. A glance at the diagram will show the proportion of useful work in the lamp circuit to waste in heating the machine, and it will be noticed that the proportion decreases more rapidly as the flat portion of the curve is reached, i.e., as total resistance is diminished and current increases. When the current is equal to A B, for example, the work expended in heating the machine is nearly one-half of the total work done in the circuit.

FIG. 4.



31. To draw the characteristic curve for 1,200 revs. Remembering that when the current is constant the E.M.F. is proportional to the speed, we have simply to lengthen the ordinates K G, C E, and B F by one-half, making them equal to K M, C L, and B P respectively. A comparison of the ordinates at the increased speed will show at once the economy in working the dynamo at high speeds, the proportion of work to waste being greatly increased. From the foregoing it will be seen that having once plotted out the characteristic curve of the particular dynamo-machine for one speed we have all that is necessary for determining (1st) what speed we must run to obtain a certain current with a given resistance; 2nd, What resistance we may put in circuit to obtain a certain current with a given speed; 3rd, What current can be obtained with a given speed and resistance. It is necessary to add that a new characteristic curve must be drawn for each machine.

E.

IRON MOULDING.—NO. V.

[20082.]—Having allowed the four pieces of the mould to remain in the stove about twelve hours, if there has been sufficient heat, each should be ready for parting. The first thing to be done is to see that the marks that have been made round each joint are in good order: if the mould, before going into the stove, is soft (with the jerking it is liable to get from the crane, and while on the carriage that bears it in and out of the stove), the joint is liable to bag, and requires to be remade. I would say the best time to mark the joint is when the mould has been dried. In the round holes that are in the ends of the lifting-plates of the cope S hooks are put, to which is attached the tackle for lifting; ropes are superior to chains. The two top lifters are made fast to the crane first, the bottom ones with a separate rope. Care should be taken when lifting the cope that one side does not start before the other, but evenly; if not, the marks are liable to get broken off. The rope that is attached to the bottom lifters is now unloosed and taken off. It now hangs by the top lifters and is rested on the bottom ones and turned over on its back, and supports put under the top lifters so as to get dressing the face. The sand that formed the blade is now taken off the face of the bottom part. Any cracks that are in the top or bottom part of mould are wet with water and filled up with red loam. After they have become stiff any unevenness on the surface is pared off, and the sharp edge, where the blade joins the boss, is now rubbed off, taking care that all are alike. Generally, a gauge is supplied for the purpose. The face is now wet all over with clean water. A light coat of soft loam that has been sifted is rubbed over the surface. A dressing-stick a little rounded on one side is now rubbed over the surface, and is kept working till the surface becomes even and regular. Separate dressing-sticks are required for the boss and edge of blade. If there is any heat in the mould when this is being done, it will soon be ready for the blackwash. If the mould is cold and damp, a fire is required to harden the surface a little. Clay-water blacking is now put on with a large brush, doing all of one piece at once: experience will tell when there is enough on. A trowel and two smoothers—one for the boss, and one for the edge of blade—are all the tools the moulder now requires. These, in their turn, are drawn lightly over the blackwash till it has become stiff, when the mould will have a finished and glossy appearance. Any blackwash that may have fallen on the bearing is pared off, and a light coat of blackwash put over the bearing, as it serves to pin and keep it from crumbling away; after which, a light touch of the brush dipped in clean water, and this part of the mould is now (what is termed) finished. All the other parts go through the same process. The copes are now turned over on their face, and put on their respective places, keeping the joints a little apart, so as to allow the steam to escape while in the stove, as they are now put in to be thoroughly dried. When taken out of the stove and about to be closed, each cope is twisted so as clean out any dust, and then put into its place, taking care that the marks correspond, so that each cope will be in the exact place where it was built. The base-plates are now lifted, and each one put into the place where it was built. The stakes that were driven in formerly will guide them into their proper place. Where the blades join each other at the centre, the joints require to be made damp and rammed tight with loam, and blackwashed if not. Owing to the great pressure, the metal, when casting, would force its way through the joints; and, besides, when the joints are made up, the casting looks more finished. The core is now put into the centre; it is made large in the centre, so as to equalise the thickness of metal in the boss and to facilitate the boring of it out. When secure in its print, so as no metal can enter into the tube the core has been built in, and which serves as a passage for the air to escape. The top covering of the boss is then put on and the mould is closed. The lifters of the cope are made fast with screws or clamps to the base-plate. The covering of the boss, and the end of the core-tube that projects through the cover, are also made fast to the bottom plate, and if not made secure, the metal would force the cope up from its seat, the metal escapes, and perhaps lose the casting. Slag or cinders are put round the open joints of the brickwork in the bottom part, and a tube from that up above the mould to allow the gas to escape that it formed when casting. Sand is now put round the mould to the depth of 12in., and rammed hard; this is repeated till the top of the mould is reached. In some propellers the pouring-gates are put on the top of boss; the best plan is to run them from the outside of boss, one slot cut in the centre of each joint. Gate pegs are put against these holes, while the mould is being rammed, these and the flow-gates are rammed up with sand to the same level which has been spoken of. A basin is made on the top of the mould in connection with the four pouring-gates, and the mould is ready for casting.

To find the weight of metal that will be required to cast a propeller: Add together the length of sections 3, 4, 5, 6, and 7, and divide by 5, the number of sections so added, which will give the mean breadth of blade. Find the mean thickness of each section separately, when the sum divided by 5 (the number of sections added) will give the mean thickness of blade. Multiply the mean breadth in inches by the mean thickness in inches, and the product by the length of blade in inches, which, when multiplied by ·263, will give the weight of one blade in pounds. Find the mean diameter of boss, square the diameter, and multiply by ·7854, then by the length of boss in inches, which, when multiplied by ·263, will give the weight in pounds; subtract what would be the weight of arc in metal. If, instead of multiplying by ·263 you divide by 4, it will give the weight in pounds very nearly.

Foundry.

EVOLUTION—THEORY AND PRACTICE.

[20083.]—A CONSTANT reader of "ours" can find nothing new in the writer's discovery in 19898. The example which he chooses (14348907) can only have two places of figures in its root, the first of which is found by inspection, and the unit of the root must be the same as the unit of the power; for the unit of the fifth power of any number will have the same figure for its unit. Without commenting further on the theory, I shall subjoin the working of an example taking his formula $a^5 + 5a^4x + 10a^3x^2 + 10a^2x^3 + 5ax^4 + x^5$.

Find the fifth root of 7717186558368; here a, the root of the first period, is 3.

Write the coefficients of x in an inverted order, namely:—

1 $5a$	$10a^2$	$10a^3$	$5a^4$	Now as $a = 3$ we have $3^5 = 243$
15	90	270	405	771,71865,58368 (378
150	9000	270000	4050000	243
7	1099	70693	2384851	52871865
157 × 7	10099 × 7	340693 × 7	6434851 × 7	45043957
7	1148	78729	2935954	782790858368
164 × 7	11247 × 7	419422 × 7	93708050000	782790858368

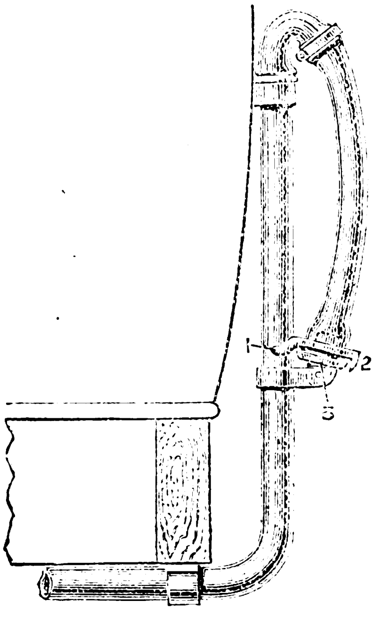
Samuel Blanco, Liverpool.

RAILWAY BRAKES—UNIVERSAL COUPLINGS.

[20084.]—IN my letter on page 195 the hose-pipe and coupling used for both the Westinghouse automatic air and vacuum brakes was illustrated; the following diagram shows the Midland (Clayton) coupling, as seen upon the end of a vehicle.



To couple the hose-pipes, the porters are instructed "to take one in each hand and lift them sufficiently high to hook the bottom horns (1) together first, and then, by lowering them, place the top horns (2) in the slots." The brake-pipe is 2in. internal diameter, which large size prevents the satisfactory use of a tap at the end of each vehicle; therefore a "blank coupling or stop-plug" (3) is provided, upon which the hose-pipe at the rear of the train is placed, as shown in the diagram. It will be remembered that upon the 2nd of April, 1881, a so-called *Conference* was held at Euston Station to consider the question of universal couplings, and that this Midland coupling was selected. Further reference to this Conference is quite unnecessary now, as the fact has already been stated in your columns that invitations were only issued to those persons who were well known to be in favour of, or interested in, the vacuum system. Of course, under these circumstances, a coupling which can only be used with vacuum brakes was chosen.

One very great objection to the Midland coupling is that the hose connections between the vehicles cannot be separated (for shunting purposes or the changing of engines) without the automatic vacuum brakes being applied with full force upon every carriage in the train. To avoid this inconvenience and delay (upon the Midland Railway) a small leak hole is drilled in each piston, which purposely allows all the brake-power to leak away in less than two minutes.

This is a very dangerous arrangement. Suppose, for instance, that a train, when ascending an incline, breaks loose, the automatic vacuum brake will bring both portions of the train to rest, but in less than two minutes the power will have all leaked away, and the brake blocks will cease to touch the wheels. Now, the question is, What is there to prevent the rear portion running back down the incline? Messrs. Bramwell and Cowper were employed by the Midland Company to consider the merits of the Sanders and Clayton brakes. The report is dated May 3rd, 1881. These gentlemen found that the latter system leaks off as above described, but they made the very extraordinary suggestion "that the two minutes are sufficient to admit of the application of scotches to the wheels." Every railway servant knows that the idea of using hand scotches in place of an efficient continuous brake which will remain "on" until purposely released is perfectly absurd. It should be mentioned that the fact that this brake leaks off in two minutes is the origin of the name, "The two-minute brake," by which it is generally known on the railway.

Clement E. Stretton.

Saxe Coburg-street, Leicester.

LATHE MATTERS.

[20085.]—IN reply to "Orderic Vital's" letter (20026) respecting lathe with front V's and saddle borne on the front of the bed, I fear the Editor would not allow the space required for a full illustration of the parts and details; also, before such are sent I should like to have it in perfect working order, which, ere this, I had hoped to have. If you will write me personally, I will give full particulars, &c., when you would be able to judge of its usefulness or otherwise.

1, Parade, Canterbury. **Geo. A. Story.**

SMALL MILLING MACHINE.

[20086.]—IN answer to 20051, I will show "Gereb Admi" all my kit any time he likes to write to me at Pitcairn's Library, King's College-road, N.W., to make an appointment. I cannot now see him without an appointment, as I am not quite at liberty at all times during the month of May.

J. K. P.

LEGAL REPLIES.

[20087.]—OATHS IN COURTS OF JUSTICE (46937).—There is an Act under which a Quaker may, as witness or juryman, make an affirmation. But those who are not Quakers have no right to affirm as jurymen, and must either take the oath or be excused from service. Every witness, however, who objects to take an oath, and who satisfies the judge that an oath would not be binding on his conscience, may make a solemn declaration. The result is that "T. W. W.," not being a Quaker, but a Congregationalist, can claim the right to affirm if he is a witness, and brings himself within this provision; but cannot act as a juryman without taking the usual oath.

Wages (46991).—It is mere nonsense to say that because wages are not paid weekly they cannot be recovered. "G. H." has clearly a right to sue for whatever he has earned; and if the amount of the wages is settled, then he can recover for the number of weeks in arrear. Should no precise sum have been mentioned, he will be entitled to claim the fair and usual rate of wages payable in his trade.

"Sunlight" has, I understand, removed from Bath. I should be obliged if any reader could give me his present address.

Fred. Wetherfield, Solicitor.
2, Gresham-buildings, Guildhall, E.C.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[45672.]—**Balloon.**—I do not think you can arrive at the weight by any direct method. The way I should do it would be to assume a weight which you consider likely to suffice for ballast, net, and balloon, add to this the weight of one man, and calculate the amount of gas required to raise the total weight. If the weight of calico you assumed will contain this volume of gas, well and good; if not, add to it and try again. I see "A. B. C." asks for a varnish. Spon gives the following ("Workshop Receipts"):—1 part, by weight, indiarubber in 5 parts spirits of turpentine; keep these some time together, then boil gently 1 part of this solution (query, will the rubber dissolve?) with 8 parts of boiled linseed oil, for a few minutes; strain and set aside to cool. It must be applied warm.—Glatton.

[45695.]—**Ivory.**—Nothing better than to wash with a small brush and soap in warm water. Ivory is much tougher than either bone or vulcanite.—B. R., 3, Back-street, St. Stephen's, Norwich.

[45702.]—**Yacht.**—I have always seen good red-lead paint applied to the interior and exterior of small steel boats. The plates are galvanised before putting together, and will stand either salt or fresh water. Of course, the red-lead can be used as a ground for any colour you please.—Assoc. M. Inst. C. E.

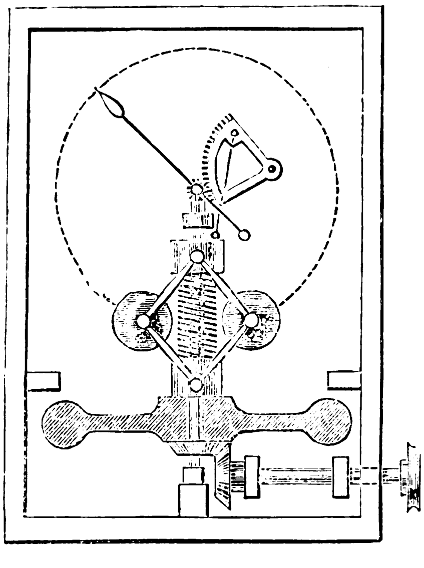
[45951.—**Shot-making.**—Shot are made of either iron or lead. All shot for cannon or great guns are made of iron; but for small arms, leaden balls are used to fit the bore of the weapon. For sporting purposes small shot are made of different sizes· They consist of globules of lead, with a small proportion of arsenic mixed with it. The object of mixing arsenic is to make the shot divide better, as it has been found by experience that lead alone does not divide so well. This mixture, while in a fluid state, is poured through a colander or sieve made of iron, and having the bottom perforated with small holes to suit the size of the shot to be made. The colanders are placed at the top of a high building like a tower, and the melted metal runs through the perforations in fine streams, and separates into single drops as it falls. At the bottom of the building the shots are received into vessels of water to cool them. In these vessels all the globules are not exactly of the same size, although the holes in the colanders regulate this to a certain extent. Moreover, they are not all round; they have, therefore, to be sorted, which is done by placing the shot by handfulls upon a board slightly tilted, so that the round ones roll to the bottom and are received in a box. Those that are crooked, &c., lie behind on the board, and are put aside to be remelted. The shot in the box have next to be sorted as to size. This is done by means of two sieves; the holes of one sieve are a little larger than the size required, and this retains, therefore, all that are too large. The next have holes a little smaller than the shot required, and this retains the right size, and lets all the shot that are too small pass through. By these simple means the shot are separated into many sizes, which are numbered. The shot have now to be finished, which is done by turning them with a little blacklead in a sort of barrel (something like what butter is churned in), which gives them the black shining surface, and rubs off any roughness.—B. R., 3, Back-street, St. Stephen's, Norwich.

[46009.]—**Guttapercha Socket.**—You might coat canvas with the guttapercha and roll it up to form your socket, afterwards amalgamating the whole by heat. Or, perhaps, wire gauze, treated in the same way, would answer your purpose.—Glatton.

[46105.]—**Power from Falling Weight.**—I see that this favourite old idea has cropped up again. A weight would be most unsuitable for your purpose. It would take just as much work to wind it up as it would to work the machine all day. Assuming that a horse would be able to drive 33 sewing-machines comfortably, each machine would be using 1,000 foot-lb. of work per minute. A weight falling 35ft. in nine hours would fall ·0648ft. in one minute. The weight must, therefore, be 1000 / ·0648 × 112 = 137¼cwt. Each time the weight was wound up you would have to raise over 6¾tons. 35ft. If, after this, you care to go on, I will give dimensions.—Glatton.

[46236.]—**Watch Mandrel (U.Q.)**—I notice a question by "Troubled" on this subject which has remained unanswered since the 3rd of March. He is quite right in supposing that chattering is occasioned by the cutter being ground to a wrong angle. In turning brass the angle should be about 80°, or nearly a right angle; when operating on steel, 60° is a more usual angle. Of course, the mandrel is well up to its bearings; if not, chattering will occur with any form of cutter. As bearing on this and kindred subjects, I would direct "Troubled" and all other watchmaking readers to a most useful book recently published, which deserves every word of the praise bestowed upon it by the "E. M.," in the review given on page 46 of the current volume. It is Saunier's "Watchmaker's Handbook," and is, I see, now being advertised in the "E. M." I am sure no one will regret purchasing it, as it affords an immense amount of information of everyday use that is not to be obtained anywhere else in the English language.—E. Devaux.

[46348.]—**Strophometer.**—Motion is communicated by a gut-band from the engine to the small pulley outside the case. This is fixed to a horizontal shaft, which, by a pair of bevel wheels, drives the vertical spindle. Resting by its own weight on the bevel wheel, near the base of this spindle, is a heavy flywheel (shown in section).



It partakes of the motion of spindle; but any little irregularities in the revolutions of the latter are eliminated by the inertia of flywheel, which slips on bevel wheel and revolves with approximately the mean speed of the spindle and bevel wheel. Attached to the boss on top of flywheel are the lower arms of a small governor, the balls of which are kept closed towards spindle by the action of a spiral spring, which forces the boss carrying the upper arms of governor away from the lower one. As the speed increases, the balls fly out and draw down the spring. The amount of this motion is shown by an indicator, actuated by a segmental rack, as shown. The connecting-rod I have sketched wrongly. Instead of being attached direct to boss, it should have a swivel, to allow of boss revolving without smashing up rack, &c.—Glatton.

[46395.]—**G. W. Tank-Engines.**—2030 (2042 class, but on a smaller scale) came out about 1853. Perhaps there are earlier ones than this; if so, I have never seen them. "Hesiod" may be one of the latter. I have made inquiries, but can obtain no information respecting her.—Clyde.

[46396.]—**Terrestrial Eyepieces.**—I notice that "Paugul" says nothing more about the rays crossing in the eyepiece, and that he now concedes their divergence between it and the erector. Perhaps I was to blame for not being more explicit; but I thought it was sufficiently well known that rays would be relatively emergent to the lens they had last passed through. The reason I did not show them crossing in the diagram was because I was not concerned with the path of the cone-rays at all, but endeavoured to illustrate the loss of light consequent on the employment of the erector. In the letter "Paugul" refers me to, I perceive he indulges in a sneer at "self-taught students of optics." I will not pretend to misunderstand its application; but, since he has been so kind as to take an interest in the matter, will confess it is not without a certain degree of truth—though not, perhaps, to the extent of making three blunders in twelve lines. I see that he is still exercised about the position of the diaphragm, and is not very choice in his language towards those who are unfortunate enough to differ from him. It would be easy to show why a central position would not be suitable for a terrestrial eyepiece; but as I am afraid the explanation would be too practical for "nous autres," I will recommend "Paugul" first to ascertain (by easy stages) whether the position in question is not the one invariably adopted, and then to go back to his tutor and inquire why it should be so, if "the merest indication would suffice to point out its absurdity."—Aldebaran.

[46418.]—**Photography (U.Q.)**—As this does not appear to be receiving attention from anyone competent to give the information, I may, perhaps, be permitted to refer the querest to an excellent series of articles on collotypic printing by Mr. Bolas, in the *British Journal of Photography* for 1879.—W. Robinson, jun.

[46468.]—**Brake for Omnicycle.**—I do not think a thumb-piece would be as simple as the ordinary mode pursued by carriage builders of allowing handle to act as a spring to hold click in notches. I send sketch of lower part of handle,

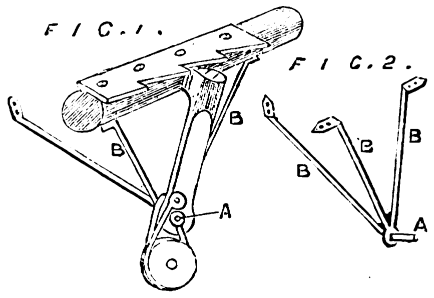


FIG. 1.
FIG. 2.

ratchet-plate to be attached to side of frame. Lever to be hinged on pin (*a*), which is carried by bracket adapted to the framework of machine, this pin to be as close to brake-pulley as the end of lever will allow. One end of friction-band on pin (*a*), the other, as shown a trifle higher up the lever. Though I answer your query, I do not at all recommend you to adopt a fixed brake. Such an arrangement might be the cause of a severe accident.—Glatton.

[46497.]—**Fortified English Cities.**—Berwick-on-Tweed is one of the few English walled towns. Its ramparts were built in the time of Elizabeth, and are still in good repair. On the north and east they are of earth faced with stone; they extend about 1 mile 5 furlongs, and are pierced by five gates.—J. A. T.

[46503.]—**Jamming of Tapered Journals.**—To "Glatton."—Such a rule as you require will not, I venture to think, be readily obtainable. In the first place, the kind of metal and its degrees of hardness, would be an important factor; most decidedly you are wrong when you assume that the weight, or the pressure brought to bear upon it, won't have a deal to do with the sticking point. Then again, the nature of the lubricant used would materially influence the result of the rub. As a practical corollary, I may mention that I am tormented with an old tap on the water-pipe, daily, as the female faction will persist in pressing it down when shutting it off, and it takes a tap of the hammer to release it.—J. J. A., Liverpool.

[46531.]—**Yacht's Deck.**—"W. R." page 199, as well as "Working Tom," page 243, both fall into the mistake, from careless reading, of fathering the query anent "Decking," upon me, the fact being that I have built a yacht or two, probably before either of them sniffed the ozone of the ocean. As a matter of fact, however, I have been lately decking a fore-and-aft schooner; but then, the material which I pin my faith upon is "tin," of which, by the way, "Working Tom" assumes that I am short of. Finally, as to the sneer anent apprentices, any one who has read the "E. M." for, say, 12 years back, will admit that I am not likely to want the advice of "any sich."—J. J. A., Liverpool.

[46581.]—**Oxalate Development.**—(1) It will not altogether prevent the solution being used in dry plate oxalate development; but copper oxalate would be thrown down, and the solution should be filtered before used. (2) You may employ other oxalates as well as potassium oxalates. The sodium and ammonium salts will do as well (theoretically), but they are not used because they are not commercial. It is just the same as with KHO and NaHO, which may be used with the same result.—A Medical Student.

[46603.]—**Induction Coil Failure.**—I am very much obliged to Mr. George Tolman for his hint as to increased battery power. I have now used two quart bichs. (series and multiple arc), but the spark is still under ⅛in. I have since made another coil, using paraffined tissue-paper for insulating secondary coils; in this I used two coils 18 silk-covered for primary, and 1lb. 36 silk-covered for secondary. Using the same condenser and batteries for both, the resulting secondary spark is about the same in both coils, viz., ⅛in., without condenser, just visible. I may mention that the shocks from the secondaries are decidedly stronger than pleasant. Why I used No. 16 with bichs. was, because on looking through back volumes of "ours," the results of the conjunction appeared so good, and they and "Dyer" were my only instructors. One correspondent (some five years back), gets a 3¾in. spark from two coils of 16 for primary, with 3lb. 38 for secondary, and two quart bichs. I don't want to use nitric acid, on account of the fumes.—B. H.

[46611.]—**Lettering Tombstones.**—If the stone is marble, perhaps the best material is black sealing-wax dissolved in alcohol; but any of the black varnishes may be used, and there is nothing better than ivory-black ground up thick in copal varnish. If the letters are covered first with plain varnish, the black mixture will hold in better. The best of all inscriptions, where permanency is desired, is to cut the letters deep, and wider at the inner than the outside surface, then fill up by driving in lead strips.—Nun. Dor.

[46624.]—**Heating Room for Drying Powders.**—Something must depend on the nature of the powders; but, speaking generally, the best and cheapest way of drying powders is to expose them to a steady current of dry air.—Nun. Dor.

[46633.]—**Organ in St. James's Hall, London.**—As I have never played this organ myself, I am afraid I am unable to answer "C. H. D.'s" queries satisfactorily. As he says, the scheme is rather unusual, but it is, nevertheless, thoroughly satisfactory. The tone throughout is extremely beautiful, probably as much on account of the swell (which covers almost the whole organ) as anything. It must be remembered that this organ was not built for solo purposes, but for use with an orchestra, which circumstance will readily account for the enormous size of the pedal organ. The builders are Bryceson Brothers and Ellis.—L. R. D.

[46638.]—**Fresh-Water Fish.**—This question is one of those that it appears to me can be answered only by making an experiment. Mere hardness of water would, I fancy, be no obstacle to the existence of fish, if there is plenty of vegetation in the pool. If there are no plants, some should be put in, and when the pool is fairly stocked you could certainly try eels, carp, and tench.—T. P.

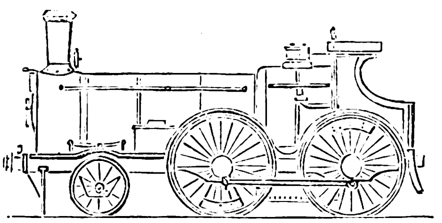
[46690.]—**Waterproofing Fabrics.**—Some years ago (possibly in the English Mechanic), I read of a plan which seems to be rational, and is exactly on the lines suggested by "Kerux," on p. 224. It was as follows:—Rub beeswax on the wrong side of the cloth until the whole surface is clouded with the fine particles of wax. Now, with a warm iron go over the other side of the cloth—the iron to be only sufficiently warm to melt the wax, which will then run up over the surface of every fibre of the cloth, coating it with a water-repelling medium, and yet leaving the air-spaces unchoked, and not altering the appearance or feel of the cloth in any way. Will some one interested in the matter try this and report?—W. T. B.

[46702.]—**Drills.**—I notice on p. 224, "Beetle Crushers" says that the edge of a brass-drill should be at a sharper angle than an iron-drill; so I read it. It is just the opposite; the edge of a brass-drill should be *more dull* than the edge of an iron or steel-drill. The old process of hardening is:—"heat the drill to a glowing red-heat, then bring it down to the colour of a raven's wing, and that will cut anything."—A. F. W.

[46704.]—**Blake Transmitter.**—(1) The microphone is attached to the spring by a screw, and the hole in the bar F is to enable the screw to be tightened, or the microphone to be removed without the trouble of taking off the bar, and running the risk of breaking the wire connections. (2) The spring tipped with platinum presses gently against the diaphragm, and the microphone against the platinum bead. This pressure can be increased or reduced at will, by the aid of the adjusting screw at the lower end of F, the proper pressure being ascertained after setting up the transmitter.—Yoshi.

[46739.]—**Nitro-glucose.**—The acids have either not been sufficiently cool, or else the sugar has been added too quickly. See that the acids are thoroughly cold, and add the sugar gradually with constant stirring, stopping on the slightest development of red fumes.—W. Robinson, jun.

[46774.]—**Bristol and Exeter Locos.**—To "Carstairs."—Although unable to give full dimensions, I send a few particulars of these engines. The B.E.R. had two classes of single expresses, the 9ft. double bogie-tanks, and a class of engine very much after the "Lord of the Isles" type on the G.W.R., but on a rather small scale; the leading wheels are also placed further to the rear. The driving-wheels are 7ft. 6in. diam., the pair of leading-wheels and the trailing-wheels are 4ft. in diameter; the axle-boxes are all outside, as in "Lord of the Isles"; the cylinders are 17 by 24. There were formerly twenty engines of this class (B.E.R., 1 to 20), but 2007 to 2014 are the G.W.R., numbers which they now bear, some of this class having been converted into six coupled goods engines, with inside axle-boxes, the dimensions of which are as follows:—Diam. of wheels, 5ft., cylinder 17 by 24; wheel-base—leading to driving, 7ft. 4in.; driving to trailing, 8ft. 2in.; firebox length, 5ft.; breadth, 4ft. 8in.; depth from crown to bars, 5ft.; length of boiler barrel, 10ft. The 7ft. 6in. singles are good runners, and it is said that they can beat the G.W.R. 8 footers. The engine of which I send sketch, 2015, is a coupled passenger-engine, having drivers 6ft. 6in. diam., and cylinders 17 by 24; 2018 was built by the company at Bristol works about the year 1870. I believe there were twelve of this class. There were some narrow-gauge engines on the Yeovil branch. I never saw any of these, but they were failures in every respect. I have to thank you for your sketches of Caledonian engines, and in a week or two I will send L.N.W.R. large "Bloomer" and "Cornwall," as I noticed in a back number your desire for sketches, which had previously escaped my observation.—Clyde.



[46846.]—**Engineering.**—Any one can set up as an engineer in this country, and put the letters "M.E." or "C.E." after his name, without knowing anything of engineering; but he can't become a M.I.C.E. without having some knowledge of the profession.—T. P.

[46847.]—**Equation.**—To Mr. J. Lane Davies.—I have read the solution which you gave of the adfected quadratic, and which you wished to submit as satisfying the equation as an adfected quadratic. Now, "satisfying" is a relative and vague expression; and your solution may have satisfied yourself and your "large circle of mathematical friends"; but I am sure that there are many who will not accept your solution, unless they shrink from the equation which at first glance looks terrible enough. The following are my objections:—1. Every quadratic must have, in one form or other, two roots (of which fact you will be well aware); 2. You apparently never noticed that equation E, and the one following E are identical—viz., $9 - xy/2 = zy/3$, and $9 + 3/2\,xy = 36 - zy$. But should you have done so, why, in all the world that bulky operation of multiplying these two equations together; why not go on in the following manner? $-xy/2 = -zy/3 + 9$; $\therefore xy/2 - 3 = -zy/3 + 6$; and, therefore, $x^2y^2/4 - 3xy + 9 = z^2y^2 - 4zy + 36$, &c. Thus, if your solution be right, it is certainly a very circuitous one; and that is a great mistake in the science of mathematics. Your mode is, further, a very artificial one, and although the quadratic should be an adfected one, you ought not to affect it too much. But is not your completing the squares on each side, in order to destroy them in the next line, an impoliteness to quadratics? After passing these remarks on the defects and mistakes in your and your mathem. friends' solution, permit me to submit the following solution to your and their criticism. I may, however, add that I am not in the least convinced of its satisfying the required conditions, as I have no large circle of mathem. friends to give me the benefit of their criticism and assistance. Anyhow, I have obtained two vals. for x, y, z resp., and the typical form of quadratic equations ($ax^2 + bx^2 + c = 0$) occurs very plainly. Where is that in your solution?

$$\left.\begin{aligned} x + y + z &= 11 \\ x^2 + y^2 + z^2 &= 49 \\ zy &= 3x(z - y) \end{aligned}\right\} \quad \begin{aligned} &\text{Let } \alpha = z + y \\ &\text{and } \beta = z - y \\ &\text{Then } z = \frac{\alpha + \beta}{2}, \text{ and } y = \frac{\alpha - \beta}{2}. \end{aligned}$$

Thus the equations become

$$\left.\begin{aligned} x + \alpha &= 11 \\ \alpha^2 + \beta^2 &= 98 - 2x^2 \\ \alpha^2 - \beta^2 &= 12\beta x \end{aligned}\right\} \begin{aligned} &\ldots\ldots\ldots\ldots\ldots\ldots (a) \\ &\ldots\ldots\ldots\ldots\ldots\ldots (b) \\ &\ldots\ldots\ldots\ldots\ldots\ldots (c) \end{aligned}$$

Hence from (a) $\alpha = 11 - x$

$\therefore (11 - x)^2 + \beta^2 = 98 - 2x^2$ or $3x^2 - 22x + 23 + \beta^2 = 0$ ………………………… (I.)

and $(11 - x)^2 - \beta^2 = 12\beta x$ or $x^2 - 2x(6\beta + 11) + 121 - \beta^2 = 0$ ………………… (II.)

$$\therefore \text{ from (I.) } x = \frac{11 + \sqrt{52 - 3\beta^2}}{3} \quad \ldots\ldots\ldots \text{(V)}.$$

Now solve for x and β from (I.) and (II.) by multiplying (II.) by 3 and subtracting. Thus $x(36\beta + 44) + 4\beta^2 - 340 = 0$, and $x = \dfrac{85 - \beta^2}{9\beta + 11}$ …. (A).

Again, multiplying (I.) by $121 - \beta^2$, and (II.) by $23 + \beta^2$, and div. by x, we get $x(340 - \beta^4) - 4(539 - 69\beta - 11\beta^2 - 3\beta^3) = 0$, or

$$x = \frac{539 - 69\beta - 11\beta^2 - 3\beta^3}{85 - \beta^2} \quad \ldots\ldots \text{(B)}.$$

But since (A) = (B), if we arrange, we get $7\beta^4 + 33\beta^3 + 143\beta^2 - 1023\beta + 324 = 0$, or $(\beta - 3)(7\beta^3 + 54\beta^2 + 305\beta - 108) = 0$. $\therefore$ necessarily $\beta = 3$. Substitute this in V, then $x = 2$ or $= 5\frac{1}{3}$; $y = 3$ or $= 4\frac{1}{3}$; and $z = 6$ or $= 1\frac{1}{3}$.—A Medical Student.

[46850.]—**Electro-Magnet.**—Probably the magnet was not wound in the right direction. After wrapping one pole with wire, the wire should be brought over to the opposite side of the magnet and wound in the opposite direction. If the wire was wound right on the magnet it ought to have become magnetised, one pole being much weaker than the other. The power to work it depends on what use you would put the magnet to. If for supporting a weight or driving an electromotor the three bichromates would do very well; if for a bell, a Leclanché or Daniell's cell should be used.—Beetle Crushers.

[46851 and 46874.]—**Queensland—Australian Railway Prospects.**—The Agent-General of Queensland, Charing-cross, and Agent-General of New South Wales, Westminster-chambers, London, will send books and information free. "Australian Hand-Book," 1882, gives much information. Published by Gordon and Gotch, Bride-street, Ludgate-circus. English trade-unions would do well to have agents in Colonies to provide labour news. Without being posted in labour market, I should say that sober men, able and willing to adapt themselves to new circumstances, should succeed. In Australasia, there are over 5,000 miles single line railways (belonging to the State), and new lines forming, besides steamers, flour, saw, sugar mills, &c. Why not work passage out on Orient line steamers running fortnightly to Sydney, and look at the Colonies before settling?—Colonist.

[46854.]—**Mechanical Action.**—My best thanks to "Glatton" for so promptly noticing my query; but his plan does not meet my want. In my query I say that "the pushing down of the rod is to control the lid." In "Glatton's" plan the lid controls the rod; consequently, when the lid opened full the zinc is wholly immersed: that will not do. I want the act of depressing the rod the first ½in. to fix the lid, at the same time allowing the rod to be further depressed as the power may be required, and on its being fully drawn up, the lid to be released.—S. J. M.

[46855.]—**Cayenne Feeding of Canaries.**—Commence to feed the young birds at the age of one month or six weeks, and continue till six months old. Chop an egg fine and grate two wine-biscuits. With this mix one teaspoonful of cayenne. Most birds will not eat it at first; but if you take all other food away, they will soon like it. Let them have plenty of canary seed and no rape.—Chas. F. S.

[46858.]—**Organ-Playing.**—If you can play hymn tunes well, and wish to be able to execute pieces, you should get some of Bach's exercises. I think, if you ask at any respectable music-shop for Bach's "Klavierwerke," you will get what you want. There are several books, and you must be sure to begin at the beginning, and not attempt any hard ones until you can play the easy ones well. They are really little fugues, and whilst there is a deal of practice in them, you will find they are also very good study, and good training for the taste. They secure for you a clear touch, which is quite as necessary for the organ as a smooth touch and take care of the time. By no means give up playing hymn-tunes: work them in together, and when you can play them well, you will be able to pass on to fairly difficult pieces, as well as less classical music. Practise scales on a piano if possible. Any more information with pleasure.—Geo. T. Fleming, Heidelberg.

[46858.]—**Organ-Playing.**—I should recommend the querist to purchase Mr. Best's book of instruction for the organ. It has proved a valuable aid to many amateur organists. Many persons who have a desire to learn music run away with the idea that they can play certain pieces quicker and better by giving their first and foremost attention to the notes of the treble stave. This erroneous idea is one of the greatest, if not the greatest, stumbling block in the progress of musical study and practice. If intending players would discard this fallacious idea and practise the bass and treble together, they would sooner attain a greater proficiency. The amount of practice daily is another important point which should not be overlooked—a practice of less than two hours per day will not produce very good results. True, some people require more practice than others, just according to the taste they have for it; if studying for the profession, eight hours per day is not an unreasonable amount necessary; probably less may do for those possessing a little talent.—G. FRYER.

[46861.]—**Cockroaches.**—The following is from the "Encyclopædia Britannica":—genus Blatta, order Orthoptera, family Cursoria. The wings of the B. orientalis, which are shorter than the abdomen in the male, are merely rudimentary in the female, and are wanting in the larvæ of both sexes. The difference between coleopterous and orthopterous insects is that the former have usually two superior wings which meet in a straight line along their inner margins. The inferior wings, which are the true organs of flight, are membranous, transparent, transversely folded, and covered and protected by the elytra or wing-cases. The latter have also four wings, but the upper pair are softer and more flexible than in the preceding order. They are semi-membranous, reticulated, and for the most part do not form, by their junction when closed, a straight line along the dorsal suture. The true wings are folded longitudinally, and usually after the manner of a fan, and are divided by longitudinal membranous nervures.—ROSICRUCIAN.

[46862.]—**Telegraph.**—You should use No. 3; silk-covered wire for the coils of your telegraphic instrument, about one ounce of wire to each. The line wire ought to be No. 20; cotton-covered will do if well insulated with paraffin wax. Certainly the No. 26 offers too much resistance, as it is not half thick enough. Once I tried to fire some powder through a line wire of that size 100ft. long, with 4 quart bichromates, and it would not go off until I had shortened the wire to 10ft.—BEETLE CRUSHERS.

[46864.]—**Canvas Canoe.**—Why not try water as ballast, by having canvas receptacles well covered with linseed oil, or have a hollow keel for the same purpose?—BEETLE CRUSHERS.

[46865.]—**Cod-liver Oil.**—I am in the habit of largely prescribing cod-liver oil. I do not remember one case in which large doses have not been perfectly well borne and digested. Take 5 grains of pancreatine (Savory and Moore) three times a day, with food for, say, three days before you commence the oil, then take the same with each dose of the oil.—M. D.

[46865.]—**Cod-liver Oil.**—In the case of this child, who refused to swallow the oil, it is very probable that her system is now to some extent saturated with it; and then, in the next place, it is not so much required in mild weather, and not so useful in summer as it is in winter. If she suffers from defective nutrition, she might take Parrish's food during the summer, and next winter she will probably take to the oil again.—H. BARNABY.

[46866.]—**Photographic.**—1. Lack of density might arise from too thin a film, but is more likely to be owing to over-exposure, insufficient or improper development. 2. 1oz. of emulsion will cover approximately one dozen quarter plates. 3. Certainly; the emulsion would not acquire anything like the same degree of sensitiveness. 4. Yes, generally speaking; but it is always advisable to have some means handy for modifying the light at will. 5. Captain Abney recommends soaking the plates or emulsion in a dilute solution of bichromate of potash 2 or 3gr. to the ounce of water. 6. See letter 19958 by "Gelatino Bromide," p. 155. The sensibility entirely depends upon the extent to which the "cooking" is carried.—W. ROBINSON, JUN.

[46866.]—**Photographic.** — (1) The principal cause of want of density in dry plates is—First, Over-exposure; Second, not being sufficiently careful of the light you change and develop by; Thirdly, by development unsuited to the plates used. Generally speaking, the development is hurried too much, and not sufficient bromide used. It is quite possible to have too little emulsion on the plate; (2) Opinions differ as to the best quantity of emulsion to use on each plate. I like a moderately dense one, and use, roughly speaking, 1oz. emulsion to 10 quarter plates; (3) Washing before heating the emulsion will change the properties of it; it being very difficult to obtain any great degree of sensitiveness after the emulsion is washed; (4) I should cover the ruby glass with one thickness of orange paper. My reason for recommending paper before another thickness of glass is that paper stops the direct rays and diffuses them; (5) Soaking shreds of emulsion in a solution of bichromate of potassium, and then well washing has been recommended, but I have not tried it; (6) I take for granted that you understand the outline of emulsion preparation. The following formula is the best I have tried for landscapes:—Gelatine, 140 grains; bromide of ammonium, 50 grains; water $2\frac{1}{2}$ ounces;—nitrate of silver, 75 grains; water, 10 drachms. Let the gelatine soak in the water with the bromide dissolved in for half an hour; then dissolve the gelatine at about 110° Fahr.; now add the silver solution (in the dark room) a little at a time, shaking the emulsion well after each addition. Now cook the emulsion eight hours at 100° Fahr., then wash by any of the usual methods. The sensitiveness is increased by longer cooking, but the above is what I prefer. See that you get pure chemicals. I have traced several failures to impure chemicals.—J. HENSHALL.

[46871.]—**Platinising Silver.**—The platinising to which you refer is merely blacking silver. It is done by applying a hot solution of perchloride of platinum. It certainly is not so suitable as the battery process when battery-plates are in question. I make a précis of the directions given in Sprague's "Electricity." Rough the silver with fine glass-paper, or dip in nitric acid. Insert in a vessel with dilute acid, and connect by a wire to a small slip of zinc in a porous pot standing in same acid—in fact, make up as a battery; but at first expose only a small portion of the zinc to the liquid. Drop into the liquid surrounding the silver a few drops of platinic chloride and stir; a faint colour forms over the silver. Add more platinum salt, and lower the zinc further into its liquid; so on, until a good coating is formed, increasing the surface of zinc exposed until the whole of the silver is covered with the black.—NUN. DOR.

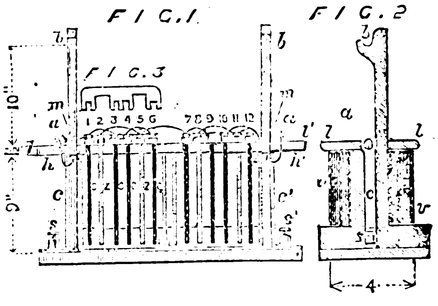
[46880.]—**Analysis of Water.**—For the purpose stated, 6 pint Bunsens would be sufficient. It would be necessary to have a small induction coil to explode the gases by passing the currents through a thin piece of platinum wire.—BEETLE CRUSHERS.

[46882.]—**Dynamite.**—Query 46882 has evidently been answered on p. 246 by somebody who knows little or nothing about explosives. He talks of dynamite "burning fast." Dynamite is always detonated by means of fulminate of mercury, and, like gun-cotton, requires no tamping. If a small piece of dynamite be ignited (say, with a hot iron) it burns fiercely, leaving the kieselghur in the shape of fine powder; but nobody knowing anything about dynamite would attempt to use it that way.—TORPEDO.

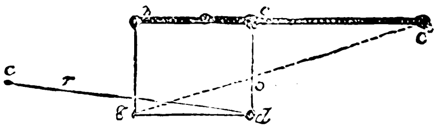
[46882.]—**Dynamite.**—The force of gunpowder explosion is not upwards, but equal on all sides from a centre—*i.e.*, the gases form from the solid substance quickly; but still they are slow enough for the pressure to find the weakest point, and thus find vent, in the case of a cannon at the mouth, in rock-blasting at the weakest side. *Re Dynamite.*—I have been an instructor in the use of nitro-compounds for years, and although authorities, makers, and miners will tell you at once the force is downwards, I do not think so, for the following reasons and examples:—Take the face of a tunnel and note the holes charged with dynamite, be they perpendicular in the roof, down in the bottom, or horizontal in the face, you will find the same crushing, pulverising effect at the bottom. Again, what I have often noted, a side horizontal hole half-way up the face—say, with a very weak bottom, you will find in many cases the mouth left intact and the bottom blown out, and that the crushing effect is not at the bottom of the holes in a line with it, but at the point of greatest resistance and opposite it. Again, find a cobble that three cartridges will break by putting them loose on the top, covered and packed airtight in clay, in the usual manner, to illustrate its downward force, but put at the side in the same manner and it will break it; now, sling it in a chain and put them underneath, packed as before, the charge against the stone, and it will break it, same as put on the top. Overburden a charge in granite or limestone, and explode it—then, blast it away with powder to get the débris lumpy, and you will find the space formed by the dynamite charges round; or bore a hole through a casting vertically, insert a charge sufficient to break it, half-way down the hole; fill up with clay at each end, set the casting about 6in. to 12in. above the ground and explode it; the iron is crushed and the sod scarcely broken through. Suspend a ball of dynamite in the centre of a hollow cast-iron ball, then suspend the ball and explode; it will break equally all round; explode one on the ground, and it breaks it at the point touching the ground with the greatest severity. From these facts I conclude the greatest effects are seen at the greatest resistance, be it up or down, which means that dynamite and powder explode on the same principle—*i.e.*, from a centre; but dynamite is so quick in its action, that wherever resistance offers it strikes with force; for instance, in a cannon it will not give time for the ball to travel, but bursts the gun. *Open Air v. a Cobble.*—The cobble offers the greatest resistance, hence showing the greatest effects. *Ordinary Blasting.*—The bottom of the hole gives the greatest resistance, as a rule, consequently shows the greatest effects.—MC.

[46893.]—**Speaking-Tubes.**—The distance to which sound can be carried depends very much on the method of fixing. Any sharp bends stop the sound to a great extent. All curves, therefore, should have as large radii as possible. I have no experience of such a distance as 150 yards.—ROSICRUCIAN.

[46897.]—**Powerful Bichromate Battery.**—To save valuable space, I send you a sketch and description of a battery consisting of two cells only, but you may easily increase their number according to requirements. I hope a few remarks will be sufficient to make the sketch intelligible. The carbon and zinc plates are fixed to the rectangular wooden lid *l l'*, so that always 4 carbon and 2 zinc plates are dipped into each of the vessels, *v v*, *v' v'*, &c. At each end the lid terminates in a round handle, *h*, *h'* with metallic ferrules, *m*, *m'*, which fit into *a a*, and *b b*, the former being lined with brass, which, when the battery is in action, *h h'* having been let into *a a*, form a connection between *m* and binding-screw *s*, and between *m' s'*; *m* is connected with the carbon, *m'* with the zinc-electrode. Carbon-plates $\overline{1, 3, 4, 6}$ and $\overline{7, 9, 10, 12}$, zinc-plates $\overline{2, 5}$ and $\overline{8, 11}$ are connected with one another, so as to form two large carbon and two large zinc plates; also 1 is connected with *m*, 5 with 7, 11 with *m'*. To make these connections, cut out strips of brass about 1-16in. thick, as shown in Fig. 3, to fit into the screws to be connected. The cells are charged up to a level of 8" from the bottom of the vessels with a solution of bichromate of potash in dilute sulphuric acid in the following proportion:—Bichromate of potash, 1lb. 1oz; sulphuric acid of spec. gravity, 1,836, 1 pint; water, 10·4 pints.—KAUTHACK.



[46901.]—**Watt's Parallel Motion.**—Neither Watt's motion nor any other in general use describes a mathematically straight line, though sufficient for practical purposes, and parts of the curves described by the levers are so nearly an approximation to the straight line that it is easy to employ proportions which shall not exceed the limit of such approximate line. The following diagram represents the



parallel motion, C' being the beam centre. To find the proper length of the radius bar *r* from *c* to *d* divide $C'h$ in c so that

$$C'c : cd :: do : oc$$

when o is the point of attachment to the air-pump rod.

$$gd : C'c :: do : oc$$

$$\text{Therefore } hc : C'c :: C'c : cd$$

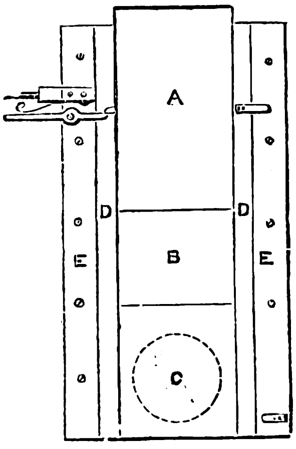
$$\text{Therefore } cd = \frac{C'c^2}{hc}$$

The length of link cd has an influence on the form of curve. It is generally made equal to the stroke of the air-pump rod, or half the length of the piston stroke.—FRED. WALKER.

[46902.]—**Maps.**—The best book on the subject is by W. Hughes, published by Longman, Green, and Co., 1864, third edition.—ROSICRUCIAN.

[46914.]—**Drop Shutter.**—The annexed sketch represents a very useful drop-shutter. The position of lens is shown by dotted lines at C. B is the exposing aperture; A is a piece of wood sliding in a groove in the frame D; by raising or lowering A, the exposure may be shortened or lengthened at pleasure; the frame D slides in the frame E; the back is one piece of wood with an aperture for lens to fit in; as described, it is ready for exposure.

By pressing the lever, which is kept in place by the spring, the frame D is released and drops by its own weight till it reaches the catch at the bottom. The exposure is made by B passing C. Make of thin mahogany: draw a sketch size required before commencing work. Describe diam. of lens, then you can easily calculate the other dimensions. The catches, &c., are made out of sheet-brass.—JAMES PARKINSON.



[46919.]—**American Organ.**—If any of your readers are the happy possessors of an American organ with a decent voice, I would beg of them *not* to follow the advice of Mr. Fryer, and clean the reeds once in six months, even with a piece of washleather. I am utterly at a loss to know who can have been Mr. Fryer's instructor, or the source whence he derives his inspiration. Probably, cleaning with bath-brick, or even emery, would not injure such American reeds as Mr. Fryer means, for they must be curiosities. Thus he says: "The reeds should be firmly secured to the blocks by two (not one, as in inferior organs) iron or steel rivets." That statement is most extraordinary—all the more extraordinary because Mr. Fryer need only refer to back volumes of his ENGLISH MECHANIC to find out his error. It must be well known to your readers (see No. 587, the "Munroe Reed") that one of the best makes of American reeds dispenses with rivets altogether; in another, equally well known, there is no rivet proper, but the metal of the block is punched through in the form of a rivet, and is closed over after being passed through the tongue. As a matter of fact, with the exception of the firm whose reeds have blocks with ⊳-shaped edges, the reeds with iron rivets are not only the worst in themselves, but they are placed in inferior instruments. And then with regard to the exceptions, unfortunately for your correspondent's statement, the smaller reeds never had more than one rivet; while those which do really require more, always have two, even in the inferior makes, which are known by their thin blocks. As to tuning, a new American organ requires, as a rule, "going over," after it has been well played for from six to twelve months, as the reeds then appear to have taken their permanent bearings, and to have settled down to their proper pitch; but after that it should last for years without being tuned. As to taking out once in six months to clean, I hope it will be sufficient to say that such a practice would be a good way to spoil the instrument, especially as it would involve frequent visits from the tuner. I have, for instance, an instrument which, for six years, has never had a reed drawn except to remove some particle which has got between the vibrator and block and muted a reed. Sometimes reeds corrode where the leather rests upon them, and they are thrown slightly out of tune. Cleaning is required then; but it is better to prevent the corrosion.—ORGANON.

[46925.]—**Water in Gravel-Pit.**—Supposing that there is no sub-stratum of very heavy clay, there will be no necessity to carry the shafts down to the spring. It will be necessary to make the shaft of sufficient capacity to hold all the water which now lies on the ground; when this is done, it will soon percolate the surrounding soil and disappear. —H. BARNABY.

[46930.]—**Hydraulics.**—I would venture to suggest that this querist has nothing to do but to put a glass tube into a cask of some coloured fluid to see for himself whether or not the orifice is filled. His friends must be peculiar mathematicians.—E. G. M.

[46930.]—**Hydraulics.**—If tank and pipe were in a vacuum the water would behave as your friends suggest. In practice, however, the pressure of the air on the water in tank assists the force of gravity to fill up the void which you assume to exist, while the same atmospheric pressure at bottom of pipe tends to arrest the outward flow, and keep back the outgoing water, as it were, while the inflowing water catches it up. In a large pipe the air might get in at the lower end, and to preserve a full bore the pipe should be tapered. Let a be the area of pipe at lower end, h = perpendicular height of level of water in tank above lower end of pipe, x = area of pipe at any point at a vertical distance, d, below surface of water in tank. Then $x = a \sqrt{h / d}$.—GLATTON.

[46930.]—**Hydraulics.**—It is quite certain that if it were a case of abstract hydraulics—that is, if there were neither friction nor capillarity, the water would not fill the lower part of the pipe; it would be "thinned down" by its acceleration from gravity, as shown by A. H. Mountain in his diagram (on p. 248). But friction being present, this will or will not happen, according to circumstances. For a certain slope and diameter of pipe the water in the pipe, if left to its own gravitation without any pressure from the head of water, would soon lose its acceleration from friction and acquire a constant velocity. If the pressure from the head of water gives the water in the pipe a greater velocity than this, the retarding friction will be greater than the gravity of the water, as resolved along the pipe, and the action of "thinning down" will not take place and the pipe will remain everywhere full. The tendency of capillarity would be to promote this result.—DUBLINIENSIS.

[46931.]—**Cuts and Bruises.**—At our works we keep a bottle of "Friar's balsam," some lint, and bits of rag. The balsam is simply poured over, and into the wound, a bit of rag saturated with the same preparation bound over it, and there you are. When working in the pattern-shop I have frequently used shellac varnish as a temporary dressing. Neither of them is sightly, but the first, I can say from experience, is most efficacious.—GLATTON.

[46931.]—**Cuts and Bruises.**—For small abrasions of the skin, rub a little drop of glue over them (glue is always handy). When your work is done wash well and dress with some good plaster. I use some of Seabury and Johnson's rubber plaster. Cuts from chisels, &c., are more troublesome because they *will* bleed. Hold under a tap; that will generally stop the bleeding, and then dress with plaster. Splinters must be extracted, the hands thoroughly washed, and a little piece of plaster put over to keep the dirt out.—TORTOISE.

[46931.]—**Cuts and Bruises.**—The most convenient and useful means of stopping bleeding from cuts through the cuticle, is a bottle of "French Polish," if a trifling wound, wrap in rag and then apply some polish, which instantly stops the flow and keeps out the air. If the cut be serious, apply the polish freely upon a lump of cotton wool. Whilst upon this subject, I may mention that for burns, nothing is so efficacious as the immediate sopping of the spot in ordinary "black ink," which being immediately applied, will prevent the formation of any blisters.—J. J. A., Liverpool.

[46934.]—**Jewelling Watches.**—Score off same as in other holes, place in mandrel; first cut a hole right through plate, half size of jewel; now cut hole to receive jewel, cut it sufficiently deep so that the jewel will go in level with the face of the plate. Now reverse the plate and chamfer, polish same, reverse plate again, press in jewel (which should fit tight) and with a pointed tool turn over. If you look at a jewel you will understand better. I shall give instructions for making a simple tool which can be fitted to any bench turns, for this purpose.—A FELLOW-WORKMAN.

[46935.]—**Electric Bells and Lightning.**—No extra risk is incurred by having two wires. The risk at all times is very slight. Resistance coils are not required. The object is to decrease the resistance of a line-wire as much as possible, not to increase it.—W. H. L. H.

[46937.]—**Oaths in Courts of Justice.**—The statutes which extend the privilege of making an affirmation to persons refusing or being unwilling, from alleged conscientious motives, to be sworn (Common Law Procedure Act, 1854, s. 20, and 24 and 25 Vict., c. 66, s. 1), make it lawful for the Court, judge, or other presiding officer, upon being satisfied of the sincerity of such objection, to permit such person, instead of being sworn, to make an affirmation. Such a person can scarcely, therefore, be said to be entitled to claim it as a right; but the words "it shall be lawful," are in practice in such a case very nearly equivalent to a direction to do the lawful thing. If the judge be satisfied that an oath would have no binding effect on the conscience of the witness, he is bound to administer an affirmation in a different form (32 and 33 Vict., c. 68, s. 4.).—SPERANS, Lincoln's Inn.

[46938.]—**Photography.**—The formula I use is as follows:—Stock Solutions: Pyro acid 1oz., glycerine 1oz., meth. spirits 6oz.; mix the glycerine and spirits, and add to the pyro bottle; label A stock solution. Bromide of potass 60gr., liq. ammonia (sp. gr. ·880) 1oz., glycerine 1oz., water 6oz.: mix, and label B stock solution. 1oz. of A to 15oz. of water, label A; 1oz. of B to 15oz. of water, label B. The stock solutions will keep for months; A, B a few days. Do not mix more than required for the day's use. If the plate has been correctly exposed, equal parts of A and B will be found to bring full detail and density. My method of developing is as follows. Before commencing, I see I have everything in their proper places (always observe the golden rule in photography—have a separate place for each article, and see you keep them there). Immerse the plate in water for a few seconds, say, till you have mixed the developer. For a plate 7¼in. by 4½in., I mix 1oz. of A and ½oz. of B; the developer must be kept in motion, to prevent any air-bells from settling; if the exposure has been correctly timed, add the remaining ½oz. of B. When fully developed, wash well, and immerse in the alum-bath for a few minutes: wash, and fix. If, after fixing, the plate should have a green or copper-coloured fog, immerse in a solution of alum and citric acid, strength not important. Are you sure your ruby glass is perfectly non-actinic? I should advise you to test it; or perhaps the dark slide, camera, dark room, admit light. If you will forward your address, I shall have pleasure in sending you a print from the negative I referred to. If you find any further difficulty, kindly write and state full particulars, and I for one will do my utmost to assist you.—JAMES PARKINSON.

[46944.]—**To Mr. Lancaster.**—Holes should be made in carbon plates, so that the lead runs through and insures a good connection, and the lead insulated with paraffin-wax. A brass terminal screwed into the lead for a connection.—TORPEDO.

[46945.]—**Leclanche Battery.**—I would recommend "W. J." to thoroughly wash the pot and its contents with water, to free the inside from crystallised sal-ammoniac. It is unnecessary to have new carbons, as these last indefinitely.—GEO. G. BLACKWELL.

[46945.]—**Leclanche Battery.**—Your porous pots are doubtless not so porous as they used to be. I should get some new pots and recharge them. The carbons will do again, well washed in warm (not hot) water. Commercial sal-ammoniac has always acted well with me, and it is cheaper than the pure salt. Reamalgamate the zincs.—TORTOISE.

[46945.]—**Leclanche Battery.**—The cells must be worn out after such a prolonged use. The MnO_2 has lost its power. The porous pots should be recharged, and would be better if entirely new. The carbon blocks ought to last for ever, but they should be cleaned. The sal-ammoniac need not be pure, but it is better for it to be so. I should think the zinc rods are nearly worn out also. It would be better to replace them also.—W. H. L. H.

[46946.]—**Goldfish.**—I would suggest that you construct a separate tank on a higher level than that you have at present. Let the rainfall accumulate in this, and when it is full, procure a bag of charcoal-dust, sprinkle the surface with some of this (the quantity to be found by trial). This, if done at eve, will leave the water pure, clear, and sparkling at early dawn. I have proved this on the Australian diggings, where drinking-water was "few and far between."—J. J. A., Liverpool.

[46948.]—**Resistance of Electro-Magnets.**—The total resistance should equal the internal resistance of the battery intended to use with it. Electro-magnets of large size are generally coupled up for quantity, forking off round each pole and back by a common return-wire, so that each pole of a horseshoe-magnet has a separate wire round it, forking into the same battery-leads.—TORPEDO.

[46948.]—**Resistance of Electro-Magnets.**—The best effect is produced when the amount of wire on the magnet is such that its resistance is equal to the internal resistance of the battery. In case of two magnets, their joint resistance should be equal to the internal resistance. This does not mean that you are to get this resistance by using very thin wire, because then the wire would be so short that there would not be sufficient convolutions. Nor should the wire be too thick, for the convolutions will be so numerous that the outer strands will have no perceptible effect on the core. —W. H. L. H.

[46949.]—**Sodium Salts.**—There are two sodium hydrogen tartrates, viz.:—$C_4H_4Na_2O_6$ + H_2O, neutral; $C_5H_5NaO_6$ + H_2O, acid. Both are crystalline, and very soluble in water. Any work on qualitative analysis will answer latter part of the query.—GEO. G. BLACKWELL.

[46949.]—**Sodium Salts.**—(*a*) Tartaric acid, being a dibasic acid containing two atoms of typical hydrogen, which can be replaced by metals, we have hydrogen sodium tartrate, NaH, $C_4H_4O_6$, as well as sodium tartrate, Na_2, $C_4H_4O_6$. I hardly think that there is another name for it, and there will be no other remedy but to use this hideous name. The best proof of the existence of hydrosodic tartrate is the circumstance that it is provided for the practical examinations in chemistry at the Prelim. Scientif. (London). (*b*) NaHO will do as a reagent as well as KHO, though caustic potash may be more powerful to a certain extent; the reactions, of course, will be correspondent. Thus caustic potash or soda throws down white zinc hydrate, $Zn(HO)_2$, soluble in excess of the precipitant.—A Medical Student.

[46951.]—**Papyrograph.**—I do not know if this process would act on the paper, but it seems tolerably obvious that "ordinary" paper would not do, as if the letters were eaten away to form a stencil, the centres of letters such as *a o b*, &c., would fall out.—Glatton.

[46951.]—**Papyrograph.**—If "Dabbler" will refer to Mr. Bolas's paper, on p. 477, No. 774, he will find a brief description of the process to which he refers. It is the ink that is the strong solution of caustic soda which acts on the previously-varnished paper. Over another signature I gave a full description of the process in No. 501, p. 177, which is known and extensively used as Zuccato's papyrograph. I may mention here that the paper is varnished on one side only, and is written upon on the uncoated side, the caustic ink thus attacking the varnish from the back. If those interested cannot procure the No., I will, if the Editor has space, copy the directions briefly.—Nun. Dor.

[46952.] — **Reaction.** — The brine probably contains magnesium chloride, which is a very common impurity, so that magnesium carbonate, which is only sparingly soluble in water, is precipitated by the potassium carbonate. The equation will be $MgCl_2 + K_2CO_3 = MgCO_3 + 2KCl$.—W. H. L. H.

[46952.]—**Reaction.**—One reason for the cloudy appearance of your mixture and for the precipitate is undoubtedly the impurity of the substances taken, for commercial salt contains, besides NaCl, calcium sulphate and magnesium chloride, and commerical potassium carbonate is mixed with alkaline sulphates, chlorides, silica, &c. And in all probability the mixing of these two solutions will have produced a double salt of KCl and $Na_2 CO_3$, and this, together with the crystals, separated from the impurities, must have effected the precipitate. Did you really see a fluorescence? Was it not an iridescence caused by refraction of the light? For as you perhaps know, Cl would tend to destroy any fluorescence. It is impossible to form the equation, unless to analyse quantitatively as accurately as possible.—A Medical Student.

[46953.] — **Pearl Ashes.** — For a very minute and accurate analysis of pearl ashes see "Quantitative Chemical Analysis," by Thorpe (Text-book of Science. Publishers: Longmans, Green, and Co., 4s. 6d.), pages 82 and 140. It would be impossible for any person to describe the process more plainly and accurately.—A Medical Student.

[46955.]—**Elementary Optics.**—The spherica aberration in a telescope objective cannot be corrected, but it may be reduced. One way is to cement the two lenses forming the objective together, leaving a very small space between them, which is done by means of a ring of paper, introduced between them, to the effect of keeping them apart. Another plan is, destroy the spherical surface of the convex lens by making the centre thicker. This is done on the principle that the refraction is greater at the ends of a lens than at its centre.—A Medical Student.

[46957.]—**Battery.**—What does "Amateur" want to plate with—copper, silver, or gold?—Geo. G. Blackwell.

[46957.]—**Bunsen Battery.**—You do not say what solution you want. To charge a Bunsen, put nitric acid in the porous cell, which contains the carbon, and in the outer cell, which has the zinc, sulphuric acid and water.—Caton.

[46957.]—**Battery.**—A Bunsen battery is not so well adapted for plating or gilding. I should not use it for that purpose. You had better have a Daniell's battery, or if you are an amateur to whom a little time is no object, use the new battery invented by Mr. Bennett. I have tried it for both gilding and silver plating, and it does the work well, but slowly. I used a solution of soda made as described by me a week or two since, and I intend shortly to give it a thorough testing, and shall make some larger batteries. The one I used was an old 2lb. meat tin (cost nil), and a flat porous cell 5 by 4. I only operated on one small article at once, but it was quite sufficient to show me what the battery is capable of.—Os.

[46958.] — **Half-Chronometer.** — I presume "Chronos" is acquainted with the lever escapement, so if I give him a description of a half-chronometer (generally called a lever chronometer, and stamped "Morton's Patent" on the plate), he will understand the difference. This escapement has the lever mode of unlocking, and chronometer mode of giving impulse. The balance staff is fitted with two rollers: the bottom one is a crank roller working the lever and pallets, same as in an ordinary lever, but the pallets have no impulse faces, and so made that the wheel has a long drop on the locking face of the inside pallet, and a short drop on the outside locking pallet. When the balance, by means of the lever, unlocks the outside pallet the wheel begins to perform the long drop, and in so doing gives impulse (by a tooth in advance of the pallets) to a small projecting jewel in the large roller on balance-staff, which is at that moment travelling in the same direction. It is an escapement not liked by watchmakers. You mention in your query an overcoil spring; this may be applied to almost any escapement, but is never put to a verge or horizontal; it would be as useless as a compensation balance to such escapements.—G. K. Stockton.

[46961.]—**Battery.**—Perhaps "Bell" has paraffined the carbons but too well, and, in consequence, has no metallic connection with the carbon. —Geo. G. Blackwell.

[46961.]—**Battery.**—It seems to me that you have used paraffin oil instead of paraffin, if so, you would of course spoil the carbons, and it would creep up all over the plates. If you cannot get paraffin, use pitch. This is commonly used, and seems to answer every purpose. You may perhaps clean your carbons by roasting them before a hot fire till the paraffin oil is driven off.—Os.

[46961.]—**Battery.**—Put your carbon plates on a clear fire till the paraffin has all burnt out of them. Let them cool, and then heat one end (about an inch and a half) over a Bunsen burner; then put a lump of paraffin wax on the end, and let it soak in, and continue putting the wax on the end till it shows a tendency to catch alight; now take your blowpipe, and direct the flame on the end of the plate, and you will notice the wax receding from the flame; continue using the blowpipe till you have driven the wax back far enough to make your connections. If you have done this carefully, you ought to have a line of wax all round the carbon, effectually preventing the solution creeping up to the connection.—Tortoise.

[46962.]—**Stereoscopic Camera.**—I would not advise "Stereo" to construct a camera solely for taking stereoscopic pictures. One may be made for the two following sizes: 6½ by 4¾, 7¼ by 4½. The latter is used in such cameras for stereoscopes; the dark slide is so constructed to carry the two sizes without the use of carriers. The first of a series of articles, fully described and illustrated by the writer on the construction of such a camera, will be found in the June number of "Amateur Work." It would take up too much valuable space in the queries of the "E. M." to give instructions, without of very simple construction. When I make apparatus, I like something ornamental as well as useful.—James Parkinson.

[46963.]—**Astronomical.**—(1) As the rotation of the earth is in the same direction as the orbital motion, the motion in space of an object on the equator at midnight is equal to the motion in orbit of the earth, plus the motion of rotation; at midday, the motion in orbit minus the motion of rotation. At midnight the motion in space is greater than a place 180° distant by twice the velocity of the earth's rotation. (2) Both the earth and moon revolve round their common centre of gravity, so it is equally correct to say that the earth revolves round the moon, as that the moon revolves round the earth. This is explained by the familiar experiment of fixing a heavy and a light ball on the ends of a stick, and revolving them on their common centre of gravity.—Mimas.

[46965.]—**Pianoforte.**—I might tell "W.H." that the best way to keep his wires from rusting would be to keep them in a dry place; but, as I am afraid this would be but stale information, I will recommend him to give them a smart rubbing with a leather and a little slaked lime. This will, at least, undo the mischief of the finger-marks that are usually left on after stringing. If, however, the rust has began to appear, he cannot do better than rub them with a rag that has been lightly touched with paraffin or sweet oil, though I should warn him that in so doing, he cannot be too careful not to let the oil touch the wrest-pins, for, if it does, it will inevitably creep between them and the wood, and cause them to slip back after tuning.—W. H. Davies.

[46966.]—**Balance-Springs.**—I do not know of anything better than to dip a small drill in your watch-oil and oil it; you must clean off the rust first; so long as the coils work free of each other, the oil will not interfere with the going of the watch.—A Fellow-Workman.

[46969.]—**Railway Curves.**—The formula is not correctly quoted; it should be $a = c / \pi r \times 90°$. Here *c* and *r* are supposed to be in feet, but as the radius is generally an exact number of chains, we may take one chain as the unit, in which case the *c* will disappear, and the formula becomes $a = 90° \div \pi r$, where *r* is the radius in chains of any length, either 66ft. or 100ft. The angle *a* will be the same for any length of chain, provided we use the same chain for all the measurements. If the radius is 40 chains, $r = 40$ in the above formula, $\pi = 3{\cdot}1416$, and it will be more convenient to reduce the 90° to minutes, which thus becomes 5,400′; we therefore have $a = 5{,}400' \div 3{\cdot}1416 \times 40$, from which it will be found that $a = 42{\cdot}97'$. If you have a table of natural sines, the angle can be found very easily. If the angle at centre, see page 287, Nov. 25th, be bisected by a perpendicular on A K, it will be seen that the sine of half the angle at centre, or angle $a = c / 2 \div r$; or taking *c* as the unit of measurement, sin. $a = 1 / 2r$; in this case $r = 40$, so that sin. $a = {\cdot}0125$, from which *a* will be found to be about 43′. The first method is the more accurate, as ordinary tables will not work to decimals of a minute, and these decimals are important in long curves.—M.I.C.E.

[46972.]—**Cheap form of Voltaic Cell.**—You might succeed in making the Leclanché cells work by soaking the porous cells (and contents just as they are) in water, and changing the water frequently, taking care to drain the cells after each soaking. If this will not do, you can take them to pieces and recharge. You could make a galvanometer for a couple of shillings, and I would advise you to do so. I cannot say why your new cell will not ring the bell, as I don't know much about bells; but I would not advise the use of the new battery for that purpose, as it requires more attention than Leclanché cells. If soda solution is used, the cells dry up. I have not tried potash, as the other is cheaper; but, any way, I think they will require at least daily attention, and sometimes more. On reading your query over again, it strikes me that perhaps you have omitted to fill the porous pot with solution.—Os.

[46972.]—**Cheap Form of Voltaic Cell.**—You do not say what you put in the porous pot with the zinc. I presume it was some of the potash solution. If the bell you speak of required four Leclanchés to work it, it is not likely that one battery such as you speak of would produce any effect. Fill the porous-pot with a strong solution of common brown potash, as it is commercially termed, cork it up after putting in the zinc; put the pot inside the tin and fill up with iron borings. You need not moisten the borings unless you want the battery to work at once. I expect you will want four or five to equal the original Leclanchés; I have not found this style of battery excel the Leclanché, though others seem to. 2. If there is no spark visible at the junction of the two connecting wires, put the extremity of one on your tongue, and then touch the tongue with the other, you will experience a slight metallic taste.—Tortoise.

[46974.]—**Horizontal Escapement.**—This is addressed to "J. P. W.," but I take the liberty to reply. The middle dot of the three on the plate of Geneve watch is for the purpose of putting watch in beat, the dot on the outside of the balance should come directly over the middle dot, when the watch stands idle. The word "draw" is often used by jobbers: it means "detent"; the detent side of the cylinder is nearest the dots. The verge watch is the only watch which has *not* got a "draw." A pointed peg would be preferable to tweezers, on account of its being lighter.—A Fellow-Workman.

[46976.]—**Canary.**—Your bird is probably being suffocated by being hung near the ceiling when candles, gas, &c., are being burnt. Even without this, the air near the top of room is by no means wholesome, as you may experience by standing on a table when windows are shut and there are several people in the room. Remedy: place the cage on table or on the ground.—Glatton.

[46976.]—**Canary.**—You should give your bird from 4 to 6 drops of canaradyne with egg food, or upon a small piece of soaked bread. You can procure a bottle of canaradyne from Mr. F. Tibbs, Wilfrid Works, 63, Chalk Farm-road, London, N.W. Continue to give the usual food, but no hempseed. I have found this an invaluable remedy for asthma in canaries; if the disease is of long standing it is not possible to entirely cure the bird; the bird should not be kept in a room where gas is burning: they lose their feathers in consequence.—Julia.

[46976.]—**Canary.**—Try the first prescription of "A Medical Student" given to a two-legged patient. No hemp-seed, but only rape, at the same time abundance of bread soaked in pure water and then pressed; continue with lettuce and watercress (twice a week). Use the following preparation:—Throw a piece of the crumb of white bread (about the size of a nut) into a cupful of milk, boiling and stirring it all the time (with a wooden spoon) until it is of the consistency of pap. Let this be perfectly cold before given to the patient, and always fresh, for as soon as it is sour it will do harm.

Give this paste only once in four days, as the asthma is but slight at present. You would do best to use homœopathic medicines besides, which, though I am an allopathist, I cannot but recommend very strongly for such particular cases. The following tinctures would be the most useful (add about five or six drops to the water, using, of course, one medicine at a time):—Ipecacuanha, aconitum, nux vomica, and if all these will not succeed, try sulphur, using the first dilution of each tincture.—A Medical Student.

[46978.]—**Canaries.**—It is a common thing for canaries to neglect to feed their young ones; I believe it to be the result of high breeding, I lost several young birds last year in the same way. The old birds were of the Norwich breed; the hen was a dark-crested bird.—Julia.

[46978.]—**Canaries.**—You are perfectly right in thinking that the cause of death is want of food. Similar cases happen very often. The mates should assist the hens in the fatiguing office of filling the little beaks, after the ladies have fulfilled their duty, consisting in sitting on the eggs and hatching the young. The hens become tired of their arduous task, and following their natural instinct, leave off the duties of a loving mother, and expect their husbands to take up the ceaseless task of feeding. But these gentlemen being too highly bred and cultivated, feel a great indisposition to work, being not accustomed to it, and so the poor things perish most miserably. The only remedy is to feed the little ones from the very first day of their life.—A Medical Student.

[46979.]—**Etching.**—I regret that I cannot give you any information about steel-plate etching. For copper-plates two preparations are required. (1) The mordant, composed of hydrochloric acid, 100 grammes; chlorate of potash, 20 grammes; water, 880 grammes. The water is to be warmed, and the chlorate of potash perfectly dissolved in it first; then the acid is added; the common muriatic acid of commerce must not be used; it gives off intolerable fumes, and is of a deep yellow colour. The proper form of the acid for etching does not fume, and has a very slight odour when mixed with water. (2) The ground for the copper-plate, consisting of a solution of yellow beeswax in turpentine, decanted until no sediment remains; the solution should be clear, and of a bright yellow colour; add one-sixth of its volume of Japan varnish. To prepare the plate, clean the surface with engraver's emery-paper; then pour a small quantity of the mordant into a shallow porcelain bath such as photographers use, and put the plate in the bath, leaving it until the surface darkens all over; if any spots remain bright, it is a sign that the plate is greasy, in which case the grease must be removed; then, when the plate is uniformly dark, wash and dry it, and pour on a little of the ground, so that it covers the surface all over, let it dry for twelve hours, then apply a second coat of ground, and without waiting for it to dry, smoke the surface with twisted tapers, holding the plate upside down—let it dry, and the plate will be ready for etching on. Etching needles can be made of ordinary sewing needles with points of different sharpness, set in wooden handles. A more satisfactory kind, however, consists of a bar of steel, about the thickness of one's little finger in the middle, tapering to a point at each end; these needles are more easy to work with, as the weight of the needle, or rather bar, is enough to penetrate the wax coating on the plate, and the hand is left at liberty to draw freely; the needle can be sharpened on a sharpening stone. Now proceed to draw on the plate, taking care that the needle goes through the wax and touches the plate; take care also that your nail does not remove the ground, or there will be a line where you do not want one. It is a good plan to have a piece of board with a hollow about ¼ of an inch deep sunk in it of slightly larger dimensions than the copper. Place the plate in this, and have a flat piece of wood like a drawing ruler, which you can place across the hollow, so that you can etch any part of the plate without fear of damaging the ground. Draw all the darkest lines first; then immerse the plate in the bath containing the mordant for three hours. Take it out, dry it with blotting-paper, taking care not to push the wax back into the lines you have drawn; draw the next darkest lines, put the plate in the bath for 1½ hour, dry it again, draw the lighter lines, put it in the bath for three-quarters of an hour, dry again and draw the lightest lines, and put in bath for three-quarters of an hour. The lines will then have bitten for 6 hours, 4½ hours, 1½ hour, and three-quarters of an hour, according to the darkness you wish to produce. Six hours is about the average time for this biting solution; but it requires a longer time in winter, and shorter in summer. The ground must now be removed with petroleum, and a proof of the plate must be taken, to see if there is anything further required. The etching is much improved by being touched up with a sharp point, filling up gaps you may have left, and making the shades blend better; this is done without acid, of course, and is more in the style of engraving; it is termed "dry point." Unless you have some experience in copper-plate printing, I should advise you to send the plate to a regular lithographer, as it will be a long time before you can print properly—the presses are expensive, £6 6s. or £8 8s.; a printer will do them for you at from 2s.6d. to 5s. or so per dozen; it depends on the style in which they are printed and the paper used. I may mention a few prices, as a guide to you: copper plates from 1s. each, etching ground 1s. per bottle, needles from 6d., double ends, all steel, 1s. 6d., porcelain baths from 1s. 6d.; the prices are probably very much the same everywhere. I get my materials from Roberson, 99, Long Acre. I forgot to say you must apply the ground to both sides of the plate, or the biting solution will attack the back when in the bath. I shall be glad to give you any further hints that you may need, if I can. I have quoted largely from Hamerton's "Etcher's Handbook," 5s., published by Roberson, Long Acre—a useful book.—R. B.

[46981.]—**Verge-Turning Collet.**—If you look at the beginning of my articles on the verge watch, you will see drawing of what you require; it will be necessary to protect bottom pallet. If you have not got the paper, write again.—A Fellow-Workman.

[46983.]—**Concrete Bed for Engine.**—To "Desoridi."—I should say use concrete in preference to either ashlar or brickwork, not only on account of its cheapness, but on account of its homogeneity; which permits the strain and jar, thrown on the bed, to be distributed throughout the whole of the foundation. I have known instances where foundations in ashlar, for large revolving chemical furnaces in North of England, have given most unsatisfactory results: the same parties have put down concrete foundations with the greatest benefit, and also at a much less cost. I do not propose to go into the matter, but simply to give "Desoridi" particulars of one large bed, about 38ft. by 14ft. by 5ft., that I have recently put down in our own works, and which appears to be a thoroughly satisfactory job. The cost may appear small, but it is the actual cost to us:—

Cost of Concrete Bed.

Broken slag (from blast furnace) 2s. 9d. and 3s. per ton, 94 tons 18 cwt. ……	14	0	0
Portland cement, £2 3s. per ton, 8 tons	17	4	0
	£31	4	0
Cost of slag per cubic yard …………		3	4
,, ,, cement per cubic yard ………		4	0
,, ,, excavating, tipping, and mixing		1	8
Total cost per cubic yard		9	0

Part of slag was 1½in. cube, and part small to fill up interstices. Engine bed was supported on rails, and the concrete mixed and tipped, and then levelled, and well packed into corners, and around holding-down bolts, &c. Ashlar would cost 2s. 6d. per c. foot, or £1 2s. 6d. per c. yard. Trusting this may be of use to "Desoridi" is the desire of—W. S.

[46984.]—**Hardening Copper.**—An addition of a small percentage of phosphorus to the copper when casting gives considerable hardness. Hammering hardens it to some degree.—Glatton.

[46984.]—**Hardening Copper.**—Certainly there is. If dipped into water when bright red it will be hardened; but when I used copper nails for a clincher-built boat, I always had to harden every nail by hammering upon a smooth anvil.—J. J. A., Liverpool.

[46985.]—**Gilding the Edges of Mounts.**—What you should use is strong size, which is equivalent to weak glue.—J. J. A., Liverpool.

[46985.]—**Gilding the Edges of Mounts.**—You will succeed better with your gum if, after putting it on the paper with a brush, you allow it to remain till half-dry; you will find it will then stick at once. Before gumming the paper, leave it for a few hours between damp blotting-paper, and don't use the gum too thin.—Os.

[46985.]—**Gilding the Edges of Mounts.**—The edges of cut mounts are gilt by very narrow strips of gold-paper stuck round them. The best way to do is to fasten the gold-paper, back up, on a pane of glass, and when dry give a coat of thin, clean glue. When dry cut into strips ⅛in. broad. Practice is necessary before you will use properly.—Belfast.

[46987.]—**Tinning or Bronzing Small Malleable Castings.**—I do not know of any method of bronzing iron without melting it; but perhaps the following may suit:—To render iron as white and beautiful as silver, take ammoniacal salt in powder, and mix it with an equal quantity of quicklime. Put them all together into cold water and mix well. When done, any piece of iron which you shall have made red-hot will, if you steep it in that prepared water, become as white as silver. You must not get the articles hot enough to burn them, and use a clean fire. A little practice would assist.—A Fellow-Workman.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

Since our last, E. Devaux has replied to 46236; W. Robinson, jun., 46418.

QUERIES.

[46995.]—**Sutton's Storage Battery.**—I have constructed a storage battery on Sutton's principle, and before using it I shall be glad if some electrical friend would answer the following questions:—In charging the cells, must they be put to the dynamo-machine to be charged one at a time, or can they be put on all at once, or can they be charged both ways? After charging the storage battery with the dynamo-machine, is there any danger in handling the connections of the battery when making the contacts to the lamp to be lighted with the naked hands? And if so, would indiarubber gloves do for insulators?—Electric Light.

[46996.]—**Italian and Spanish Locomotives.**—I would be much obliged to any correspondent who would give a description of any Spanish, also of any Italian, express passenger locomotives.—Tyke.

[46997.]—**Piano Warranty.**—To Mr. F. Wetherfield or Mr. W. H. Davies.—I have a trichord upright piano, without the check-action, catalogued at 44 guineas, and warranted for five years. Three years of the warranty term have expired, and two strings of the highest G have broken, thus affecting, also, the G-sharp above—one long string being adapted for two notes instead of two short strings. The touch has also become somewhat loose, which detracts much from the pleasure of playing the instrument. The wires have become rusty where pieces of flannel or some stuff underlie them only. As I am rather disappointed with my purchase, I should be glad to hear whether these defects should be made good by the makers?—J. Jones.

[46998.]—**Organ.**—I am intending to add two rows of pipes to my organ. It has at present four rows, as follows:—

Stopped Diapason… ..	56 pipes,	wood,	8ft. tone.
Principal …. …………	56 ,,	metal,	4ft. ,,
Wald Flute……………	56 ,,	wood,	4ft. ,,
Piccolo …………………	56 ,,	,,	2ft. ,,

The pipes I am thinking of adding are as follows:—

Open Diapason ……	56 pipes,	metal,	8ft. tone.
Dulciana ……………	44 ,,	,,	8ft. ,,
Bourdon ……………	32 ,,	wood,	16ft. ,,

I would like to place some of the pipes in a swell-box; but I am not sure which of the rows of pipes should be chosen for this. I should be greatly obliged if some of your numerous correspondents could assist me in this, and if they think a reed-stop would be advisable of 8ft. tone in the swell. I would like the swell-box to be as small as it is possible to have it. The room in which my organ is placed is not very large.—Cairn Hostie.

[46999.]—**Piano Repairs.**—Will any of the readers of the "E. M." kindly give me information on the following points?—1. To put new strings in an upright piano? The strings are not fastened at the bottom, but simply pass round a peg, the same string being used for two consecutive notes—e.g., G and G-sharp. 2. With what to clean rusty wires? How to remedy a somewhat loose touch? I know none of the names given to the different parts of the construction, but am a good hand at tuning, and tuning only—no repairing.—J. Jones.

[47000.]—**Model Steamboat.**—I have a boat which has, up to now, gone by clockwork; but I want it to go by steam. It is of the following dimensions:—Length 1ft. 11in., breadth 4½in., depth 3¼in. Would an engine ½in. bore, 1in. stroke, be sufficient to drive the boat at a moderate speed, with a screw 2½in. in depth? If so, what size boiler would it require? Would a boiler 6in. long, 4in. diam., with bottom ends flanged for a lamp, be sufficient to drive the engine? Any hints would oblige—Amateur.

[47001.]—**Miniature Electric Light.**—To Mr. Lancaster.—Would you oblige by telling me how to make a miniature electric light for a scarf-pin?—the battery, &c., to be carried in the pocket. I read about them at the Electric Exhibition in London. Please give full instructions about the making of it.—H. A. P.

[47002.]—**Black Paint for Window-sashes.**—Can any of your readers, from experience, recommend a black paint with a fair amount of gloss that will stand upon window-sashes in a direct southern aspect without blistering?—G. V. Ball.

[47003.]—**Storage Battery.**—Will any brother-reader kindly answer the following questions?—1. If the current of the storage cell would do to ring an electric bell through about 50 yards of wire? 2. If the current of a storage cell of dimensions below is any stronger than the battery which charges it, say two ½-pint Bunsens? 3.

How long a current from a storage cell in which lead plate was 72 sq. in. and copper 60in. would last if connected for 20 minutes each day?—Electrician.

[47004.]—**Bread.**—How is it that English bread is so inferior to foreign? My foreign friends when they first come over can't stomach your bread at all. They call it "semi-dried dough." How *is* English bread made? Does the fault lie in the material, manipulation, or in ignorance of the proper method of making?—Disgusted Foreigner.

[47005.]—**Bank of England.**—I should feel much obliged if anyone of "ours" would kindly inform me about the following?—I want to pay into the Bank of England a certain amount, say £500, in one sum or in instalments, such amount to be converted into a life annuity, payable to my heir after my death. What rate per annum does the Bank of England pay, if the £500 is non-returnable—*i.e.*, if the £500 remain in the Bank *in perpetuum*?—Canstall.

[47006.]—**Collodion Balloons.**—Will someone of "ours" kindly inform me how to make the above, of, say, 4 to 6in. diam.?—Paolo Ebimo.

[47007.]—**Photographic.**—I use Swan's dry plates, but my negatives are frequently disfigured by small round spots of clear glass, which I would like to get rid of. The negatives seem all right till nearly dry, when small pieces of the film burst up and detach themselves. Would somebody kindly inform me of the cause and remedy? If I cannot prevent the spots, how should I touch them out?—Perthshire Farmer.

[47008.]—**Ferrous Oxalate Development.**—Can negatives developed by ferrous oxalate be intensified? I can get abundance of detail in my negatives, but they are not dense enough to insure a good tone to the prints. —J. B. S.

[47009.]—**Naval Architecture Govt. Sc. and Arts Exam.**—Will some reader kindly say what are the best books to study for the elementary stage of this subject?—Volvox.

[47010.]—**Magneto-electro Machine.**—Can I magnetise 7in. horseshoe magnet of steel 1in. by ⅜in. by current from Smee's battery of 60 cells, plates 2½in. by ¾in.? What amount and sized wire required, and how wound on horseshoe? Would same current passed through wire on bobbins of machine answer purpose as electro-magnet with which to magnetise the horshoe? And lastly, how should wire be wound on bobbins of ordinary magnets—both same or reverse ways?—G. H.

[47011.]—**The Voice.**—A few practical hints from any of your readers as to the best means to pursue for self-cultivation of the voice, and to strengthen, preserve, and improve its quality and clearness for singing in public? Further, to avoid huskiness? Also, dryness of the mouth and throat just previous to and during singing, will be received with best thanks by—An Amateur.

[47012.]—**Transmitter.**—I should be glad if any reader would kindly give a description of, and information how to make, the best and simplest transmitter in connection with the Bell receiver? I want the telephone for use between house and stable—a distance of about 100 yards.—A. Reel.

[47013.]—**Steam-launch.**—I should like to keep a small steam-launch, but do not live on the waterside. I have made inquiries of several watermen, and they tell me that I could lay a small launch off any stairs, provided I did not anchor in what is termed the watermen's way. Now in front of our stairs at Deptford, there is plenty of room and shelter, as the cattle-market jetty runs out a good way. The boat I propose would be about the size of a waterman's boat.—Steam-Launch.

[47014.]—**Steam-power.**—I am a wood-turner, and I wish to drive my lathe by steam-power. Is there any official to interfere (Board of Trade, for instance), or have I to register my engine and boiler, or the fact that I am a user of steam power? In short, is there anyone to prevent, excepting, of course, the Insurance Co., who insure the house? Also, will the water company charge for use of water for 1 h.p. boiler?—Steam-power.

[47015.]—**Portable Greenhouse.**—The glass panes slide in grooves, the edges of any two adjacent panes making (or rather being intended to make) a butt joint with one another. As a matter of fact, very many panes are not cut square, and some are as much as ¼in. apart. I have thought of applying strips of tape covered with indiarubber solution as plasters to cover these gaps, but doubt if the sun would not cause them to peel off. What cement would be the best?—Glatton.

[47016.]—**Repairing Ebonite Dish.**—I have broken an expensive ebonite dish. One large piece with clean edges that exactly fits the hole is out of one side. How can I mend this to withstand photographic chemical solutions—all used cold? The ebonite is no thicker than cardboard, and the dish must not be patched with anything that will much reduce the size of the dish.—W. T. B.

[47017.]—**Tricycle-making.**—Will any correspondent give sketch (dimensioned), from which parts might be purchased and fitted up at home? I should like it be a convertible, that is, by detaching a smaller wheel at side, and inserting the treadle and a second driver, or as the Coventry tricycle, which, I think, would be easier to make. But is it (that is the design) patented, or is it only some particular part, as I know if the general design is patented, I should not be allowed to make. I prefer the open front machine, by what I can see of the advertisements in your paper, if I cannot make the Coventry tricycle.—J. O. E.

[47018.]—**Marine Screw-propeller.**—I shall be glad if any kind reader can inform what advantage I shall obtain by having two screws on same shaft in lieu of one I already have 2½in. dia., with three blades, and pitch 5in., as I want to increase the speed of my boat, as I have plenty of engine-power, and oblige—Thrust Disc.

[47019.]—**Disinfection.**—I am most anxious to become acquainted with the most recent and approved scientific principles involved in, and methods of, disinfection. I mean especially with reference to large quantities of clothing, bedding, furniture, rooms, &c., and the apparatus necessary for carrying out the same on a large scale. Perhaps our valued correspondent, Dr. Edmunds, or some other gentleman practically acquainted with the subject, will kindly inform me where I can obtain such information, or refer me to some work from which I can gather the required knowledge?—T. R. S.

[47020.]—**Mus. Bac. Degree.**—I should be very glad of any information about this degree. Is it possible for any but students at the Universities to compete for those at Oxford and Cambridge? Where can I obtain particulars of the examinations, and of those for the London degree? When are they held, and which is considered the easiest exam.?—L. R. D.

[47021.]—**Telescopes at the Crystal Palace.**—It is with great pleasure that I inform you that your excellent journal is making great progress amongst the students of the Wigan Mining and Mechanical School. Nearly two-thirds of the students are weekly subscribers, and as new scholars keep coming in every session, your circulation will keep increasing, as when once they commence to be readers, they look with pleasure for its appearance. Since last year I have myself introduced it to three improvement societies, and they, too, are now taking it in weekly. I should be very much obliged if any of your London readers could inform me who is the maker of the telescopes in the tower at the Crystal Palace? Also, the dia. of the object-glasses? As I have been told they are wonderful telescopes.—A Student.

[47022.]—**Shafting.**—I have a short piece of upright shafting, and the top bearing at times makes a screaming noise. It never gets hot; all the oil I can pour on it makes it no better, and there seems nothing wrong with it or the foot-step.—J. A.

[47023.]—**Seasick.**—To Dr. Edmunds.—Will you kindly tell me what to take when sick at sea, as I am an abstainer?—A Rechabite.

[47024.]—**To "Sigma."**—I wish to use a Swan's lamp of 20-candle power occasionally, and to have power always available. It appears to me from what I have read in the "E. M." that this could be readily accomplished by means of a Sutton secondary battery of copper and amalgamated lead plates. Will you please say the simplest way of constructing one of sufficient size in the most compact form, and the best battery to use for charging the same in the most economical manner? Also, how to charge the secondary from the ordinary cells? The secondary must be large enough to work for 10 hours at a time if required. I think the information will be acceptable to many readers besides—Incandescent Light.

[47025.]—**Medical Coil.**—To Mr. Fred. Walker.—I shall be very grateful for the promised directions (with sketch) as soon as possible, having plenty of time to spare at present, which may not occur again. Only please bear in mind my purse is not very long. I should like to know the price of wire per lb.; and if you think silk-covered is preferable, I will use it instead of cotton-covered.—G. D G.

[47026.]—**Melting Brass Dust.**—I have a quantity of brass turnings and filings which I wish to melt up and cast myself. Which is the simplest way to do the same? I have a large fire-place in my cellar where a range has been taken away; the flue runs three stories high. Myself and friend thought of building a furnace with bricks and lining with fireclay, coke fire.—Brass Dust.

[47027.]—**Electric Current.**—Does the current in a Gramme armature arise from the influence of the field-magnet on the coils, independently of the iron of the ring? Or is it solely caused by the iron of the armature? Or if both contribute, in what proportion each? In taking current off commutator, do all the coils yield, or only the two coils at the neutral points? Is there a better ring armature than the Gramme, or any other form that would not give alternating currents?—David.

[47028.]—**Slow Motion for Lathes.**—To "F. W. G."—I beg to tender my most sincere thanks to "F. W. G." for his able reply to my query, *re* Four-jaw Chuck. The illustration is all that could be wished. Should I find any technical difficulties in the construction of same, I will apply to him again. I should like to know if any reader or correspondent of "E. M." has tried the slow motion described by Mr. Young a short time ago (working with a chain from crank to pulley), and whether it gives satisfaction?—Chuck.

[47029.]—**Difficulty with Coil.**—To Mr. Lancaster.—I have made a coil of the following dimensions: Length of reel 7in., the tube made of cartridge paper, thoroughly glued and well dried, with ebonite ends 4in. square and ¼in. thick; the tube is ⅞in. interior dia.; the ends are glued on; core of about No. 18 iron wire 7¼in. long, sufficiently soft to show but little polarity; primary two layers of No. 16 cotton, weighing about ¼lb.; last layer paraffined, so as to soak through to the other layer; between primary and secondary a layer of paraffin, sufficient to fill up the interstices of primary, while allowing the rows to be seen through it. Secondary, which is wound direct on to this layer of paraffin, consists of 1lb. of No. 35, averaging 1,400 yards to the lb. There are a good many soldered joins in this, on account of its being a job lot. It is insulated with paraffin, first brushed on to each row, and then ironed in, and between each row are two or three layers of guttapercha tissue, fastened by paraffin and a hot iron. There are 18 rows of secondary condenser, 66 pieces of tin foil 5¼in. by 4¾in., separated by paraffined note-paper, neither thick nor highly glazed. Tin foils project about 1in. After having made the condenser, I heated it and pressed it very tightly, so that the paraffined paper stuck together. This coil, with a battery of six bichromates, plates 6in. by 3in., arranged for intensity, gives a spark barely ¼in. long, when used with a contact-breaker. Without the condenser the spark is just visible. I may mention that the breaker is one of the vertical form. This result puzzles me, for, when I had only 12 rows on and used it with only one bichromate, I got a spark ⅜in., and occasionally a forked one ½in. long. I noticed, as I proceeded winding the wire beyond 12 rows, that the spark slightly decreased, but attributed it to the declining power of my battery; but when I came to use six cells I found that it had decreased still more. I do not think I have used too much battery power, as I lowered the plates gradually and tried the coil with them at different degrees of immersion. I have now taken off the ebonite ends, thinking that there might be a leak there, but can discover none. Can you suggest the cause of this decrease in strength?—B. B.

[47030.]—**Repairing Watch.**—To "Alfojoe."—My best thanks are due to you for your reply to my last query, and through your instructions I have put the stopwork in perfect order; but with regard to my second query I riveted on the 'scape-wheel of the verge watch as you directed, but cannot now get the watch in beat. The pallets are too far from the 'scape-wheel, as no matter what angle I place them at, the watch runs down when wound. I have the pallets broken of two other verge watches, and would be glad to know how to put new ones in and to remedy the above? Also, the necessary tools required, and the price of them? Hoping I am not troubling you too much.—Country.

[47031.]—**Blocking Brass Musical Instruments.**—Could any reader kindly inform me how to do the above?—Mundamental Bass.

[47032.]—**Stonehenge and Sun Worship.**—I am much obliged to "F. R. A. S." for kindly answering my query (46888). As the subject is a really interesting one, perhaps someone acquainted with Stonehenge would say what is the evidence connecting that mysterious old relic with the worship of the sun? Does it possess angles, avenues, or isolated standing stones pointing in the direction of earliest or latest sun-rising?—Neo.

[47033.]—**Mining Questions.**—Would some kind reader answer the following questions?—1. How would you rebar an oblong shaft 6ft. by 14ft.?—the wood being very much decayed. 2. What is the rule for putting column pipes for pumping into a shaft with regard to plumbing and staying? 3. What is the rule for putting wood guides into a new shaft?—Miner.

[47034.]—**Dog-chuck for Lathe.**—Will any of "ours" kindly give description (with sketch if possible) of a dog-chuck for lathe? and oblige—E. D.

AND

WORLD OF SCIENCE AND ART.

FRIDAY, JUNE 2, 1882.

A CROWN-GLASS ACHROMATIC TELESCOPE.

THE instrument to which I propose to give this name, and to introduce to the notice of our readers, is so called because crown-glass is the only kind of glass which is used in its construction; and the lenses used are a convex one to receive the rays, and a concave one to correct the aberrations, both of the lenses being of crown-glass.

I had at first supposed that the only advantage would be a diminution of expense; but, on further examination, it would seem that there is so much advantage in the use of only one kind of glass, that a well-constructed telescope of this kind will bear very favourable comparison with any that can be made with two sorts of glass. I propose to show what reason there is for such a hope.

Achromatism of the Instrument.—Now, as it is obvious that the lenses will have to be at a certain distance apart, the instrument will be a sort of *dialyte;* and, therefore, the most natural thing to do first is to compare it with a dialyte of the common construction having a flint correcting-glass.

To do this with regard to achromatism, surely all that we have to do is to write down, side by side, the conditions necessary for it in the two cases severally. For the ordinary dialyte, then, the condition is:

$$\frac{b-d}{f_2}\,\frac{\mu_2-\mu'_2}{\mu_2-1}+\frac{b\,(\mu_1-\mu'_1)}{f_1\,(\mu_1-1)}-\frac{d\;b}{f_1f_2}\left(\frac{\mu_1-\mu'_1}{\mu_1-1}+\frac{\mu_2-\mu'_2}{\mu_2-1}\right)=0\ldots\ldots\text{A.}$$

And for the other it is:

$$d=\frac{f_1+f_2}{2+\frac{f_1}{b}}=0\ \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\text{B.}$$

It needs no argument to show which of these will practically be most liable to error in the application of it. But, in addition to this, the formula B, for glasses of the same kind, has this great advantage—that, as Dr. Parkinson observes, "irrationality" has no place, and therefore we are *free from the inconvenience of the secondary spectrum arising from it.* And this is one of the main advantages which the proposed instrument will have, not only over a common dialyte, but over every other kind of telescope in which two sorts of glass are used; and which, if there were no other advantage, would seem to be sufficient to deserve attention.

The equations given above are those commonly used for making rays of different colours *emerge parallel,* and this is what is commonly meant by "achromatism." But there is another sense in which the term may be quite as properly used, and which would seem to give better results. It is when the rays are made to converge to the same point. Let a ray falling upon the first lens at P, Fig. 1, be resolved into a red and a blue ray, which meet the second lens in R and B, and after refraction emerge parallel, so as to meet the axis in r and b. Then, in this case, the chromatic aberration—that is, the distance between b and r—will, though much reduced, be not destroyed, as they would be if they met in some common point f, and where the chromatic aberration is consequently destroyed. Moreover, when the rays meet the axis in b and r, these points cannot simultaneously be in focus, so that when viewed by the eyepiece, there will be more or less indistinctness, which should not exist, if they met in a point.

Let us, therefore, investigate the conditions under which they may come to a common point, and first suppose that the rays which fall upon the first lens are parallel to each other and to the common axis. Then, after refraction through the first lens, they meet the axis at a point whose distance from it is f, and whose distance from the second lens is therefore $d - f_1$. Call this u, then if v be the distance from the second lens of the point where the ray meets the axis after second refraction, we have $1 / v - 1 / u = 1 / f_2$, or $v = uf_2 / (u + f_2)$.

FIG. 1.

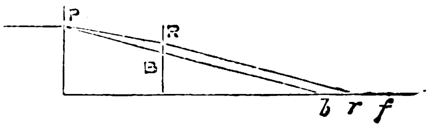

FIG. 2.

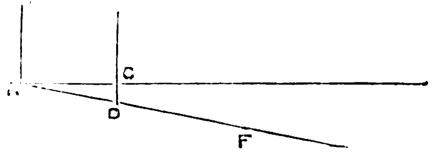

Suppose now that for another ray f_2 becomes $f_2 + \delta f_2$, and u becomes $u + \delta u$, and v becomes $v + \delta v$, then, since these are to meet in a point, $v = v + \delta v$ or $\delta v = 0$.

Taking, therefore, the variation of v in the above equation, and putting the result $= o$, we have $(u + f_2)\ (u\delta f_2 + f_2\delta u) - uf_2\ (\delta u + \delta f_2) = 0$, which is easily reduced to

$$u^2\delta f_2 + f_2^2\delta u = 0\ \ldots\ldots\ldots\ldots\ldots\ \text{C.}$$

Now, if f_1^1 and f_2^1 are corresponding values of f_1 and f_2 for the other ray, $\delta f_2 = f_2 - f_2^1$, and since $u = f_1 - d$, $\delta u = f_1 - f_1^1$, and eq. C. becomes $(f_1 - d)^2\ (f_2 - f_2^1) + f_2^2(f_1 - f_1^1) = 0$. or $(f_1 - d)^3\ f_2(1 - f_2^1 / f_2) + f_2^2 f_1(1 - f_1^1 / f_1) = 0$; but since the lenses are of the same material, $f_2^1 / f_2 = f_1 / f_1 = \alpha$, say, then the last equation is divisible by $f_2(1 - a)$, and gives finally

$$(f_1 - d)^2 + f_1f_2 = 0\ \ldots\ldots\ldots\ \text{D.}$$

This, then, is the condition required, and whenever it is satisfied rays of different colours and parallel to the axis will meet it in the same point. And it is evident that for the values of d to be possible, f_1 and f_2 must have opposite signs, that is to say, one lens must be convex, and the other concave.

Suppose, now, that the parallel rays make a small angle α with the axis of the lenses, then, equation C is the same for both cases. But in the latter the value of u is D F, Fig. 2, or A F — A D or $f_1 - d \sec \alpha$. So that all we have to do in this, or in similar cases, is to write $d \sec \alpha$ for d. This, of course, will not give absolutely the same value of d for all values of α; but as we are only concerned with rays which enter the eye, it will suffice to examine what can be the extreme value of α for such cases. Its value will be angle which the telescope moves through, as the star apparently moves from the centre to the circumference of the field of view. Suppose that, in doing so, the instrument moves through 10′, this will be the value of α for that case, and its secant is so very nearly equal to unity that we may suppose it actually so without the least sensible error. And thus, what is true for the axial point of the image, or field, will be sensibly true of every other point also.

If we had attempted to form the equation of condition for meeting in a point where the lenses are of different material, we should get an equation involving μ', &c., which will be about as far from being simultaneously satisfied for all rays as is the equation for rays being made parallel.

These two methods, therefore, of producing achromatism by a crown-glass correcting lens may both of them be proposed:—That which makes the rays emerge parallel, and that which brings them all to a point; and of these the latter would seem to be the best, inasmuch as it would be possible to focus the instrument more accurately than it could be otherwise, which, of course, is in every way a gain, especially, perhaps, for close double stars. For, when an instrument does not admit of being focussed very exactly from uncorrected aberrations of whatever kind, the general effect will be the same as in a perfect instrument thrown slightly out of focus—that is, would give a slightly larger and worse defined image, and, therefore, the images would have a greater tendency to overlap.

It may here be asked, "Is there not a *third* way of correcting aberration, which would have an advantage over either of the former—namely, by slightly *over*-correcting, so as to make the blue end of the spectrum fall farther from the o. g. than the red end, in order to adapt it better for viewing through a Huyghenian eyepiece?" This kind of correction has often been used, but, I believe, without much success; and as it is altogether a haphazard one, it is needless to say more about it, further than this—that I have prepared the plan of an eyepiece adapted to the second method of correction, which I hope to give an account of after having, in the next number, described the correction of spherical aberration in the proposed instrument, which I hope to be able to show, is capable of being corrected to any amount of exactness.

W. G. Penny, M.A.

(*To be continued.*)

REVIEWS.

The Marine Steam Engine. By Richard Sennett. London: Longmans.

THE author of this treatise is a chief engineer in the Royal Navy, and holds the position of first assistant to the chief engineer at Devonport Dockyard. His object in writing the work was to provide a textbook for students of marine engineering, which might also be found useful by those Naval officers who desire to obtain a knowledge of the machinery in the vessels they may be appointed to command. For these purposes the work is well adapted, being neither too theoretical nor too general, but eminently practical in character, especially from the point of view of the marine engineer in the Royal Navy. Mr. Sennett has not hesitated to utilise the material he found ready to his hand, but in preparing his book has availed himself of anything that could render it as complete as possible within its own lines. Thus in the chapters on the properties of steam, the author derived much assistance from the writings of Prof. Cotterill, and in other parts he has utilised the teachings of Prof. Rankine, making all suitable acknowledgment. The historical portion of the subject is wisely reduced to a mere outline, which is quite sufficient for modern students; but in practical details, as well as in theoretical explanations, the author has spared no pains to make the work complete. After a brief introductory, Mr. Sennett proceeds to treat of the prime mover of the marine engine—the boiler and furnace—and having explained the nature of combustion, and the reason why a certain quantity of air is required to burn a given weight of coal to the best advantage, he gives Rankine's formula for finding the weight of air theoretically necessary, and then proceeds to show under what conditions the result found by the formula may be modified. The author's remarks are the outcome of practical training, and render his work of more value than the usual run of text-books, written by men who have had no personal experience of the actual working of the apparatus and machines upon which they write. The various forms of boilers and their numerous accessories are fully described, and the Admiralty rules and tables are given where desirable. The chapter on the corrosion and preservation of boilers is as important as it is interesting. From it we learn that the plan of filling boilers with solution of lime to preserve them when not in use has been abandoned, and that carbonate of soda solution is preferred. New boilers in store are first carefully dried, and are then hermetically sealed after pans of quicklime have been placed in them. Another plan is to put burning charcoal or coked coal into the boiler, and then close up all cocks and valves. By this means an atmosphere heavily charged with carbonic acid is produced, and there is little risk of oxidation. The steam, the mechanism, and the propeller are treated in the same manner, illustrations being freely used where they serve to elucidate the subject. The book contains chapters on the indicator and the diagrams produced by it, on pumping, water-tight and fire arrangements, also one on the materials used in the construction of the marine engine and its accessories. Amongst the appendices is a fairly exhaustive list of examination questions, and an index renders the volume complete and well adapted to serve its purpose.

Lectures on the Science and Art of Sanitary Plumbing. By J. Stevens Hellyer. London: B. T. Batsford.

These lectures were delivered at the request of the National Health Society to working plumbers and others in the hall of the Society of Arts. It will be remembered that they attracted so much attention and gave rise to so much lively criticism that the subject of plumbing obtained more than the usual amount of notice from sanitarians, and even found a spare corner in the daily papers. The book before us presents the subject in six lectures, the first being introductory, treating of the trade and its members, of the public attitude with regard to the trade, and of the importance of plumbing being properly performed in order to secure healthy houses. The other lectures deal mainly with technical details, which, of importance to the plumber, are in some cases not without interest to the householder, who can, from a perusal of this book, learn the difference between good and bad arrangements and how to detect bad work—not an easy matter with plumbing. The necessity of traps, of trap ventilation, and of the other sanitary arrangements now adopted in well-appointed houses, are dealt with in four of the lectures, the second being devoted to a technical description of the art of joint-making and pipe-bending. The work is freely illustrated with woodcuts and plates, some of the latter being very valuable, as they show clearly the evils of the arrangements depicted. Many of those who have heard the lectures delivered will, no doubt, be glad of the opportunity of possessing a permanent record neatly printed, with such extracts from the discussion as the author has thought it advisable to append.

William Hedley, the Inventor of Railway Locomotion on the Present Principle. Newcastle: J. M. Carr.

The author of the little work before us believes that William Hedley is entitled to stand at the head of the list of inventors who have helped to make the locomotive what it is, and he has endeavoured to bring forward evidence establishing Hedley's claim to be the inventor of the locomotive. It may be conceded that justice has not been done by the majority of writers to the part played by William Hedley in the development of the locomotive, mainly because he was frequently hidden under the name of Blackett, the gentleman who appears to have done no more than find the funds; but the author of this work goes too far when he asserts that "without William Hedley, George Stephenson might have lived in vain. It was William Hedley who gave the locomotive its life and power, and made the work of other men possible." Hedley claimed the "principle of locomotion by the friction or adhesion of the wheels upon the rails"; but Mr. Zerah Colburn probably puts the claim on its proper ground when he says that Hedley was the first to work up the adhesion of the driving-wheels upon a commercial scale, for there can be no doubt that Trevithick had demonstrated the sufficiency of the adhesion of the wheels before the experiment was made which satisfied Hedley. The author is quite right in complaining of statements, still often made, that Stephenson was the inventor of the locomotive, when it is clear that Hedley made the first locomotive which was a practical success, by continuing in work for a period of half a century; but his little book can scarcely be accepted as more than the case from the advocate's point of view.

Progress. By James Platt. London: Simpkin, Marshall, and Co.

This is the concluding volume of a series of cheap and readable works, which have met with considerable success. The titles of these are thus introduced by the author in his concluding words:—Reader, make all you can from "Business," remember "Morality," use "Money" wisely, after studying the true principles of "Economy," and believe that "Life" rationally and wisely led must end in national and individual "Progress." The contents of the last-named can be imagined when we say that, amongst the subjects are capital, free labour, employés, technical education, production and distribution, and though the ideas are not altogether original, the author quotes Montaigne as a defence of his method of writing a book:—"I make others say for me what, either for want of language or want of sense, I cannot myself express." In his chapter on technical education Mr. Platt has taken a full grasp of the subject, and has enforced the absolute necessity of training in every branch of life, for the national existence depends on the utmost economy in production and distribution; but "technical education," he says, "will be deprived of half its benefit, unless we encourage inventive genius at the same time, by a complete alteration of the Patent Laws. At present, we stifle inventive knowledge, or, rather, deprive the nation of its benefit, by a tax that discourages rather than opens out the minds of those who might be benefactors to mankind." Those who have read the previous volumes of Mr. Pratt's series will not need advice to procure the concluding volume.

Electric-Lighting. By Le Comte Th. du Moncel. Translated by Robert Routledge, B.Sc. (London: Geo. Routledge & Sons.)

This is a translation of the second edition of Du Moncel's popular treatise "L'Eclairage Electrique"; and though considerable advances have been made since its original issue in 1880, the translator has preferred to leave the matter unrevised. So far as its omissions are concerned, the author will have little cause to complain, but we suspect that he would have altered some of the statements contained in the notes. As a popular treatise, the work will give just that information which the public so much need just now, the illustrations of machines and lamps being numerous, though necessarily not including the more recent inventions. Descriptions of these the translator has endeavoured to supply in an appendix; but as, speaking of incandescent lamps, he tells us that the "subdivision of the electric light presents no difficulties," and that "Fox-Lane" uses a string of flax from which to prepare the carbon filament, we can only regard it as a pity that he did not obtain the assistance of some electrician in writing the appendix. Much of the text has already appeared in English dress in various periodicals; but the work will, no doubt, be widely read by those who wish to know something about electric-lighting.

We have also received *Hot-Water Heating*, by F. A. Fawkes (B. T. Batsford), a useful and handy guide to all wishing to know how to arrange and put up heating arrangements for hot-water. —— *Mechanical Dentistry*, by Chas. Hunter (Crosby Lockwood and Co.) is the second edition of a manual that has been received with considerable favour. The most considerable alteration is the re-writing of the chapter on celluloid, a material which has recently been more extensively used in dentistry.——*A Treatise on Mathematics as Applied to the Constructive Arts*, by F. Campin, C.E., is the second edition, revised and enlarged, of a well-known volume of Weale's series. The work is especially adapted to the wants of those who have not received a mathematical education; and this, the second edition, includes a second part dealing with the higher mathematics.——*Hints for Investors*, by Walter M. Playford (Crosby Lockwood and Co.), is an explanation of the mode of transacting business on the Stock Exchange. which will be very useful to small capitalists.——*An Elementary Treatise on Conic Sections*, by Charles Smith, M.A. (Macmillan and Co.), and a *Treatise on Elementary Trigonometry*, by Rev. J. B. Lock, M.A. (Macmillan and Co.), are books which may be recommended to students, who must have some difficulty in choosing works of the kind.—*Picture-frame Making for Amateurs*, by James Lukin, B.A. (L. Upcott Gill), is a handy guide to the art of making-up picture-frames of various kinds, and will be found interesting by those who can handle such tools as are required. It is freely illustrated.

THE ORGAN: A COMPREHENSIVE TREATISE ON ITS MANUFACTURE, PROCURAL, AND LODGMENT.*

By John Watson Warman,

Associate of the College of Organists, London.

u. (8) *Passing Through of Key-Action.*—Whenever an Organ possesses more Manuals than One, and at the same time Two or more of them are to admit of being independently Coupled to the Pedals, it is inevitable that either the Key or the Coupling-Actions will have to *Cross;* that is to say, one Set of such Action will be compelled, at some one point, to pass *through* some other such Set. It has already been seen (at *g*, ante) that it is in some respects best for the Tails of an upper Manual to overhang the Tails of the one beneath it: it is now to be noted that whenever such overhang is secured, any necessity for the Crossing of the Actions from such Manuals to the *Pedals* is avoided; but that at the same time a Crossing in the Actions leading from these Manuals to the *Palletts* is thereby rendered almost inevitable. It is hardly required to remark that a Crossing in the latter Actions is of the more import, because of the greater number of the notes on the Manual than on the Pedals.

The most usual way of effecting such

---

* All rights reserved.

Crossing of the movement to the Palletts is to Skew or Crank, on *plan*, one—we will here assume the Upper—of the two Sets of Keys, so that its Tails come exactly opposite the *spaces* between the Tails of the Lower Set; and therefore the set of Stickers rising vertically from such lower Tails pass exactly between the said upper Tails, —each of the latter being so Notched on both its side-faces as to furnish a Mortise or Slot between each pair of Tails, for the said Sticker to move freely through: see further at *d*, next. And provided that the Notching-out be sufficiently large for the Sticker to have a little clear space all around it, and the Sticker-foot be wired into its Key-tail in the usual way—to prevent any chance of the Sticker's rubbing against the Notch—, this Treatment will answer very well. Whenever the Sticker is super-broadened (see *m*, next, 2nd parag.) the Notching must of course be elongated accordingly.

v. But there exist at least Five objections to such a method of Crossing. These are:—(*a*) sometimes additional work involved in sawing out the Keys: (*b*) extra wear sometimes thrown on to one side of the Mid-Pin mortise: (*c*) interference with the placing of a Coupler between two Sets of Keys (see *s*, ante): (*d*) the "throwing out" of the Action Points of one Set of Keys with respect to the same Points in the other such Set, and consequent frequent necessity for a *second* Skew or Slant somewhere, —to restore the coincidence; thus, for instance, if both of the Manuals possess a Coupler to the Pedals, it will be here impossible to make *one* set of Backfalls [beneath Manuals] serve for *both* of such Couplers (see *g*, ante), and not only is this so, but one of the two sets of Backfalls will have to be placed slightly *Slanting* in order to bring its front Noses into coincidence with the Noses of the Backfalls to the remaining Manuel: (*e*) an *End-gap* or *Key-gap*, will in some cases become unavoidable (see 93 *q*; also *z*, next, 3rd parag.)

For the best directions and treatment in the cutting of the Key Slant or Skew see under Head of SCALE (at 93, *r*).

w. With the object of obtaining the upper Manual Tail Overhang, without having either to dispense with the Sticker just spoken of, or to Skew or to Crank the Key, several methods have been devised, only one of which, however, needs mention here. It consists merely in passing the lower-Key Sticker through a suitable *Mortise* cut in the Tail of the upper Key. This Treatment does away with all the Five preceding objections, but it introduces in their place Two fresh ones, viz., (1), interference with Removal of the upper Manual, and (2), liability to Cyphering in both of the Manuals. The second of these objections can, however, be got over, provided the Lay-out admits of the Stickers' being made long enough in proportion to the vertical distance-apart of the two Sets of Key-tails (see at this point with *Contracted Levels*, at 92, *q*), by simply *omitting* the Foot-Wire of the said Sticker,—the said Foot thus merely resting on the [lower] Key-tail, and so being free to follow any lateral casting or crooking of the upper Key-tail. The Mortise through which Key passes must of course be then made very accurate in form and size, as it has to furnish the sole *guide* for the lower end of the Sticker.

x. An *Instance* of the foregoing Treatment may be seen in the Organ, of 2 Manuals and the Equivalents of about 10 Sounding-Stops, Rebuilt (see 22, *s*; and 60, *v*) for Mr. Martin Bradley, of Leominster, Herefordshire, in 1867,—at which time this particular Device first occurred to the present writer. The plan here answers very well; but of course the difficulty of removing the Swell-Org. Keys remains. (The employment of any preferable arrangement was here rendered impracticable by reason of the necessity for the new work's being grafted into the existing old.)

y. In another Rebuild—also of 2 Manuals—, in 1876, by Gern, of London (see 28, *j*), for St. James's, Addison-road, London (W.), the preceding arrangement has been adopted along with the *retention* of the Foot-Wire of the Sticker. This is, as just implied, always a really objectionable Treatment, for the Mortise must, obviously, be then made large, in order to ensure freedom for the Sticker within it, and this as manifestly tends to improperly reduce the substance of the Key; and even notwithstanding such increased freedom in the Mortise, a *Cyphering* is still liable unless the Keys be made of thoroughly seasoned material, for the corresponding Tails of the two Manuals may quite possibly cast or warp in *opposite* lateral directions. It is right to add that the Keys used by this particular Builder appear to be generally so "dry" as to materially lessen the chance of any unbidden sounding from such a cause as the foregoing.

z. After a considerable amount of thought and attention, I have come to the conclusion that in many cases (see here at *p*, next, 8th parag.) the really best method of Crossing two Key Actions will be found in an exact *Cranking*, by means of a suitable *Wire*, of the proper portion of such *Action* itself,—whether such portion be a Sticker or a Tracker.

In order to explain this Treatment, we will suppose it to be desired to apply it to such a pair of Manuals as those last named (at *y*, ante), and in which pair the upper Keys are, so far as the direction to right and left is concerned, exactly vertically *over* the lower Keys at every point. The lower part of the Sticker had here better be made entirely of Wire,—of the ordinary *Button* kind (see *Department* KEY-ACTION): this Wire will rise in the usual way from the lower Key, but, a little before reaching the under-face of the upper Key, it (the Wire) will take a sharp square turn or bend sideward for a distance exactly equal to half the plan-distance apart—centre to centre—of the Key-tails semitonally; the Wire will then ascend vertically till it is a sufficient distance above the upper face of the Swell Key, and then turn sharply sideward—precisely as before, except in the contrary direction—so as to return vertically over its first starting point; it will then be continued vertically for a short distance, so as to form a *tang* for insertion into a suitable Sticker,—continued and finished in the ordinary manner. In all cases where any Action Noses which rest on the Tails of the Upper Manual (see *d*, next, 4th parag.) do carry Regulating Buttons, it will be desirable to form the upper elbow of the Cranked Wire at a point *high* enough to favour the access necessary for such Regulation. And whenever such Noses, whether Regulating ones or not, do extend actually *between* the Cranked Wires, the said upper elbows are obviously *compelled* to be made sufficiently high to keep properly clear of the said Noses, even when the latter are risen with their Key Tails.

It will thus be understood that the Wire or Cranked part of the Sticker passes between two Keys in each case. It will manifestly be necessary to cut a little segmental or semicircular shaped *Notch* into the side faces of the Keys,—for the Wire to work freely through; and this Notch will be lined with *Cloth*, if required. A similar Clothed Notch will sometimes be required on the inner face of one of the two Cheeks of the Key-Frame (see 86, *t*).

Where the Sticker is short enough, it should be composed *entirely* of the Wire; and, where there is a sufficient amount of length on both sides of the Cranking, a Wood portion should be applied at *both* of such sides.

The treatment for a *Tracker* will be adequately understood by what has now been said.

When the Cranking passes between Backfalls, Squares, or Levers, the treatment will naturally be even more simple than as aforesaid with the Keys; for even *Thick* Backfalls will contain enough space between them to accommodate the Wire without any Cutting-away whatever. A small patch of Cloth may be attached, at the proper point, to *one* side of each of the Backfalls, Squares, or Levers.

zz. The slight increase which this *Crank-Wire* Treatment involves in labour and material, as compared with the simple Skewing of the Key, is hardly worth naming; the whole of the previously mentioned difficulties are avoided; and there remain, in addition, the following palpable advantages:—(*a*) the amount of substance at the Crossing being so small, much more freedom can be insured at such point, and this obviously diminishes the chance of an unbidden sounding through a "sticking" of the action; also in cases where the Noses of two Backfalls, Squares, or Levers are actuated by a single Key-tail (see *f*, next), or where the Backfalls are required to be thick enough for a Wire Tracker to pass through a Piercing in each of them (see *Department* KEY-ACTION), the Cranked Wire will often afford the only means possible for passing a Sticker between such Backfalls, Squares, or Levers: (*b*) the Removal or Replacing of the Key is facilitated,—its Tail being readily drawn out or pushed in between the two Wires: (*c*) Regulation of the Action is made easier, because the Cranked part of the Sticker or Tracker acts as a stopper to prevent it from turning round, and so there is usually no necessity for grasping the Thread-Wire with a Pliers: such Regulation is also rendered easier when it has to be performed by means of a Tool inserted between each two of a set of Stickers, because such Stickers are made of wire—so widening the opening—at the point of such insertion,—as when the Swell-Organ Key-tails do carry a set of Regulating Noses in rear of the Great-Organ Sticker line (see here the No. 4 *Treatment*, commencing at *p*, next): (*d*) the same causes act to render the entire removal of the Regulating Buttons (when taking Action to pieces) easier: (*e*) there is no possibility of the Great-Org. Sticker's becoming jammed through getting askew; and this advantage is obtained *without* either the additional work of super-broadening such Sticker and elongating the Notching (see at end of *u*, ante), or of passing the Sticker through a Key-tail: (*f*) it becomes quite practicable to allow the Noses of Squares, Backfalls, or Levers—especially if they be of Non-Regulating kind—to enter and lie actually between the [Cranked] Stickers: (*g*) it is now possible (and is not so by any other method) to let Stickers or Trackers pass through a Fanned or otherwise irregularly distanced Action,—because the plan-amount of the Crank elbow can be varied in every note, or in as many of them as is required: (*h*) the cranked part can be altered, by bending the Wire, so as to *follow* and accommodate a lateral casting or warping in the Keys or other portions through which such Cranking passes: (*i*) there is less liability of a Sticker's or Tracker's dropping away between Backfalls, &c., or slipping through a piercing in a single one of latter, immediately upon its Button being removed; and yet the Cranked portion of such Sticker or Tracker can be made to admit of being drawn out at pleasure through such piercing: (*j*) more space is left for a possibly desired Button-Clip for Participation (see descrip. at *j*, next, 1st parag.), if the Button itself be *not* in advance of the Great-Org. Stickers (see at *h*, next, 9th parag.) For any other advantages of the *Crank-Wire* method of Crossing, see *Departments* COUPLING-ACTION and KEY-ACTION.

zzz. No *Instance* of the *Crank-Wire* Treatment is as yet known to the present author,—it being his own Device.

(*To be continued.*)

PRACTICAL NOTES ON PLUMBING.—XXXIV.[*]

By P. J. Davies, H.M.A.S.P., &c.

Lavatory-Basins.

In fitting up lavatories great care should be taken in the selection of suitable fittings for the class of work that has to be executed, not forgetting simplicity of arrangement, cleanliness, and substantiality of the fittings. Such being the case, I propose to commence this branch of the trade by first describing the most simple, and gradually leading my readers, as it were step by step, to the most elaborate and intricate patterns and systems at present in use. The general height for lavatory-basins is 2ft. 6in., and in schools from 2ft. upwards.

By referring back to Fig. 120 in the BUILDING NEWS for Oct. 28, 1881, at 19 and 20, the reader will see a simple lavatory-basin suitable for its situation and work. All that is required is a round basin 13in. or 14in. in diameter, having a washer and plug fixed in the bottom, and an overflow-arm for the overflow-pipe 23, which may be branched into the waste-pipe, as shown at 22; below the basin should be fixed some kind of trap having a cleansing cap and screw, as shown at 22; from the top of the trap should be taken an air-pipe, as shown at 24, and carried up as shown at 25; to prevent siphonage and corrosion, or the outgo of the trap L W may discharge into a properly constructed open trap-head or otherwise; but in this case it is branched into W (waste) pipe, as shown at 37. Should the expense of carrying up an extra vent-pipe be too great, it is possible that this pipe may be taken back and branched into the main waste-pipe at about 33, and if this is too much trouble, use a thoroughly well constructed open-top trap on the inlet end of the waste-pipe, or a proper ▭ trap, as shown at the lavatory-basin (Fig. 121.) It should be remembered that I am not always in favour of the ▭ trap, but ever prefer to have them properly ventilated. I mention this to prevent any quibbling, and to show that I am quite aware that in certain situations an ∽ trap will answer every purpose. It is under such circumstances that the plumber must exercise his own judgment or discretion. By again referring to Fig. 121, published in this journal Nov. 11, 1881, it may be seen that this basin has an additional fitting: instead of the simple washer and plug as fitted in the basin (Fig. 120) it has a pull-up quick-waste, as exemplified at L W (Figs. 50, 52, 53, and 54, in issues for August 12 and 19, 1881.) It will also be noticed that to the waste-pipe from the trap there is no vent-pipe, but the end of this waste-pipe is taken right away to the gully-trap, shown in the left hand corner of Fig. 122, or if circumstances will allow, it may be taken to the fresh-air inlet, part of the main in the right-hand corner of the fig., as the sink-pipe does; but under these circumstances do not branch the lavatory or other waste-pipes into the waste-pipe of the bath, simply because by so doing you are very likely to interfere with the draught of the bath-waste, and so cause it to run sluggishly and noisily; and further, it is a matter of very common occurrence for the bath-pipe water, by its induced action, to empty the other traps, more especially if the trap is not of the ▭ pattern or kind, having an exceedingly small inlet or dip-pipe in proportion to the body.

---

[*] From the *Building News*. All rights reserved.

In order to prevent siphonage I have fitted a full-sized 9in. deep by 6in. wide ▭ trap with an only 1½in. dip-pipe, and found it effectually prevent siphonage under the most trying circumstances. Having settled about the basin waste-pipe and class of trap, the next thing for consideration will be the outlet. The washer and plug is known to all plumbers, therefore let us next examine Fig. 196. Quick-waste A is a bracket to be fixed to a wooden block to the brickwork or otherwise; B the union for fixing with a leathern washer on the *inside* of the basin; this union has a fly-nut C for holding the union firmly to the basin; the union may with white-lead be bedded to the basin; F is a lining for soldering or connecting to a short length of leaden pipe, so as to connect it with the lining G of the valve; H the outlet valve; E the lining leading to the trap; J the pull-up knob, fixed by the fly-nut K to the slab or top; L the deep nut or lining for connecting the stand-pipe M, or valve, with the pull, which may be done with copper-wire-chain or otherwise. It will readily be seen that with such valve arrangement as this there is not any provision for overflow, and therefore an overflow arm must be fixed on the side of the basin, as shown in the dotted lines X (Figs. 197 and 200), or a branch inserted into the pipe, fixed between the valve and washer in basin as at N (Fig. 197) and in such a manner that the pipe O may be taken or bent up to the water-level of the basin, as shown at overflow, and having an outlet to discharge either into the open air or otherwise, as discretion or circumstances may dictate, taking care at the same time that this pipe does not siphon out the basin. If the outlet of this pipe has to be taken down below the top or water-level, an air pipe should be branched into the top at P, which will of course stop siphonage. Within the last few years the standing waste-pipe, so well known in connection with cistern-work, has been introduced for the outlet valve, which will be easily understood on examination of the diagram (Fig. 198).

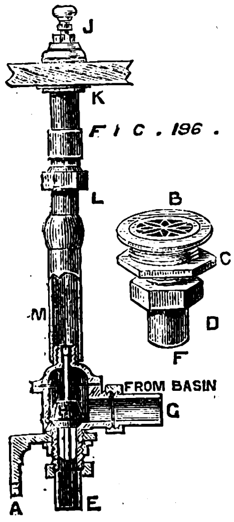

FIG. 196.

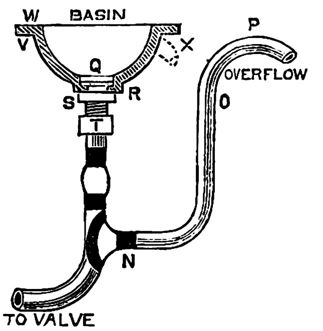
FIG. 197.



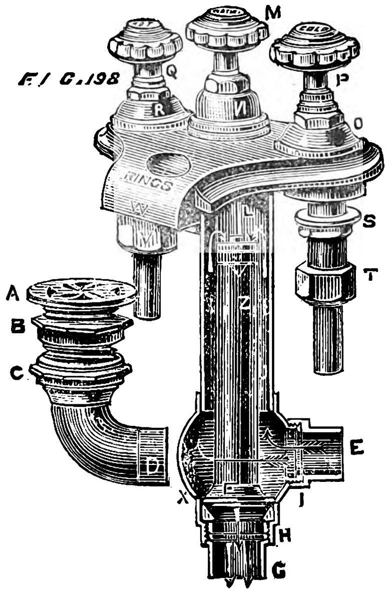


FIG. 198.

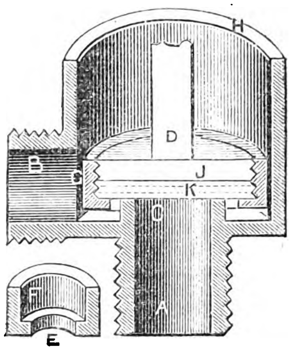
Suppose the washer A to be fixed to the bottom of the basin, and the union bend D to be attached to the body X, water from within the basin can run down through the union and charge the body up to the top of the stand-pipe Z, and overflow, as shown by the arrows at K, so that it would be impossible for the basin to overflow, assuming always that the overflow is large enough. Next, by the knob M and rod L, pull up the stand-pipe Z; by so doing the valve F must also be opened, which allows the contents of the basin to run full-pipe bore away; but suppose you let go the knob before the basin is emptied (say when half empty) unless you have a good air-pipe or a properly constucted ▭ trap to allow plenty of fresh air, the seal of your trap will be instantly destroyed, and the stink arise through the standing waste. There is, however, a remedy which only to-day I have invented, and put into practice. It is as follows:—Fix an inverted cup on the rod L, so that its mouth or lip shall cover the standing waste-pipe when the knob is let go in a similar way that the bell-trap does, but let it dip to about the bottom of the basin. More will be said about this diagram in Water Supply, as also in chapters on Bath Work.

It frequently occurs that the wastes of lavatories are fitted to work with a kind of stool valve, as shown at Fig. 148, with levers and chain connected to the ordinary pull; when such valves as these are fitted, make the ordinary outlet B (Fig. 148) the inlet from the basin, so that all the water from the basin may drain entirely away, and see also that the rubber on the valve is properly fixed, with a pillbox lid nut G (Fig. 199), which will prevent the rush of water having any effect upon the edges of the rubber, which otherwise will have a tendency to pass into the seating; as a matter of course, when the rubber is fixed to the valve in this manner, the seating must be a raised one, as shown at C (Fig. 199) and D (Fig. 152) &c. This raised seating is to allow for the bottom part of the pill-box nut, which otherwise would prevent the valve from closing, unless a washer were fixed round the seating.

FIG. 199.



Water Supply to Lavatories (Fig. 200).

There are many different methods whereby the water supply can be accomplished, some of which are of the most intricate nature. I shall, however, be content to describe some of the more simple ones that I have fitted up myself. Fig. 200 is a very good lavatory, similar to one that I fitted up in Portman-square 18 years ago, and, moreover, one not likely to get out of order. A is an 18in. white and gold basin, with inlet pan B from hot and cold supply

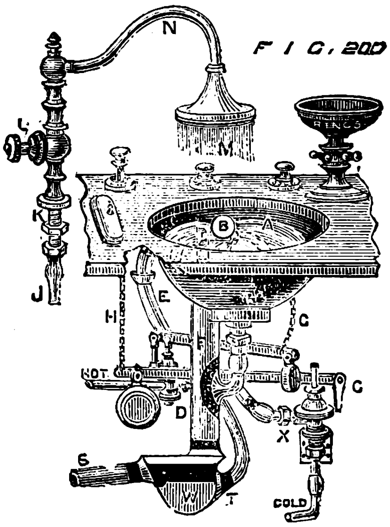


FIG. 200.

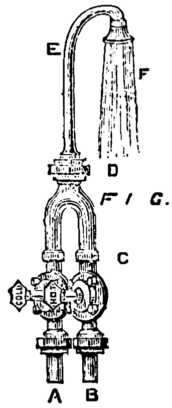

FIG. 201.

valves; E is the overflow pipe, brought from the arm of the basin into the heel of the ⊂⊃ trap; F is the quick-waste, constructed in the dip of the D trap, the valve being a 2in., ground in long pump spindle valve, worked by the use of a rod and sling attached to the pull-up knob "WASTE"; the levers of the hot and cold supply are attached to the knobs by the use of the chain G H. Of course the pulls are made in such a manner that by giving them a quarter turn they will hang up. To this basin is fixed the swing pillar-bracket L, which is used for shampooing, &c. The pillar is fixed to the marble slab by means of a fly-nut, as shown. The swan-neck may be fitted with universal-joint, or sometimes only made to swing in a side-direction, or it may be fitted with india-rubber tubing; the valve L may be dispensed with, and a double valve, one for hot, the other for cold; or it may be supplied through a breeching-piece, as shown in Fig. 201.

WATCH-CLEANING AND REPAIRING.

By "A FELLOW-WORKMAN."

(*Continued from page* 255.)

IT does not matter what job you do, you must have a foundation to work upon, and also a rule; we will, therefore, find the foundation of a barrel; Fig. 57, therefore, shows the foundation and also the rule. The line B to C should be a true surface of the outside of the teeth; B to A, D to E, and C to A should be at right angles; A to F would be the centre through the barrel.

FIG. 55.

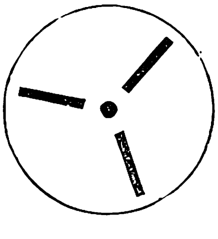

FIG. 56.

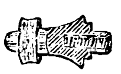

FIG. 57.

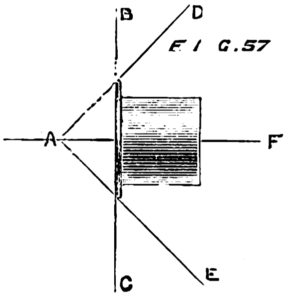

FIG. 54.

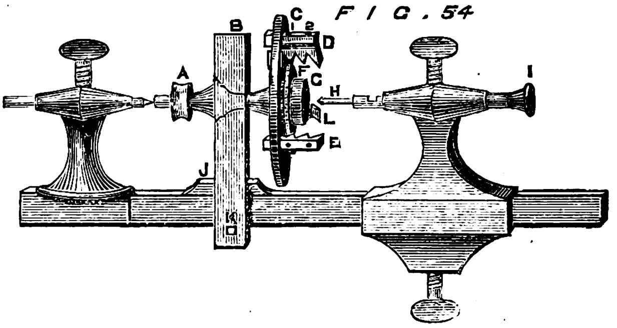

We will, therefore, say that you have filed up the holes in lid and barrel, and you wish to cut a dead centre from F to A without loosing the other angles; to do this you must fit your barrel, as shown Fig. 54, on a true surface, and the outside of the teeth must run true; then the point of your drill must enter at a dead centre, and when you have drilled a hole right through the barrel, you will find, on trying it, that the teeth run perfect. You must be careful to put lid on in its right place.

Fig. 54: A is rose for drill-bow, and also Fig. 56, which runs through B, as shown by dotted lines. J is foot for B, to hold it more firm, and K is a square wedge, which goes right B and holds it down firm. C is chuck, D double clamp, with screws at back, as shown at E. The jaws are screwed on to the chuck by means of a nut at the back. You put up E and L in position, and then D; then you tighten D by means of screws 1 and 2. F is a washer or ring, which holds barrel, and H is the drill. Fig. 55 is face of chuck with jaws removed the black lines are slots for jaws to run in, and the dot in the middle is for a male centre to be screwed in, which I will speak about another time. Fig. 56 is A in Fig. 54; the section shows a hole with a thread; the chuck C (Fig. 54) is screwed into this hole.

(*To be continued.*)

SPRAGUE'S ELECTRIC METER.

THE specification is just published of a patent taken out for improvements upon the electric meter, invented by Mr. Sprague in 1878, which greatly simplify the construction and action of the instrument, while extending its applications. This new patent contains also several additions made to the meter to increase its utility, and appears to cover every mode by which electrolytic actions can be practically used to register the quantity of electricity passed into a circuit.

The original idea of plates of metal acting alternately as anode and cathode, reversing the direction of the current by the weight of the metal transferred, and registering the number of reversals, is still the basis of the instrument; but all the mechanical modes of supporting the plates by springs or balance-beam are done away with. A single moving plate is used, which floats in the liquid like a hydrometer, and which sinks or rises in the liquid exactly in proportion to the weight of metal added to or taken from it. As the quantity of metal which serves as the measure of the electric quantity is added to the electrode, it sinks till the limit is reached, when a contact is made, which sends a current into a reverser, whereupon the relations of the electrodes being changed, the metal dissolves, and the plate rises to its upper limit, and again actuates the reverser.

Several forms of reverser are shown, which are intended to permit the whole of a large current to pass, and in which all sparks are prevented in a very simple manner, as both ends of the wires are connected together, by the motion of the reverser, before the contact at which the spark would appear is opened, so that the extra current has a closed circuit in which it passes without sparking. The register is actuated in a very simple manner by the reverser. The moving part of this carries a small wheel, upon which lies a lever also carrying a small wheel, and when the reverser is at rest these two wheels are in close contact. The motion of the reverser, therefore, lifts the lever by the action of the two wheels passing each other, and each such raising of the lever moves the indicating-train one tooth.

An automatic heating arrangement, which may be applied to various other uses, is employed to prevent the solution from being frozen. This consists of a coil of fine wire inclosed in the space between two glass tubes placed vertically in the liquid. When this wire is heated by the current, a stream of warmed liquid will run up these tubes, and thus warm the liquid generally, and the same appliance is of use to prevent stratification in the liquid. The current is sent into the heater by an automatic thermo-regulator, consisting of an air-thermometer fitted with wires, which close the circuit whenever the temperature falls to a fixed degree.

The influence of change of temperature upon shunt ratios is guarded against by balancing the liquid and metal of the meter circuit by a shunt composed of graphite and German silver, so adjusted that the variation is equalised in both circuits; but the care taken in the various designs shown in the specifications, appears to indicate that the intention is rather to do away with the complication of shunts by sending the whole current into the meter—a plan which will no doubt give less scope to the suspicions of consumers.

There is another mode of action shown which is based on a new idea, which may, however, be seen foreshadowed in the 1878 patent. In this construction two metal plates are employed, which would require exchanging for each other periodically as the metal is transferred from one to the other without reversal; but these plates and this metal, though they do the work, have nothing to do with the measuring, and therefore do not require weighing. The current passes from them to a cylinder floating between them on bearings. As one side of the cylinder receives metal while the other dissolves, the centre of gravity is displaced, and the cylinder rotates on its axis, and by its motion records the electricity passing. The idea is no doubt promising; but how it will perform in practice, would probably require to be determined by action in use.

But another modification appears to offer considerable promise of utility in connection with electro-metallurgy. The motion of the electrode is transferred to an index which traverses a scale showing the subdivisions of the interval between reversals. This scale may be made to show ounces of silver or gold, and a shifting contact is placed over any desired quantity: thus, if a silvering vat contains articles on which it is desired to deposit five ounces of silver, the stop would be adjusted at that point. When the indicator reached this spot it would touch the stop, and send a current into a connected apparatus, which would either disconnect the work, or ring a bell to call attention. If found to work in practice, this would evidently save a great deal of work, and also loss of valuable metals, or deficiency of metal deposited.

If electric-lighting advances with the rapidity its advocates look for, the question of measuring the current will become of very great importance, and it will remain to be seen whether electrolytic action will furnish the best means of measurement practically, as it does theoretically. If so, it is obvious that self-registering instruments must be preferred, to any mode of merely weighing a deposit at intervals.

EDISON'S CURRENT METER AND OTHER IMPROVEMENTS.

A MEANS of measuring the quantity of current passed along a given wire is as much a necessity of the general system of lighting by electricity as the gas-meter is to the existing system. It may be remembered that Mr. J. T. Sprague patented a simple device for calculating the quantity of current by the amount of copper deposited in a shunt circuit, and it so happened that Mr. Edison patented, or applied for a patent, for an invention which is practically identical. He has recently obtained a patent for a modified form of the invention, and according to the specification (4576, 1881) the new meter indicates a correct result with a smaller current than was required by the copper cell. The invention has been on view at the Crystal Palace, and was briefly described by us some time ago. It consists of amalgamated zinc electrodes in a solution of sulphate of zinc, and the sum to be charged to the consumer of current is ascertained by the increase in weight of the receiving plate—zinc, being deposited on one electrode, and dissolved off the other. According to the specification, a heavy coat of zinc is deposited on the plates, which zinc is thoroughly amalgamated while being deposited; but according to the descriptions of the process given by those connected with the invention, the plates are coated with chemically pure zinc, so as to reduce local action to a minimum, and they are then amalgamated. The plates are about the size of microscope slides, 3in. by 1in.; they are a quarter of an inch thick, and are kept apart by little strips of ebonite about a quarter of an inch thick, and clamped together by ebonite screws passing through the centre of their length. The depositing cell is arranged in a shunt from the leading conductor of the house or other circuit in which it is desired to measure the amount of current consumed,—a resistance being placed in the line to shunt a small definite portion of the current through the meter. In the wire leading to the latter is another resistance to compensate for the effects of change of temperature. This resistance is formed of copper wire, the electrical resistance of which increases with a rise in temperature, while that of the solution in the cell diminishes. A sufficient length of copper wire is, therefore, put in the circuit to equal the loss of resistance in the cell, and the arrangement is then permanently compensated for temperature. Arrangements are, however, made to prevent the temperature of the apparatus falling below a certain minimum; for when that is reached an Edison lamp is thrown into circuit, the heat from which quickly raises the air temperature of the box in which the meter is contained. When no current is being supplied, an electro-magnet breaks the shunt, thus preventing the establishment of a counter-current and the recomposition of the solution. In practice it is proposed to use two meter-cells placed in a cast-iron box so connected that one registers at a greater rate than the other, but in strict proportion. One of the cells would be examined monthly by the ordinary officers of the company; the other would be in the sole custody of superior officers, and would be examined quarterly. It is proposed that the inspectors, on coming to "take the meter," should remove the cells and replace them with fresh ones, the cells so removed being taken to the head office, and the plates carefully weighed after being separated. The difference in weight will be calculated in webers, ampères, coulombs, or whatever term may be used to designate the amount of current consumed, and the bill will be made out accordingly. Whether it will be paid ungrudgingly remains to be seen, for it is difficult to see what check the householder will have on the Electric Light Company, and remembering the perennial outcry about gas bills in face of the tell-tales, which every consumer can read if he will try, we are afraid grave charges will be made when consumers have no check at all. The copper cell, with the tipping beam, which registers the current consumed on dials similar to those of a gas-meter, is considered too delicate for use in the houses of customers, but will be employed at stations.

Another of Mr. Edison's improvements is a method of regulating the generative force of a dynamo-electric machine. In this invention (4552, 1881) a device is adopted for diminishing the mass of the yoke uniting the cores of the field-magnets. The electromotive force of the generator is kept constant by means of an electro-magnet, which acts upon a conical block, fitting a conical opening in the centre of the yoke. In Edison's well-known vertical machine, this method of a conical block drawn into the hole in the yoke by an electro-magnet and forced out by a spring and its own weight, can be easily adopted, but for other forms he provides means for partially shunting the magnetic currents or lines of force away from the field in which the armature is revolving, by adjusting levers to connect the pole pieces with the yoke, or to connect the brushes together.

Another invention recently patented relates to means for maintaining the electromotive force of a current from secondary batteries by reinforcing the primary current from time to time, so as to keep up the electromotive force in the consumption circuit; but as the arrangement cannot be explained without diagrams, we must refer those interested to the specification, No. 4553, of 1881.

WILLOUGHBY SMITH'S INDUCTOPHONE.

We mentioned in the "Scientific News" last week that Mr. Willoughby Smith had, in the course of some investigations into the phenomena of telephony, made a remarkable discovery—viz., that an iron plate, so held that the magnetic lines of force from a flat coil of insulated wire could impinge upon it, would produce the same musical note as that given by a tuning-fork used as a make-and-break contact in the circuit with the coil, although there is no visible connection between the iron plate and the coil. The apparatus, which has scarcely yet taken a definite form, has been called the inductophone, a name which sufficiently expresses the nature of the phenomena. It consists of a board, on which is mounted horizontally a tuning-fork, one arm of which carries a light contact piece normally bearing against the point of a binding screw placed on one side of the fork. Between the arms is a small electro-magnet, which, when the current is passed, maintains the vibrations of the fork indefinitely. The connections are so arranged that the current alternates, when the fork is vibrating, between the main line and a short circuit, and in the main circuit is placed the flat disc or coil, made up of insulated wire, rather fine, held between two pieces of cardboard in a frame so as to resemble in shape an ordinary bedroom looking-glass. One end of this coil is connected to the battery—Mr. Smith used a number of Leclanché elements—and the other is connected through the tuning-fork with the other pole of the battery—that is, when the contact is made. The fork being set in motion, the current passes through the coil of the magnet, and a rapid make-and-break arrangement is set in full swing, corresponding in number of contacts to the normal pitch of the fork. Thus, if the latter is an ordinary fork giving staff C, the number of vibrations per second is 512, and it follows that exactly the same number of magnetic changes take place in the coil or disc of insulated wire—consequently, also in the magnetic field which it creates. If, then, a telephone, a telephone-plate, or any suitable piece of iron is held in such a position as regards the looking-glass-shaped coil-frame, that the lines of force can impinge upon it, a sound is produced which is identical with that due to the tuning-fork, although there is no mechanical connection between the receiver and the flat coil. It must be confessed that this is a remarkable discovery, for the action is perfect, even when the transmitter and receiver are separated by a brick wall and several feet of air, the actual distance being limited only by the delicacy of the apparatus. It is obvious that the greatest effect will be found in that position in which the largest number of lines of force can impinge upon the receiving plate, and this will be found in the centre line of the flat coil or transmitter, the intensity varying as the square of the distance. The greater the number of lines of force, and the greater the intensity of the field, the greater will be the effect produced upon the receiving diaphragm. As to the distance through which the effect is produced, we believe that experiments are being made to determine it with some degree of accuracy; but as it obviously depends, to a certain extent, upon the apparatus employed, endeavours will, no doubt, be made to perfect that first. Meantime we have given sufficient particulars to enable experimenters to take up the study of a very interesting phenomenon.

ELECTRICAL ACCUMULATORS, OR SECONDARY BATTERIES.*

By Prof. Oliver J. Lodge, D.Sc.

(*Continued from page 256.*)

A PLANTE and a Faure cell, though the process, and more especially the time, of formation is different, are, when formed, pretty much the same thing; and consists of two plates of lead, one coated with black peroxide of lead (PbO_2), the other with a spongy material consisting of metallic lead in a fine state of division and more or less alloyed with hydrogen; both plates immersed in dilute sulphuric acid of about ordinary battery strength. Two plates in this condition must, as explained last week, give a current when connected by a wire, the positive current flowing along the wire from the peroxide coated plate—the + plate—to the spongy metallic — plate, and back through the liquid in the other direction; the spongy lead becoming gradually oxidised, and the peroxide reduced to some lower oxide, all the time the current lasts—*i.e.*, until the condition of the surfaces has become either temporararily or permanently the same. In order to bring the plates into the active condition they are first coated with oxide of lead, either electrically — by Plante — or mechanically — by Faure, which is then acted on by an electric current passed through the cell for some considerable time, the current being made to enter the liquid at the plate which is to be peroxidised, and to leave it at the plate which is to be reduced. Hence the former of these plates may be permanently labelled +; for when charging the cell the current enters at it, and when discharging the cell the current sets out from it. The other plate is similarly always —. There need, therefore, be no ambiguity about these terms. The + plate is always to be connected with the positive pole of the dynamo, whether the latter is supplying the current to the battery and charging it, or whether the dynamo is receiving the current from the battery and being driven by it.

Theory of Electro-chemical Decomposition.—It was stated last week that electricity was conducted through a liquid by means of two opposite processions of the constituent—dissociated—radicles of whatever substance in the liquid is undergoing decomposition, and that every such radicle possesses a certain definite charge of electricity which it carries with it and delivers up to the electrode, either when it is set free by combination with its fellows, or else when it is made to combine with something in metallic communication with the electrode. It was also stated that the charge of electricity possessed by a dissociated monad radicle is constant; and that diads have twice this charge, triads thrice, and so on. From these considerations it follows—as was proved by Faraday—that for a given weight of substance decomposed, a definite quantity of electricity is required; a quantity which will be known as soon as we know the number of atoms liberated, the electrical charge of each, and the weight of each. Let q be the dissociation charge of a free hydrogen or other monad atom or radicle. We do not know the value of q yet, we only know that it is perfectly definite and unchangeable. Let μ be the weight of any atom or compound radicle released from a combination in which it acted as a k-ad; in other words, let its active atomicity have been reduced by k, or let k be the number of bonds which have been broken in the act of making it a free radicle—whichever way of expressing it is preferred—then it is necessarily possessed of an electrical charge kq.

Let N be the number of such atoms delivered up to an electrode in any time, then in the same time a quantity of electricity $Q = N k q$ must have passed through the cell; and the weight of the substance liberated at the same time is $N \mu$—call this M. Then

$$\frac{M}{Q} = \frac{\mu}{k q}$$

Now, in the right-hand side of this equation k is the only thing we know; we only know the relative weight of different atoms, not the absolute weight of any. Let h be the absolute weight of a hydrogen atom, and m the number ordinarily known in chemistry as "atomic weight"—viz., the number which expresses the weight of any atom relatively to hydrogen, so that $\mu = m h$; then the above equation may be written

$$\frac{M}{Q} = \frac{m}{k} \cdot \frac{h}{q}$$

Now, though neither h nor q are yet known, their ration has been determined by careful measurement, and it is 1·9505 in C. G. S. units; in other words, the electrical charge of a free hydrogen atom is 9505 times its weight in grammes. And the charge of any other radicle of atomic weight m and with k free bonds is $\frac{9505\,k}{m}$ times its weight in grammes.

If the weight of the substance be expressed in pounds, and the quantity of electricity concerned in its liberation or decomposition in Ampere-hours—as for practical purposes is rather convenient—the above number 9505 becomes 12,020, or, with sufficient accuracy in ordinary cases, 12,000. So we will now repeat the above equation in an easy and practically useful form:—

$$\frac{\text{Weight of substance acted on in a single cell, in pounds}}{\text{Quantity of electricity passed through it, in Ampere-hours}} = \frac{\text{ordinary ``atomic weight'' of the substance}}{\text{12,000 times the number of bonds released per atom of the substance}}$$

Whether the "substance" is the constituent which is liberated at the positive or at the negative pole, or whether it is the original compound, which is not "liberated" at all but decomposed, matters nothing. The above statement is perfectly general and universally applicable. It applies also when it is recomposition that is going on instead of decomposition.

The expression "number of bonds released or joined per molecule" is not a happy one, but the phrase "change of valency" is no better, and the very simple meaning intended to be expressed is best conveyed by an example. Suppose $CuSO_4$ is being decomposed; two bonds are released when Cu separates from SO_4, hence

$$\frac{\text{Weight of sulphate of copper decomposed}}{\text{Quantity of electricity passing through it}} = \frac{63{\cdot}5 + 32 + 64}{24\ 000}$$

But we might equally well write—

$$\frac{\text{Weight of copper deposited}}{\text{Quantity of E required}} = \frac{63{\cdot}5}{24{,}000}$$

---

* From the *Engineer*.

Take as another example the decomposition of common dilute sulphuric acid, with copper electrodes, say,

$$\frac{\text{Weight of hydrogen set free}}{\text{Quantity of E passed through cell}} = \frac{1}{12,000}$$

$$\frac{\text{Weight of sulphuric acid decomposed}}{\text{Quantity of E}} = \frac{98}{24,000}$$

$$\frac{\text{Weight of sulphate of copper formed at the expense of the oxygen electrode}}{\text{Quantity of E}} = \frac{159\cdot5}{24,000}$$

Suppose nitrate of silver is the substance acted on. Here only one bond is released per molecule, so

$$\frac{\text{Weight of silver deposited}}{\text{Quantity of E}} = \frac{108}{12,000}$$

$$\frac{\text{Weight of nitrate of silver decomposed}}{\text{Quantity of electricity}} = \frac{170}{12,000}$$

Finally, suppose the substance acted on is Pb O, the protoxide of lead, then

$$\frac{\text{Weight of litharge oxidised to peroxide}}{\text{Quantity of E required}} = \frac{223}{24,000}$$

Weight of litharge reduced to metallic lead, the same.

Thus a current of one ampère is able to oxidise on one side of a Faure cell $\frac{223}{24,000}$ lb. of litharge per hour, provided there is no waste, nor any gas given off, and to reduce the same amount on the other side. Or, every pound of litharge on either side of a Faure cell requires 108 ampère-hours for its reduction and oxidation.

If, instead of one cell, a number *n* are taken and arranged in series, and the current sent through them all, the above action goes on in each cell, so of course the total decomposition will be *n* times as great.

SCREW-CUTTING BY EAST INDIAN NATIVES.[*]

ONE of the engineers of the great India and Peninsular Railroad in India, told me that he quitted work and loafed a month to watch the natives build some heavy press screws without machinery of any kind whatever. There were eight screws five inches in diameter, twelve feet long, threads about one and a half inch pitches. The natives worked out-doors in the sand; far away from anything suggestive of art or industry. They secured bars of native iron, excellent in quality, but neither round, straight, nor of uniform diameters along their length. They filed these bars bright and wrapped around them, spirally, a ribbon of some fibre, the space, &c., being regulated entirely by accurate native eyes. They then made mud-lined trenches which they filled with some kind of home-made acid. They soaked the screws over night in this acid, and in the morning had a well-developed corrosion in the way of a thread. They then neutralised the acid by bathing the screws in water, after which they stripped off the fibre and set to work with chisels and files and cut the threads to proper depth. Here were screws, but they were not round, nor of uniform pitch, nor with uniform thickness and depth of thread. They then made a mould in the earth and stood a screw upright in it for a core. A long nut of native brass was then cast upon the screw. The nut was then worked loose, and the screw chipped at and filed at till the nut would run from end to end. This was one step towards uniform accuracy. The nut was then melted and cast again upon the screw. The screw was re-dressed till this nut run all right. This kind of business was kept up till about twenty nuts had been used for each screw. My friend said that the final work was as perfect a job of nut-and-screw fitting as he ever saw in his life. There was no perceptible difference to be felt in running a nut from end to end on a screw.

It is not uncommon in our Southern States to see old sugar-cane presses built entirely of wood, with a wooden screw about five feet long, 14 inches in diameter, and with a thread, as near as I can remember now, about three inches wide, which would be six inches pitch.

The nut is formed in two immense wooden blocks firmly keyed together. These screws and nuts are cut out with a mortising chisel, mallet and saw. The work is all accurately marked off geometrically, before the cutting is commenced. Many of the southern millwrights particularly pride themselves on their ability to lay off these nuts and screws. The student in mechanical drawing who has advanced to the projection of a section of threaded nuts, would probably find himself stumped if he attempted to put his knowledge into practice by laying off the lines in the hollow cylindrical surface of a half nut.

Few lathesmen ever lose faith in the accuracy of the lead screw of a lathe. If they will take a walk along the length of a lathe they will be able to see the difference between one part and another. The actual number of threads to the inch make but little difference because they can do whatever they wish to do with the aid of the change gears. But it is very important to know that the number of threads to the inch is regular throughout the length of the screw. A ten-thread screw should have a hundred threads in ten inches; but measure one and see about it. One inch will be found to have ten threads; the next, ten and one-hundredth, perhaps; the next some other trifling variation; and so on throughout the length. Not only will every inch vary from the other inches, but one thread is likely to be a different pitch from the thread right along side of it. It will be at once seen that the screws made by the natives in India were probably much more accurate than they would have been, if they had been cut in a lathe with the lead screw in the ordinary condition.

Lathe makers throughout the world follow the plan of cutting their lead screws from a master screw, procured from the shop of Sir Joseph Whitworth & Co., in Manchester, England. Whitworth early discovered that screws were not accurate enough, even for ordinary shop-work, and at once commenced to produce a reasonable standard. As near as I can understand the matter, Whitworth's work stood unquestioned just so long as it stood untested. Every one who has gone into any class of work which was to be based on the accuracy of a screw, such as measuring machines, graduating machines, &c., &c., has quickly found that the best screw to be had was a Whitworth screw, and that a Whitworth screw was not good enough for the work. These parties have generally contented themselves by using a Whitworth screw in connection with a device for correcting the errors discovered. Some of them have gone into the matter of constructing an original screw, by methods which will in themselves insure the accuracy of the work. I understand that The Pratt and Whitney Company, in the construction of their gauges, have determined to go to the bottom of the thing, and that they are now in the midst of a laborious research after an accurate inch and a screw of uniform pitch.

One of the Whitworth devices to overcome errors was as follows: He cut ten screws a foot in length, taking great care in the operation to use the same part of his lathe screw all the time. When these short screws were done, they were, of course, copies of a single foot of his old lathe screw. They had the errors of that foot, but had not the errors of any other foot. He then bored a hole through these screws and faced them accurately to a length, testing them in his measuring machine which measured to the millionth part of an inch. He then strung them on a bolt and thus made a long screw of them, of which every foot was bound to be the same. There might be twelve different kinds of inches in each foot, but the feet were uniform. He then made a nut of great length, so that it could not be said to be governed by any one particular inch of a foot, and thus became operated on by at least two of the sections at once. With this built-up screw he cut a long screw, and it looked as if he had certainly eliminated all sources of errors. But still the first close tests made of them showed that no one thread was like any other thread, and that no one thread maintained a uniformity of spiral during its complete, single convolution.

[*] Extracted from a paper by "CHORDAL," in *American Machinist.*

EFFECT OF HEAT ON A BATTERY.

AMONG sundry recent attempts to improve the galvanic battery, we note one by an Italian engineer, Signor Gaudini, who describes in *Natura* the results of experiments in heating batteries. He considers that this application of heat is of much interest, both from a theoretical and a practical point of view.

Of the various types of batteries tried, that which yielded the best results was as follows:—A cast-iron vessel containing a porous vessel of terra-cotta, surrounded by a hollow cylinder of zinc, which acted as the positive electrode. A prism of carbon within the porous pot served as negative electrode. The exciting liquid was a solution of chloride of sodium, and the depolariser a supersaturated solution of bichromate of potash and sulphuric acid.

In the cold state, this couple gives an intense but inconstant current. When placed, however, on a small gas-heater, its current increases considerably in intensity, and continues constant, with closed circuit, as long as desired if properly managed. The flame should be regulated so as to keep the temperature of the various parts at about 100° C.; and one should add, from time to time, to the porous vessel a few crystals of potassic bichromate, with sulphuric acid, and to the outer vessel some salt water.

With such care the battery will furnish a current much more intense than that produced in the cold state. The increase of intensity arises from a diminution of the internal resistance, and a notable increase of the electromotive force, as will be seen from the following:—

	E	R
Battery used cold	2·10	0·82
„ „ hot	2·44	0·71

Here the values of E are expressed in Volt units equal to 100 millions, or to 10^8 absolute units of electromotive force, corresponding nearly to that of a Daniell element; and the values of R are expressed in ohm units equal to a billion, or 10^9 absolute units of resistance, nearly corresponding to that of a column of mercury at 0°, one metre long and 1 sq. mm. in section.

The fact of diminution of the internal resistance is in perfect harmony with known properties relative to conductivity of liquids, and need not cause any surprise. The increase of electromotive force deserves more consideration: it may, perhaps, be explained by supposing that the heat promotes the chemical action, and the osmotic current through the porous diaphragm. As to the constancy of the current, it is certainly a consequence of the lessened polarisation of the electrodes; because, with increase of temperature, the development of gaseous bubbles is facilitated.

In fine, the advantages claimed for this heated battery are as follows:—

1. A great and constant electromotive force.
2. A small and invariable resistance.
3. No noxious emanations.
4. Easy composition, always presenting the same conditions.
5. Facility of adding new materials.
6. Cost comparatively slight, since the unproductive consumption being small, the saving in that part quite compensates the greater expense of heating.
7. Lastly, a battery of six elements, formed each of an iron vessel about 6in. high, and 3½in. diameter, with all the rest in proportion, may cost about sixty lire (say, £2 5s.), and, used with heat, will give a current comparable to the maximum obtainable from a Paciuotti dynamo-electric machine, modified by Gramme, which, with supports, will cost about 900 lire (say, £40). It may be added that this battery in the cold state will give a ready current of brief duration, as it remains a long time unaltered with open circuit.

UTILISING THE MOTIONS OF THE SEA.

SEVERAL methods of utilising tidal motion and the action of sea-waves for obtaining a store of motive-power have been proposed, and some of them have been patented, but have not at present been brought into use, the expense of erecting the necessary works being probably out of all proportion to the power to be gained. In *La Nature*, a method of utilising wave-motion is described as the invention of M. V. Gauchez, who would suspend a large float by ropes from a pulley outside of a stone inclosure built a short way from the beach. Within the inclosure is a bell-shaped iron vessel, suspended from a central-pulley system, connected with the float pulley. This moves up and down in correspondence with the float, on a block of masonry, which has passages communicating with the air-space above and with a pipe below, extending to a reservoir on shore. The bell, in rising, sucks in air through valves in its upper surface, and, in falling, forces the air along the passages to the reservoir. The ropes are kept always taut by means of a weight hung in air from a pulley connected with the central system, and the bell has at its lower part a caoutchouc membrane connected with the block of masonry. M. Gauchez specifies the dimensions which, he thinks, would insure a rapid flow into the reservoir and involve no excessive heating. Another scheme, by Prof. Wellner, of Brünn, is described in *Dingler's Journal.* Fixed along a sea wall is a sort of air-trap—a metallic case, open below, now in air, now in water, as the waves beat on it. At the top this communicates through valves and pipes with a reservoir, in which the air is compressed, and the force thus supplied may be directly utilised for some purposes. Prof. Wellner brings a pipe from the reservoir to the lower part of an air-wheel, which is like an overshot water-wheel, immersed in water. The air displaces the water from the cells, and drives the wheel round, while expanding and rising to the surface. The system works with different degrees of compression, if the air-conducting tube be provided with several valves, so that the air may be admitted to the wheel at different depths, according to the pressure. With small waves and compression it is admitted higher. This arraratus Prof. Wellner proposes to use for supplying cooled air to beer-cellars, larders, &c., in hot climates.

SCIENTIFIC NEWS.

BY the end of this week comet Wells will cease to be above the horizon at night, and it is now considered to be scarcely bright enough to be seen during the day, even when it reaches its brightest. The position on June 10, according to Dr. Oppenheim's ephemeris, will be R.A. 5h. 6m. 37s., N. Dec. 21° 38·7′, Berlin midnight. After that date we may possibly hear of some good observations being made in the southern hemisphere.

According to the *Dun Echt Circular*, No. 52, the spectrum of the nucleus of Comet Wells deserves the closest attention, as it shows a sharp, bright line coincident with D, as well as strong traces of other bright lines, resembling in appearance these seen in the spectra of γ Cassiopeiæ and allied stars.

Mr. O. Stone has published, in the sixth number of the publications of the Cincinnati Observatory, the results of a series of micrometrical measurements of 455 double stars made with the 11in. refractor. The stars selected are in two classes—those which are to form part of a general catalogue of double stars between the equator and 30° S. Dec., and those in either hemisphere which Mr. Burnham noted as requiring further observation.

On June 1 Mr. Clement L. Wragge expected to have all his apparatus in working order, and to renew his observations at Ben Nevis and Fort William. A new fixed station is being established near the Lake at an elevation of more than 1,800ft. above the sea, and Mr. Wragge will make observations during the ascent and descent by means of travelling instruments, so as to localise disturbances in the atmosphere between the summit and Fort William. On the summit itself he will make five observations at intervals of half an hour between 9 and 11 a.m. Self-recording instruments will take the temperature at 9 p.m., and the apparatus supplied by Dr. Angus Smith will measure the actinism of the sun's rays and of daylight. Mr. Browning has also sent a rain-band spectroscope.

Lord Rayleigh, professor of experimental physics, at Cambridge, has been awarded the Hopkins Prize for his papers connected with the theory of vibrations, and especially for that on the theory of resonance.

The 49th annual report of the Royal Cornwall Polytechnic Society, as usual, contains some interesting papers, with notes on new inventions, and the meteorological tables. This society does a large amount of good, and we are pleased to see that it is progressing in every way satisfactorily.

Mr. Stretton has issued a third edition of his brochure on Railway Accidents, which can be had of Simpkin, Marshall, and Co., or of Messrs. Spencer, Leicester. There are four plates—viz., a diagram showing the arrangement of Sykes's electrical signal apparatus, the diagram for calculating the efficiency of brakes, and two plates showing the details and general arrangement of the Westinghouse automatic brake. The text has been revised, and several additional paragraphs inserted.

The 68th annual report of the Council of the Royal Geological Society of Cornwall contains the president's address, the reports of the officers, and several useful papers. The accounts show that the financial condition of the society is satisfactory.

The society of Telegraph Engineers and Electricians have appointed a committee to report upon the fire-risks of the electric light. The committee consists of Professor W. G. Adams, Sir C. T. Bright, Messrs. R. Crampton, R. E. Crompton, W. Crookes, Warren De La Rue, Professors G. C. Foster and D. E. Hughes; Messrs. E. Graves, W. H. Preece, Alexander Siemens, Spagnoletti, A. Stroh, and Sir William Thomson.

A peculiar effect upon workers in a bichromate of potash factory in Russia has been noted: a hole being made in the septum of the nose, the partition after a time disappearing entirely. Some of the men have been employed for ten years without being affected, while others are attacked in the first month; but that the disease is somewhat more than an individual peculiarity is evident from the fact that an inspection of all the hands proved that more than 50 per cent. of the men had diseased noses. The early symptoms are a slight tickling of the part affected, followed by bleeding, but with no uncomfortable feelings, and, in fact, the destructive process is painless.

Mr. J. L. E. Dreyer has been appointed successor to the late Dr. T. R. Robinson as director of the Armagh Observatory.

The ultimate effects of a *régime* in which small doses of arsenic are given from time to time are in striking contrast with the earlier ones. According to MM. de Poncy and Livon, cats so treated seem improved at first; they eat more, and fatten, and have all the signs of very good health. But by-and-by they begin to grow lean, are subject to diarrhœa, loose appetite, and seem languid; and at length they die in a state of poverty of blood (anæmia) and leanness. On examination, one finds the muscles (the heart included), extremely pale; the liver, lungs, kidneys, and mesenteric ganglions all have the characters of fatty degeneration.

A valuable report by a French Government Commission, on the rupture of cables in mines, appears in a recent number of the *Annales des Mines*. Among other points, we note the affirmation that metallic cables, both steel and iron, may be used with as much security as cables of textile material, proper care being taken in providing and maintaining them (and more is needed). In very moist pits, especially with acid water, aloe cables are preferable; in pits, with return of air, and somewhat high temperature, metallic cables. Where flat cables are used, the textile allow of better equilibrating the motion of the engine than the metallic. Round metallic cables are more easy to make well than flat ones, and with conical or spiraloid drums, admit of regulating the engine's motion very conveniently. (French managers, it is stated, do not, in ordering cables, specify details and conditions of working sufficiently.) The resistance to rupture of hempen or aloe cables varies largely with choice of material and mode of manufacture, and careful experiments should be made with the yarn or cable (the cable should not contain more than 20 per cent. of tar). The wires of a metallic cable should likewise be tested, both for flexure and torsion. Marks of fatigue of a cable generally appear outside; but with metallic cables, long used, it is well to make direct experiments on isolated wires, or on the ends. The importance of diameters of winding being as large as possible is greater for metallic than for textile cables, and for steel than for iron cables. The minimum diameter for iron cables should be 1,300 to 1,400 times that of the wire, and 2,000 for steel. It should be 80 to 100 times that of the cable diameter in metallic cables, and 50 times in textile. Thick metallic cables should not be worked beyond a tenth of the force required to break them; small round cables a sixth; good aloe cables a seventh, or an eighth. Cutting off the ends of a cable (too much neglected in France) should be done every two or three months. Once a week, at least, a cable should be passed for examination slowly up and down before the eyes of a competent agent. (Directions as to conveyance of personnel and various other topics are also given by the Commission.)

Mellogen, the new substance obtained by Signors Bartogli and Papasogli in their recent remarkable experiments of electrolysing distilled water about six weeks—first with strong, then with weaker batteries, and carbon electrodes—is a solid, dark, very shiny matter, soluble in hot water and in alkalies, insoluble in most mineral acids, and in ordinary solvents such as alcohols or benzine. It does not fuse, is not crystallisable, burns difficultly, and has strong colouring power. Its most salient property is its combining easily with oxygen, and giving rise to acids of the benzocarbonic series. The best oxidant is hypochlorite of soda. The formula of mellogen is $C_{11}H_2O_4$. If alkaline solutions be used as electrolytes in place of distilled water, mellic acid and its congeners are largely formed, but very little mellogen; on the other hand, with an acid electrolyte, the mellogen is abundant, and the former products are almost wholly wanting.

A new aperiodic galvanometer, described lately to the Paris Academy by MM. Deprez and D'Arsonval, consists of a rectangular frame with fine wire wound round it, supported between the two branches of a horseshoe magnet, placed vertically. The support consists of two silver or copper wires; one above, with mirror, proceeding to the end of a bent stand, having two movements by which the frame can be either displaced vertically or turned round; the other connecting the frame with an elastic strip below. These wires serve both as an axis to the frame, and in conveyance of the current. Within the frame an iron tube is supported, to intensify the magnetic field. The instrument is very sensitive, distinctly indicating a current, *e.g.*, whose intensity is a ten-thousandth of an ampere.

With regard to the operation of the will on the muscles of the eyes, Helmholtz says we are limited to efforts for the attainment of single and distinct vision. Mr. Le Conte Stevens (New York), finds this incorrect. Though never troubled with involuntary double vision (through paralysis or other weakness), he is able at any time to converge or diverge the visual lines without using any external points of fixation, thus securing two separate images of a given object (*e.g.*, a door-knob), keeping these apparently separated at any desired angle within certain limits, and fixing the attention alternately on either image, separately, at pleasure. This power was not suspected till revealed by special experiment; but there is no reason to suppose it is not possessed by most others whose eyes are healthy.

A blowpipe has been patented in Germany by Schlag and Berend, of Berlin, in which the air blown into the mouthpiece passes through a valve into a caoutchouc bag, which is inclosed in the tube, and serves as regulator of the issuing air, in the case of intermittent blowing. (The valve prevents return of the air forced in.)

A Brazilian exhibition is being organised in Berlin for October to December this year, by the Central Society of Commercial Geography. Prominence will be given to the raw materials which Germany does not, or not sufficiently, produce, and for which Brazil is so eminently adapted, *e.g.*, ores, cotton, coffee, cocoa, tobacco, hides, silks, tanning materials Opportunity will be given German merchants of finding how their share in importation from Brazil may be advantageously increased. By means of books, maps, pictures, models, photographs, &c., a full representation of the country and its population will be aimed at. In Antwerp, an international exhibition of all objects connected with gymnastics takes places in August.

La Lumière Electrique gives illustrations of three small pieces of apparatus lately exhibited in Belgium. The first is a telegraphic sounder in which, by way of strengthening the sound, the armature, is terminated by a small hammer which strikes on a brass drum. Next a harmonica, devised by M. Somzée, for indicating the presence of fire-damp, consists of a flame burning in a glass chimney, the draught being so regulated that the flame is silent in pure air, but begins to sing when a certain proportion of fire-damp is present The third apparatus, also by M. Somzée, is an electric regulator, in which inclined passages conduct fine carbon power into the arc, increasing the number of solid particles raised to incandescence (an idea M. du Moncel does not think practical.)

In the neighbourhood of Rheims, recently, M. De Lemoinne found sufficient remains of a remarkable bird (of new species), belonging to the Eocene epoch, to give a fair idea of its structure. A thigh bone of the same animal had before been discovered by M. Planté, the well-known physicist, at Meudon; it was about 18in. long. The bird was of gigantic size, having a height, when erect, of at least 10ft. The skull was comparatively large, and less disproportionate than that of the ostrich. In the opinion of M. Alph. Milne-Edwards, judging by the skeleton, the bird had affinities to the duck, but it has peculiarities which forbid the ranking of it in any of the present natural groups. It has been called *Gastornis Edwardsii*. (Various anatomical details, with a representation of the skeleton, are given by M. Meunier in *La Nature*, 466.)

The revival of industry in Italy is witnessed in various ways at present. According to *Les Mondes*, Baron Cantoni, impressed with the fact of Indian cotton going past Italy to England to be spun and returned as thread, has formed in Venice a cotton spinning company under the name of "Cotonificio Veneziano," with a capital of ten million francs. The first factory has been built, and will receive 80,000 spindles. At Venice, too, a company for river-navigation has been formed. By means of barges, towed by steam-power, to Cavanella, Pavia, and Magadino, it will transport merchandise to the foot of the Gothard, saving a third of the cost of railway-carriage from Genoa. Lately, for the first time, railway-carriages of national make were exhibited at Milan; but the axles and wheels, it was stated, came from France. The last financial statement in the Chambers, by Signor Magliani, showed that the floating debt had diminished about 100 million francs in three years; that the exportation and importation balanced each other for the first time, and that the receipt of imposts exceeded the ordinary expenditure by 49 million francs.

The early French beans in Algeria have been extensively affected this year by a disease unknown before, at least in these crops. It attacks stems, branches, leaf-stalks, and fruits; which acquire a white covering, in some parts like tufts of wadding; this being the mycelium of a parasite fungus, which also deeply invades the bark, and sometimes penetrates to the pith. M. Prillieux finds some evidence that the same disease attacks other plants of very different nature—as clover and hemp.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent-garden, W.C.*

All Cheques and Post-office Orders to be made Payable to J. PASSMORE EDWARDS.

⁂ *In order to facilitate reference, Correspondents, when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."

ABERRATION AND PARALLAX—COMET α 1882 (WELLS)—SPHERICAL ABERRATION—RELATIVE MOTIONS OF THE EARTH AND MOON—POINTS OF SUNRISE ON THE LONGEST AND SHORTEST DAYS.

[20088.]—I WAS rather interested in your précis on p. 234, of the paper read by Mr. Downing at the Royal Astronomical Society on the 12th, on his discussion of the observations of γ Draconis made with the Reflex Zenith Tube at Greenwich. That the parallax should be a minus quantity, in other words that measurement should show that this star is farther than infinitely far off (!) does introduce an element of uncertainty which somewhat vitiates the result; but, at the same time, they cannot fail to possess value for the physical astronomer. As is known to a large number of those who will read these lines, the Constant of Aberration, as determined by Struve, = 20·4451″. Combining this with Michelsen's beautiful determination of the velocity of light, we obtain a solar parallax of 8·810″; while employing Michelsen's light-velocity with Downing's Constant of Aberration, the solar parallax rises to 8·838″. Inasmuch as recent researches (with the exception of the Ascension Observations of Mars) all point in the direction of the larger parallax; this, pro tanto, would afford an argument for the superior correctness of Mr. Downing's results.

The drawing of Comet Wells, given by Mr. Mills in his letter (20037) on p. 237, certainly seems to me curiously to exaggerate the visible breadth of the Coma in proportion to its length. In saying this, however, I so far speak under correction that I have had no experience of the aspect of this body as viewed in a 12¼in. reflector. But as seen in a smaller instrument, the tail is both longer and straighter than it appears to be in the engraving. It does travel very quickly. The rapidity of its motion must strike the least practised observer. By the bye, it is by no means increasing in brilliancy in the predicted ratio.

"E. P" (query 46955, p. 249) heads his question "Elementary Optics," the fact being that the destruction of spherical aberration in an achromatic object-glass is a difficult problem in analytical optics, quite incapable of explanation within the limits of such a paragraph as this. Spherical aberration is quite curable. For some practical details "E. P." may consult the *Philosophical Transactions* for 1821.

A few elementary considerations may suffice to remove the difficulties which beset "Gimel" (query 46963, p. 249). The first passage in Sir Edmund Beckett's masterly book which has puzzled your correspondent has reference not to the earth as a whole, but to any given point on it. A figure will make this clear at once. Here we see the earth describing her orbit round the sun in the direction indicated by the big arrow; while she rotates at the same time on her own axis, as pointed out by the smaller ones. Does not "Gimel" see that any place, say, at *a*, on the night side of the earth, is travelling in precisely the same direction as the earth herself; whereas when her rotation brings that point into daylight, say at *a′*, it is, as it were, moving backwards with reference to the direction of the earth's orbital movement? The second stumbling-block which "Gimel" has met with may be surmounted quite as easily. If he will fasten two unequal weights to the end of a stick and whirl it up into the air, he will note that the centre of motion approaches the heavier weight in proportion as it is heavier. Now, in our figure, E represents the earth and M the moon, and as it must be abundantly evident that the common centre of gravity of the system cannot coincide with *e*, the earth's centre, let it be at *c*; then will your querist see that it is round *c*, and not *e* at all, that the moon must revolve, and that as she must, so to speak, always carry the line joining her centre and that of the earth, with her, the earth's centre must describe the little orbit *o o* round *c*; and this is what Sir Edmund Beckett means. If "Gimel" will rigidly connect a card earth and moon by a wire, and pinning his card earth near its periphery down to a board, cause the moon to describe a circle round the pin as a centre; he will note at once how the earth, ex-necessitate, describes a little orbit round it, and hence, in a sense, round the moon, too.

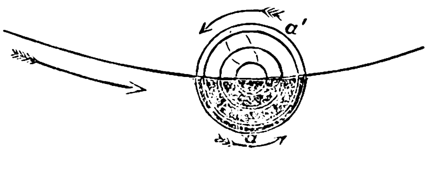

FIG. 2.

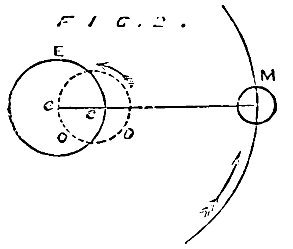


From what "Neo" says in query 47032 (p. 272), it is evident that it was *not* Stonehenge to which his original question (46888) referred. I only wish to say here that if your correspondent should not be familiar with trigonometrical computation, and will tell me whereabouts his "circle of large stones, now buried and planted with trees," is situated, I will give him the point of the horizon at which the sun rises on the longest day in that locality, as also the approximate variation of the magnetic needle; so that, armed with a common pocket-compass, he can stand in the middle of the stone circle and see whether a line passing through it and the monolith is, or is not, in the direction of the point of sunrise at the Solstice.

A Fellow of the Royal Astronomical Society.

ONE MORE PUFF—NEWSPAPER SCIENCE—WELLS' COMET—VISIBILITY OF NEBULÆ—ASTRONOMICAL EYEPIECES—MICROSCOPE POWER.

[20089.]—THE political newspapers are always ahead in matters of science, telling us what we could have known in no other way. The *Leeds Mercury* says: "We may fairly expect that the heroes of the next meeting of the British Association will be Mr. Lockyer and his colleagues of the eclipse expedition. There seems every reason to anticipate that they will be able before long to make known very important and interesting conclusions with regard to the nature of the sun and his marvellous appendages." (N.B.—Blessed is he that expecteth nothing, &c.)

To us readers, thinkers and workers in astronomy, the words "important conclusions," "successful results," and others of the *Leeds Mercury*, have a familiar kind of ring which we understand perfectly. Of course, there is no reference to Mr. Ranyard; but, considering the origin of the inspiration, we could not "fairly expect" that. My excuse for wasting so much valuable space with the above quotation, must be that if it is not noticed in some such journal as this, it would be allowed to pass, and if we care anything for astronomy, or for truth, we ought to show up these things.

What can "F.R.A.S." mean where he says (letter 20035, p. 236), speaking of the comet,—"It will not become a daylight object until it has passed too far to the south to be visible in the British Islands at all" [at night?] Did he intend to add the words I have placed in brackets? Or will the declination of the comet be more than 45° S. during the first half of June?

It is certainly true, as "Mizar" says (query 46279, p. 626), that a greater quantity of light is gathered up by a large object-glass or mirror than by the unaided eye; but (in the case of nebulæ) if the sky is not perfectly dark, it also is made correspondingly brighter. A nebulosity of appreciable extent ought to be more easily visible to the naked eye; but as a large telescope gathers more light than a small one, and there is nearly the same proportion of light lost in each, a large one should show more. There are, however, some curious anomalies in the visibility of nebulæ.

Stopping out bright stars to prevent their glare interfering with faint nebulæ only mitigates the evil, some of which is done in the telescope, by reflection from the glass surfaces before the rays reach the eye. A low power acts as a stop, because the eye is not large enough to take in rays from all parts of the object-glass or mirror. By the way, Mr. Mattieu Williams' remark, on p. 467 of last Vol., just after Mr. Ranyard referred to a common hand telescope, is too irrelevant to be of any value.

"Aldebaran's" letter (20069, p. 289), tends to show, what I have not hitherto seen, where his fundamental misconception lies. The replies he has given to query 46396, have made it abundantly clear that he has made some central mistake, vitiating all his results, but he gave us no hint of its nature. Now we have it. "Aldebaran" says: "In all telescopes there are two sets of rays to be dealt with. 1st. The cone of direct rays from the object-glass, which is the only one represented in text-book diagrams. 2nd. The rays diverging from the image, and which alone can be utilised for vision." Apologising again for a long quotation, I would ask "Aldebaran" how the 2nd set of rays got into the telescope at all, if they are not part of the "cone from the o.g."? In the next paragraph he tells us that the position of the apex of the cone of rays, relatively to the e.p., is "not of the slightest importance." Why, "Aldebaran" does not even know what "focus" means; he has not learnt that "focus" is equivalent to "apex of cone," and that the image is formed there. And yet he wants me to go and hunt up a tutor to explain to me matters which I am accustomed to teach, and which any first-stage science student (in optics) would regard as simple. Can "Aldebaran" say where Mr. Proctor says the determination of ray-paths is difficult? Does it astonish "Aldebaran" to learn that there is but one set of rays in a telescope; just those that come down from the o.g., and neither more nor less?

Just remarking (in connection with letter 20074, p. 261) that a 1½in. does not magnify nearly 7·5, $l = 12$, I would say that it would be quite as correct to divide by 15 as by 7·5, near the end of paragraph 2. The o.g. magnifies (assumed) 6·8, and o.g. and e.p. magnify 34; therefore the e.p. magnifies 34 / 6·8 = 5 times. The amplification the o.g. gives on 12in. has no more connection with it than its amplification on 24in., because neither of these lengths is being used.

Paugul.

COMET-SEEKING.

[20090.]—THE announcement that "Mr. H. H. Warner, of Rochester, New York, has offered a prize of two hundred dollars for each discovery of a new comet made in North America or the United Kingdom" will, it is hoped, prove an incentive to observers for increased diligence in this department. It is true that amateurs have no mercenary motives whatever in astronomical work, but indulge in it because it is congenial to their tastes, and productive of more genuine pleasure than is afforded by any other line of research. To them it is a "labour of love," and a source of continued and varied gratification. But Mr. Warner's munificence will none the less be appreciated by them as a practical encouragement to an original branch of observation which, certainly in this country, has been languishing only too long.

As to the systematic search for comets, which I referred to in the English Mechanic, No. 888 (19859), several additional observers have lately volunteered assistance, and I trust that arrangements will soon be made to insure the complete and rigorous examination of the most promising regions of the sky at short intervals. My own share in the work has been necessarily very limited during the past few months, owing to ill-health; but I now trust that the direction and better organisation of the observers will emanate from Lord Crawford's observatory at Dun Echt, where so much effective aid has already been given to cometary astronomy. It would be a matter for congratulation should Lord Crawford decide to take in hand the further organisation of comet-seeking in this country, where so much observing strength is capable of being utilised to this end.

Bristol, May 29. **W. F. Denning.**

QUADRANT OF ALTITUDE.

[20091.]—A short time ago, in working some problems upon the celestial globe with the quadrant of altitude, the idea struck me that if a more flexible substance than brass could be used, a greater facility in working would be obtained. As I determined upon a method by means of which I was enabled to make a quadrant of altitude, combining in itself a minimum of cost and a maximum of facility, I now venture to submit the idea to the appreciation or condemnation of your readers. In the first place, a slip of stout drawing-paper was procured, about $\frac{5}{8}$ of an inch in breadth.

This was laid along the equinoctial line from 0 to 90°. Next, it was divided into spaces, which corresponded to 10° each; then these spaces were divided again into 5°, afterwards into 1°, and the ultimate process of division was that each 1° was divided into thirds or spaces of 20′ each.

After this somewhat tedious operation was completed, the paper was pinned on the drawing-board, and all the divisions carefully ruled.

The next desideratum was to give the paper a coat of white varnish (as this prevented its being easily torn) and the whole was finished.

I am in perfect ignorance as to whether the idea is original or otherwise; but, certainly, it claims a position in the scale of economy.

Referring to the list, I find that the price of quadrants of altitude for 20in. globes (which is the size mine was made for), is 6s. 6d. each. The one which I made cost nothing but simply one hour's time. **A. Manock.**

High-street, Doncaster, May 27th.

WENHAM'S NEW MICROSCOPE.

[20092.]—The statement is reiterated by "Another F.R.M.S." that I was led to devise my new microscope in consequence of some remarks by Dr. Edmunds on Wale's microscope, published in the *Journal* of the R. M. S. in Dec., 1880.

I trust that this allegation will fall to the ground when I state positively that my microscope was designed before the date of Dr. Edmunds' remarks.

As to the modification proposed in Wale's microscope on 10th November, 1880, by Dr. Edmunds, I can corroborate your correspondent, "Akakia," that I worked at that idea, as he states, some two years before, and gave it up as impracticable. I agree also with this correspondent that "no single individual" has any right to claim the *principle* of radial illumination as centralised on the object and I have been careful to avoid any such claim in my patent, confining myself simply to a particular method of carrying out the *principle*.

The delay in registering the patent is easily explained: Messrs. Ross preferred that a patent should not be applied for until the microscope could be submitted to the test of practical work, and two or more of these instruments were actually completed before the specification was filed at the Patent Office.

This is all that I need say concerning the claim set up for Dr. Edmunds, and it must suffice that I entirely repudiate the statement that I have appropriated his non-practical suggestion.

F. H. Wenham.

[20093.]—In your current number I see a further letter (No. 20071) from "Another F.R.M.S.," to which I am compelled to ask space for a few words in reply.

Passing over the attempt of your correspondent to distort the meaning of certain words which he finds in the description of my microscope into something which they were never meant to convey, their intended signification being perfectly plain, and I may add perfectly true. I find the sum and substance of his letter to be simply a reiteration of the charge previously made against me—viz., that I had stolen (there is no other word for it) the principle of construction embodied in my new microscope from Dr. Edmunds.

In the endeavour to make good this charge (which of course is well known by all having any cognisance of the matter to be without the slightest foundation), he tells a very circumstantial story of my being present in person at the eventful meeting of the Royal Microscopical Society on Nov. 10, 1880. That I sat by and heard Dr. Edmunds make the great "enunciation"; that my silence on the occasion goes to prove that I could question neither its value nor originality; and further, that I stood by and listened with interest to the instructions which Dr. Edmunds was giving to Mr. Swift to enable him to carry out the great principle of construction then for the first time "enunciated."

Your readers, too, will be able to appraise at its full value not only this claim of Dr. Edmunds, but also the character of the means taken to uphold it, when I say that there is not one word of truth in this story. It is from beginning to end a—well—pure fabrication.

So far from being present at that meeting, I was not even in London, but some two hundred miles away in my quiet home in Lancashire, totally unconscious of the great "enunciation" which at that moment Dr. Edmunds was—*pro bono publico*—giving forth to the world. **John M. Moss.**

[20094.]—I must ask permission to say a few words upon the new stands patented by Mr. Moss and Mr. Wenham.

1. On Nov. 10, 1880, at the Royal Microscopical Society, I fully explained the principle of a concentric microscope, which I had been constructing, and I pointed out the applicability of that principle to the Wale stand for rough purposes.

2. Mr. Swift informs me that Mr. Moss stood by after the meeting, listening to further explanations which, at Mr. Swift's request, I then gave; but I am not able, of my own knowledge, to endorse the statement that Mr. Moss was one of these gentlemen, as I have not the advantage of knowing him.

3. The principle of my concentric microscope was in no way suggested to me by the sight of Mr. Wale's stand, and it was entirely new so far as I am acquainted with microscopical literature. My concentric microscope was completely planned and in hand during the year 1878, and on Dec. 15, 1878, I made a communication to that effect to Mr. Frank Crisp, the honorary secretary of the Royal Microscopical Society—a communication in accordance with the remarks which at the moment I rose and made at the Microscopical Society nearly two years later. Mr. Crisp has given me permission to say that he was then (Dec., 1878) perfectly aware of the object that my new stand had in view, and that he will state as much if requisite.

4. I have nothing to do with any abortive diagrams which Mr. Wale or Mr. Wenham may have made upon a drawing-board years before. There is no suggestion that I could have known anything of such sketches or drawings, and they are now suggested only on the faith of anonymous writers. Such rights of priority are decided by well-known law—*i.e.*, that of priority in publication in a scientific journal, or in communication to a learned society in public meeting assembled. Under this law my position is unassailable; the dates of the patents of Mr. Moss and Mr. Wenham follow directly upon my publication of the principle, and their specifications were mere attempts to expropriate my principle by monopolising various mechanical contrivances for applying it. On those contrivances I do not comment; what I claim is to have originated and published the general principle of "the Concentric Microscope," a microscope concentred round the intersection of the two axes of reference which I specified and evolved by means of a purely geometrical conception in which the optic axis is regarded as the polar axis; the optic plane as a meridian plane; the stage plane as the equatorial plane; and the centres of the object and the lamp plane as two points in the plane of an ecliptic. On the other hand, the principle of my microscope is not deducible from that of the telescope to which Mr. Wenham now refers back as having suggested it to him. The fact that an experimenter twenty years ago stuck a hemispherical lens over a diatom by means of balsam, and saw it very clearly, does not make him the inventor of the principle on which our homogeneous immersion lenses are constructed, simply because he had neither the mathematical knowledge nor the brains which were needed in order to perceive the principle of what he saw. Just so, random diagrams, such as those now furtively suggested, would not give a title to having anticipated this important principle, and it is repugnant to common sense to ask us to believe that astute commercial men like Mr. Wale, Mr. Moss, and Mr. Wenham, if they had really conceived this principle and realised its far-reaching consequences, would have let it sleep for years, and then, directly upon my publishing it, that Mr. Moss and Mr. Wenham should run against each other at the Patent Office in their attempts to appropriate it.

5. The statements made by Mr. Wenham, and repeated and amplified by "Akakia," as to my having "deliberately undertaken an alteration of Wale's microscope" and failed, are absolutely without foundation. I did nothing but give to Mr. Swift the permission for which he asked with regard to his students' microscopes, and his not going fully on with the matter was due, I understand, to his discovering that Mr. Moss and Mr. Wenham had forestalled him by lodging specifications for patents on the subject. Having in my own study seven stands, including a large Powell and Lealand stand, with every accessory made by them for me, I was little in need of another stand, and having no sort of commercial object to serve, it is not wonderful that, with my engagements, the completion of a stand with my own hands has been delayed. But I shall shortly hope to have the privilege of submitting my "concentric microscope" to the Fellows of the Royal Microscopical Society, and to their judgment I now leave this question. **James Edmunds, M.D.**

WHAT SHALL I DO WITH THE MICROSCOPE?

[20095.]—This question has been often asked and often answered; but, as I wish to suggest a subject not previously mentioned, perhaps the Editor will courteously insert the following: it is on the intestinal teeth of insects, and as it can be worked out with simple means, and an object-glass of 1in. focus, I hope it will prove of interest to many beside myself:—

The directions given to me were, to pull off the head of a cricket, drag with it the stomach, and attached to it the gizzard or organ containing the pyloric teeth, skin off the muscular coat with your thumbnail, cut off any portion of intestine; then mount. It is a small conical organ 1-20th of an inch or more long, and contains six vertical rows of toothed plates, slightly overlapping each other; on each side is a row of tooth-like processes, outside these another row; then comes a plain column giving rigidity to the whole. It may be slit up, mounted whole, point downwards, or cut transversely into rings. The mole cricket, the field, and, I believe, the house-cricket, have it, with slight differences in the form of the plates, and some have brushes of hairs covering or attached to the teeth. This plan I was content with till I found I missed many interesting points in the stomach and gullet; but even in this simple way you can produce most beautiful objects. I now kill with a drop of benzine, cut off the extreme tail, pull off the head, cut off the whole intestine, and put it in a 1oz. phial with 5 or 10 drops of liquid potash. After it has stood about half an hour, I partly fill with water and shake it well to detach the muscular coat and tracheæ; then slit it up, wash and adjust on a slide. Drain away any moisture, apply a drop of carbolic acid, and place on the thin glass. After a few minutes this will absorb all moisture, and render it quite transparent. If it does not, put a drop of acid at the edge and tilt the slide to drive off the first acid; then put a little balsam on the edge, tilt the slide, warming it to render the balsam more limpid, and it will gradually take the place of the acid, the lines of demarcation between the two being distinctly visible.

If you can obtain a cockroach, begin with that; the teeth are like small anvils. Then crickets, grasshoppers, beetle-grubs from the garden, beetles, gadflies—in fact, everything. I have found spiny teeth in the parasite of an albatross; the flea has a multitude of concentric hairs. Some stomachs are covered with fine spikes, arranged on a tesselated pavement; scarcely any are identical, but all are most beautiful.

We have a large yellow and black flying grasshopper in Australia; its stomach is about $\frac{3}{4}$in. long, with several rows of hairs at the upper part, then small teeth or spines scattered, then in larger numbers arranged obliquely in rows, then scattered, then arranged in groups of three or four in vertical rows, then more scattered; the stomach terminates in six prominent conical folds, studded with transparent prominences, which, on an irregular fold, show themselves as minute teeth; between these are minor folds, similarly studded.

This part, although continuous with the stomach, I consider to be the representative of the cricket's gizzard, and a similar arrangement is seen in many insects. The true intestine of about the same length has no teeth, but its middle portion is corrugated to give greater surface for absorption. I have said nothing about examining the tracheæ and muscles, but probably some microscopists will be led on to dissect in a more scientific manner, and in all cases it would be much better to have the names and the order to which they belong, as the differences in structure may then be found to indicate the nature of the food and the habits of the insect.

Brelli, N.S.W. **T. J. Sturt, M.D.**

MICROSCOPIC.

[20096.]—I see that your invaluable correspondent, Mr. Lancaster, accidentally found that a concave lens increased the magnifying power of the object-glass when used with the lantern. I have occasionally used, for several years, a bi-concave spectacle lens fitted to the draw-tube for table purposes, and find that a 2·3in. can be used to magnify to the same extent as a $\frac{1}{4}$in. Of course, the errors, if any, of the o.g. will be also magnified; but still, I find it handy, as the focus of the o.g. has to be but very slightly altered, and it saves the bother of using another lens. I would sooner use this arrangement with a good $\frac{1}{8}$in. than have an inferior $\frac{1}{4}$in.

T. J. Sturt, M.D.

MICROSCOPY—WIDE-ANGLE OBJECTIVES.

[20097.]—At the last meeting of the Royal Microscopical Society, a paper, by Prof. E. Abbe, "On the Relation of Aperture and Power in the Microscope," was read, in which many very interesting and knotty questions in scientific microscopy were discussed in their most intimate practical bearings. The summary of the first part of the paper, published in your report of the meeting ("E. M.," May 26, p. 275), briefly touches upon the main points; and I trust, sir, that you will find space for the paper *in extenso*, for it is rare indeed that we meet with anything on the theory of the microscope that is not a *réchauffé* of elementary platitudes such as do duty as "introductions" to our textbooks of the microscope. Prof. Abbe is well known to have done more towards elucidating the theory of the microscope than all the "authors" of textbooks put together of our generation. It is said that an elaborate exposition of his theory exists in MSS., which is only waiting a final revision by the Professor before being published in the *Journal* of the R.M.S.

There was one point in the paper, which is only lightly indicated in your summary, but which appeared to me not reasoned out with Professor Abbe's usual clearness and precision; and I would most respectfully invite his attention to it.

Referring to the application of diaphragms behind wide-angle objectives to cut down the aperture, and so add to the "penetration," Professor Abbe condemned the suggestion *in toto*, on the ground (as I understood him) that in all wide-angle objectives the aberrations of the marginal zone can only be corrected *practically* by leaving the central portion of the aperture more or less defective. In other words, the Professor's opinion appears to be—that the correction of the marginal aberrations necessarily entails imperfection in the central portion of the aperture—an incurable imperfection inherent to all wide-angle systems.

The question whether or not we can obtain "penetration," in any useful degree, by diaphragms to reduce the aperture, is not what interests me for the moment, but whether the cutting off marginal zones from an originally wide-angle system forces us to use a badly-corrected portion of the aperture, the central portion, which Professor Abbe says is designedly left defective in the constructions adopted by all practical opticians?

If this opinion of Professor Abbe's holds good, it would follow that no wide-angle objective can be of service, unless the conditions of the object and the illumination be such that the action of the extreme marginal aperture largely preponderates in the production of the microscopical image. Is this supported by experience? Let us experiment with the objective of largest aperture hitherto constructed, and see how far the results agree with his opinion.

The new homogeneous immersion $\frac{1}{8}$ of Powell and Lealand has a numerical aperture of 1·47 = 150° in crown glass). Assuming the marginal 10°, or probably even 30°, of aperture are in excess of what can be fully utilised with that initial magnifying power; then, in order to develop the utmost resolving power, the direct illuminating beam must make an angle of 60° to 70° with the optic axis in the focal medium of index 1·5. There can be no doubt the marginal aberrations of this lens are well corrected, for with this obliquity of illumination on suitable immersed objects the definition is excellent. In this instance the object is in a refracting medium of sufficiently high index and illuminated by proper immersion means; we are thus utilising principally the marginal aperture, and the good definition proves that the aberrations are well corrected.

But we find this lens also gives a fine image of dry *Podura* illuminated by a small axial pencil. What part of the aperture are we now utilising? Every expert will doubtless admit that in viewing with this lens a *Podura* scale mounted on the slide, having an infinitesimally thin film of air between the scale and the cover-glass, the effective aperture is cut down to less than 1·0 N.A., for the *maximum* aperture from such a medium as air is represented by 1·0 N.A. The aperture is reduced from 1·47 to 1·0, through the object being in air, and this reduction appears to me precisely equivalent to the use of a diaphragm behind the objective, limiting the pencil at exit to 1·0. In this instance the extreme marginal aperture of our lens cannot preponderate in the production of the microscopical image, for it is cut off. The image, then, is produced by the central portion only of the aperture—the part which Prof. Abbe says is designedly—nay, necessarily—left defective in all wide-angle systems!

It would be quite erroneous to suppose the central portion of the aperture incurably defective. The image seen of dry *Podura* entirely negatives that supposition; the clearness and sharpness unmistakably prove that the aberrations of the centre are quite successfully corrected by means of the "collar-adjustment," which Messrs. Powell and Lealand were the first to recognise as an essential addition to homogeneous immersion objectives for this very purpose.

In all cases within my experience, if the images are to be judged critically, the "correction-collar" must be brought into play. In the opinion of some of the best object-glass makers—such as Tolles, Spencer, and Powell and Lealand—the "correction" cannot be dispensed with if we desire to obtain the finest defining power of our wide-angle objectives with every class of object.

Prof. Abbe's experience is said to have been principally confined to the homogeneous systems with "fixed" mounting, in which assuredly the reduction of aperture from 1·47 to 1·0 would exhibit errors in the central corrections. But, surely, a defective centre that can be remedied by the application of a correction-adjustment must not be regarded as incurably defective—defective from the exigencies of the construction, but should be a strong practical reason for applying the "correction" to *all* wide-angle objectives? The additional difficulties of centring, &c., involved in the mounting are mere workshop difficulties that should not weigh for a moment against the production of a more perfect instrument. A few careful experiments with the correction-adjustment applied to such a lens as the $\frac{1}{8}$ I have alluded to, would probably convince him that at any rate between the apertures 1·47 and 1·0, the aberrations can be dealt with successfully. That being so, his opinion that the construction of wide-angled objectives necessarily involves a badly-corrected central aperture would need to be qualified.

In the above remarks I have limited myself to the case of the highest aperture on record. It is obvious that if Prof. Abbe's opinion of the necessity of bad central corrections in all wide-angle objectives can be shaken on that one example, we shall convert him into advocating the "correction" for *all* high powers, homogeneous, immersion, and others. I would have it understood, however, that my special advocacy of the correction-adjustment for homogeneous immersion is based on a series of careful trials with a number of objectives both with fixed mounting and "movable" adjustment. For severely critical tests, I consider the "fixed" mounting a mistake. Beyond the difficulty I have mentioned, of obtaining the finest definition, on both immersed and dry objects, with the objective lenses mounted in a fixed setting, there is the further difficulty that no fluid-medium has yet been found strictly identical with the front lens in refractive and dispersive power. The mounting fluids, too, vary from the low refraction of water to the high refraction of phosphorus in bisulphide of carbon, with a still larger range of variation in dispersive power. The correction-adjustment will certainly not enable us to cope successfully with all these difficulties, but it enables us to do so more effectively than the fixed mounting.

Akakia.

DYNAMO MACHINES.

[20098.]—Your correspondent is likely to remain "Faint Hearted" if he expects to obtain a current equal to 14 or 18 Bunsen cells from his machine. If his armature had been 7in. by 4in. (I presume it is of the I form), it would have been much better. With the gauge wire he has on it would produce a current equal to so many Leclanché cells, instead of Bunsens, the 18 wire would still add Leclanchés.

Wind the armature with 10 wire; join the F.M. in multiple arc. He will then get all it is possible from that size armature. Also try it as a shunt dynamo with the 10 wire; but join F.M. in ordinary manner.

George Tolman.

NOTES ON DYNAMO MACHINES.

[20099.]—In the very useful, practical, and interesting "Notes on Dynamo-machines," No. 20081, by your correspondent "E.," I notice two statements which I find it difficult to reconcile, viz.:—

26. "If the speed of a magneto be increased, we know that E.M.F. is increased in the same proportion." And

29. "With large currents we approach the condition of things in a magneto-machine, the E.M.F. remaining constant."

Now, the latter statement agrees with my preconceived ideas on the subject. The former does not. Does not the E.M.F. depend upon the strength of the magnetic field? This in a "magneto" is constant, and the increase of speed should augment the *intensity* of the current. In the case of a "dynamo," before the point of saturation of the field-magnets is reached, I can understand—armature, brushes, field-magnets, and lamps forming one continuous circuit—that as the speed increases, the *intensity of the current increases*, and this increases the strength of the magnetic field, which in its turn increases E.M.F. And when the point of saturation of the field-magnets is reached, increase of speed increases *intensity* (or quantity of current in a given time) without further increasing the E.M.F. Is this not so?

Ligurian.

ELECTRO-MAGNETIC MOTORS.

[20100.]—The conversion of current energy into mechanical energy being to me one of the most attractive problems, I read Mr. Huxley's letter (19997) with interest; but after examining the factors given by this gentleman, I obtained results which made me rather doubtful as to the possibility of utilising the motion of the particles of an iron bar, while under the varying influence of an electric current, and I cannot find much encouragement in Mr. Ponton's letter (20046), with whom I seem to share two or three ideas. However, we have not got so far yet that we could give up this subject, and "nil desperandum," I think, is as applicable to electro-motors as anything else. Trying to act in accordance with this, I shall briefly enumerate the most important data with which I am furnished at present.

I share Mr. Huxley's idea that we lose power by utilising armature-attraction; but as to the seat of the power, which by Mr. Huxley was considered to be the magnet itself, I attempt to go further, taking the current itself as such.

According to my knowledge, a bar increases in length when magnetised, and does not decrease, as stated by Mr. Huxley. This, of course, does not interfere with the principle of the motor, but still has a mechanical importance—*e.g.*, if my statement, which is based upon authority, is correct, Mr. Huxley's as well as Mr. Ponton's devices would have to undergo certain mechanical alterations; but an instrument constructed on Mr. Ponton's principle would easily settle this question, if necessary.

The bar, if magnetised to saturation, increases in length to the amount of 1-270,000th of its length, a result which could be obtained by a pulling-force of 25,300,000 / 270 000 = 91lb., 25,300,000 being the modulus of elasticity for wrought iron; and 91lb., I think, could hardly be called an "enormous" force.

The next statement of Mr. Huxley I had to quarrel with was, that magnetising and demagnetising could be done with the "utmost rapidity." It is true, a circuit can be made and broken with the utmost rapidity, as far as I can see, only limited by existing mechanical means; but the rapidity with which an iron bar can be magnetised and demagnetised is very limited indeed, according to the law that "an electro-magnet requires time to attain its maximum power."

Having obtained these results, I was pretty well convinced that any attempt to multiply that minute motion by leverage would be fruitless. On the other hand, I have reasons to believe that the path opened by Mr. Huxley is well worth being followed up, only in a different direction.

The only contrivance in which, as far as I know, this principle has been made use of is the Reis's telephone (1861), in which the making and breaking of a current passing round a small bar of iron was effected by a diaphragm, caused to vibrate by speech, &c., so that the bar was rapidly lengthened or shortened, the total effect of those changes being a reproduction of the vibrations of the diaphragm.

Finally, I should like to remark that, although hitherto I have done more to keep Mr. Huxley's ideas back than to advance towards a perfect machine, I have as strong hopes as he that something in this direction will be found yet.

R. Kanthack.

NEW ELECTRO-MAGNETIC CLOCK.

[20101.]—I may inform J. H. Huxley (letter 20077) that his idea of applying the magnetic force to the top of the pendulum is not altogether new, as I have made one or two clocks actuated in this way, so far with success. I venture to think, however, that if Mr. Huxley had put his plan into practice, he would find it rather unsatisfactory, in more ways than one. His compensated pendulum is an abortion: he appears to ignore the fact that the weight of the ball should be equally distributed on each side of the plane of vibration, and not (as appears from his sketch) some inches in front of it.

J. E. Floyd.

CUTTING CARBONS.

[20102.]—To cut carbons for galvanic batteries is what electricians call "a very tough job"; but, recently, I was in the atelier of a clever scientist, and I saw him cut them with ease and facility. He used for the purpose a machine called a "paper-cutter's knife," such as the reader, doubtless, will see at any bookbinder's establishment. With this instrument the block or shingle of rough carbon was held firm, whilst a cutter passed backwards and forwards above it quickly, making a groove. When this groove was about half-way through the operator struck the carbon with a mallet, causing its severance.

The cutter was not that ordinarily used for cutting paper-edges, but a highly-tempered tool like the parting tool employed for turning cast iron. **E. B. Fennessy.**

LECLANCHE BATTERY CONNECTIONS.

[20103.]—"W. J.," in letter 20078, page 263, describes a method of making a connection to the carbon in the Leclanche cell without the trouble of melting lead. In my opinion, his method is more trouble than melting the lead; and, after all, he gets a connection which, to say the least, is doubtful.

Now, what can be more simple than the method given in back numbers by, I think, our friend "Sigma"?—to electrotype the carbon-ends, and solder the wire or binding-screw, then cover with paraffin?

The way I do them is as follows: I get a jam-pot, about half-full of a saturated solution of copper sulphate, and hang a small bag of crystals in it; place a porous cell, containing diluted sulphuric acid (1 to 10) in the jar. Let the solutions be about the same level. Place a strip of zinc in the porous cell, and wrap a copper wire round the carbon, and connect to the zinc strip; then hang the carbon in the copper solution, so as to dip about ¾in. in it, and leave all night. Now wash well, and solder your connections to the copper head; now melt some paraffin (not lamp-oil) in a jam-pot in the oven, and dry and warm the carbon and place in the melted paraffin, so that the copper is well covered, and leave a short time for the paraffin to soak in. Then you have a connection which can be depended on.

A correspondent in a back number advises amateurs never to use a binding-screw where a drop of solder will do. I think that if amateurs would keep this in view, we should hear less of batteries failing without apparent cause.

J. Henshall.

THE ELECTRIC LIGHT FROM A CONSUMER'S POINT OF VIEW.

[20104.]—It has been often questioned whether the electric light produced by any system now exhibited will prove to be cheaper than gas. I have not met with reliable data wherefrom to compute the cost of the electric light accurately; but, after reading Mr. Hepworth's little history (Routledge and Son), I took such data as I found therein, notably those referring to Siemens' machine, p. 65, and endeavoured to arrive at an approximate result. Thinking that it may interest your readers, I send the accompanying table of comparisons between the system of Siemens and of ordinary gas lighting. I may have exaggerated some of the items against the electric light system; but, on the large scale, over, say, 2,500 candles, it proves equal or superior in cheapness to gas, as the table shows. I have allowed fully for contingencies; I have assumed the cost of the fittings to be the same for electric and gas lighting, and I have computed capital to be redeemed in about fourteen years, which may be taken as the probable life of a machine and its engine. The electric light approaches to 2s. 6d. and gas to 4s. per candle per annum. Perhaps some of your readers may throw further light on the matter, making it, possibly, still more favourable to electric lighting than I have shown. **M. Jonson, C.E.**

89, O-street, Kensal Green, 26th May.

A Comparison between Gaslight and Electric Light (Siemens' System).

Description.	Electric	Gas.	Electric.	Gas.	Electric.	Gas.	Electric.	Gas.
Power of engine	2 h.n.	—	3 h.n.	—	4 h.n.	—	8 h.n.	—
Number of hours of lighting daily	9	9	9	9	9	9	9	9
Number of burners	1	86*	1	215	1	430	1 or +	1000
Number of candles	1200	1200	3000	3000	6000	6000	14000	14000
Dynamo machine, with gearing complete	£ 75	£ —	£ 100	£ —	£ 115	£ —	£ 250	£ —
Ditto fixing	15	—	20	—	25	—	50	—
Engine-motor and gearing	120	—	160	—	200	—	360	—
Ditto fixing	24	—	32	—	40	—	72	—
Fittings to and on premises	95	95	227	227	452	452	1050	1050
Contingencies, 10 per cent.	33	10	54	23	83	45	178	105
Capital outlay	£362	£105	£593	£250	£915	£497	£1960	£1155
Coal, or gas, oil, &c.	£ 25	£ —	£ 38	£ —	£ 50	£ —	£ 100	£ —
Engineer and repairs	140	—	140	—	140	—	140	—
Carbons and waste	82	—	205	—	410	—	957	—
Contingencies, 10 per cent.	25	—	38	—	60	—	120	—
(Gas at 3s. 4d. per 1,000 cubic feet)	£272	236	£421	588	£660	1177	£1317	2737
Interest at 5 per cent., and redemption of capital	£ 36	10	£ 59	£ 25	£ 92	£ 50	£ 196	116
Yearly cost	£303	£246	£480	£613	£752	£1227	£1513	£2853
1 candle per annum	5s. 1d.	4s. 1d.	3s. 2d.	4s. 1d.	2s. 6d.	4s. 1d.	2s. 2d.	4s. 1d.

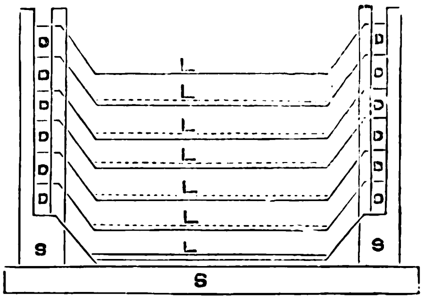
---

* The gas-burners are supposed to consume 5 cubic feet per hour, having an illuminating average power of 14 candles. Fittings have been taken at £1 1s. per burner for capital outlay, and electric patent rights and gearing at the same figure.

A SIMPLE FORM OF STORAGE OR SECONDARY BATTERY.

[20105.]—Having constructed a small secondary battery, on, I believe, a new and simple plan, I have thought a description of it may be suitable for your columns.

It consists of a series of shallow thin lead trays, L, about one-fortieth of an inch thick, pressed and hammered into shape in a wooden mould. These trays are arranged one over another in a wooden frame S. The trays are kept at an equal distance from each other, by pieces of wood which slide up and down in the stand, the ends of the slides being shown at D. The dotted lines in the bottom of the tray represent layers of red-lead, or oxide or reduced lead. On this is poured an acid solution of sulphate of copper, just deep enough to immerse the bottom of the tray above. The trays should be varnished all round the edges with Brunswick black or some other acid-resisting varnish. Wires for poles are soldered to the bottom of the bottom tray and to the top of the top tray. The battery may, of course, consist of a greater number of trays, and a series of batteries may be connected together.

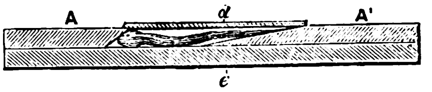


The advantages of this form of battery are, the oxide of lead can always be kept at the most advantageous thickness. The plates or trays can also be arranged at the most advantageous distance from each other. No diaphragm of any kind is required, and therefore, however long in action, no reduced lead can weaken its action. The only disadvantage I can see is that the battery must always be kept level; but in the majority of instances this would not matter. Of course, it could not be used in tramcars, &c.

In making batteries on a large scale, it would be well, perhaps, to cast the trays in an iron mould, and then it would be well to have one corner of each cell cut off; and let this be done on alternate sides to facilitate the inspection and supply of liquid. It would be well then to mix antimony with the lead to harden it. Possibly the trays may be made of carbon. **W. Symons, F.C.S.**

TADPOLE SLIDES.

[20106.]—As your readers seem fond of elaborate arrangements, I send sketch and description of "Schultze Tadpole Slide;" which I think they will find an improvement on that of Mr. Stokes, but I cannot help thinking the simpler the arrangement the better, and so I send you the following:—Form a groove or cell on an ordinary slip of glass with folded blotting-paper saturated with water; lay the tadpole in between on the glass, tail flat, cover the body over with saturated blotting-paper, the tail (if necessary) with thin glass. Keep the whole well saturated and the tadpole will live for many exhibitions.



Schultze tadpole slide is made as follows:—

To one side of a thick slide is fastened by means of Canada balsam a piece of another slide cut as represented at A, and to the other side a second piece of the shape seen at A', so that there is a small cell in the centre of the slide of the form shown in the section in the figure, a cover glass "*d*" closes the cell.

To place the larva *e* in the cell the cover-glass is taken off and the larva fished out of the water in a small watch glass and poured with the water into the cell. By manipulating with a brush its head is brought into the hollow of the glass at A, and the tail placed on the sloping surface at A'. The cover is then quickly replaced, care being taken that the cell is full of water. The animal is excluded from air and water, which, when it evaporates, can be replaced with the brush. In this way the circulation of the blood in the tail may be observed for hours at a time.

John Alex. Ollard, F.R.M.S.

Enfield.

AMERICAN ORGAN.

[20107.]—If "Joiner" likes to advertise his address, I will avail myself of his offer to see his instrument at first opportunity. I have been in the harmonium and American organ line nearly 17 years, and think his sketches a credit to him. I am sorry to say I have only taken in the "E. M." this last four months, but I mean to recommend it to all I know, as I think it may be taken in with advantage by practical workmen as well as amateurs. I will endeavour to give information, and shall be glad to receive the same, as I am not one of those men who profess to know all, and there is always something to be learnt about harmoniums and American organs. I think "Joiner" has not enough spring in his reservoir. I always put 24lb. in a one row; 30lb. in a 1½ row; 36lb. in a 2 row; 48lb. in a 2½ row, with sub-bass and octave coupler. I mean coupled through, not only one octave as in some instruments. I should put in the same class of instrument as he has constructed at least 60lb. I see Mr. Fryer, in No. 895, conveys the idea that all those instruments whose reeds have only one rivet in are inferior. I must certainly differ with him, as some tongues are not riveted to the box, or block, as he calls it, but slide in a groove or dovetail, and when properly done never shift. Then, again, in Ramsden's melody instrument (Dawe's patent) only one screw is used, and where are there better, both in tone and work? Then, again, he says in 99 cases out of 100, by merely wiping dust off the tongues of reeds, the instrument will be in proper tune again. Surely he must mean instruments that have had very little use. He is the first I have heard say such a thing; I admit it is a help, but he is a lucky man if he has come across anything like the quantity he says that did not want anything more done to them than dusting.

I will, at some future time, send the proper names of things used in American organs, as I find some things are called by very peculiar names. I am now finishing an American organ with 15 stops; it would be better for any who intend to make or finish an organ to put a ½in. wood button on the top of the plunger (see Fig. 1), and a regulating screw in the keys. It is much better than filing plunger to regulate; also, for convenience, I put an arm at each end of the key-frame. (See Fig. 2.) Let it run as long as the width of case. I put a screw in slot A into the end of case, so that the key-frame can be lifted up and down, not taken off as in most organs. I also put a dowel in the end blocks on soundboard for key-frame to drop on, as you are sure then of key-frame being in position; and some persons, in replacing frame, are not careful in getting screws into the same hole again. I inclose a sketch for "Beta" (Fig. 3), who, with patience, will get a good sub-bass if he does it properly. A, reeds; B, ¾-frame and partitions between each note glued on; C, box of pine over sub-bass notes; D, pallet covering holes to let wind in; E, pallets letting wind out into bellows; the holes in soundboard above pallet E I make 1½ long, ⅜ wide; F, stems pinned; G, rail to carry stems; H, rail to carry tracker I; tracker is grooved for wire staple ⌐¬ to go across the tracker into rail H; J J, two springs of light wire. My sub-basses done this way always come out well. K, regulating screw.

H. Hanks.

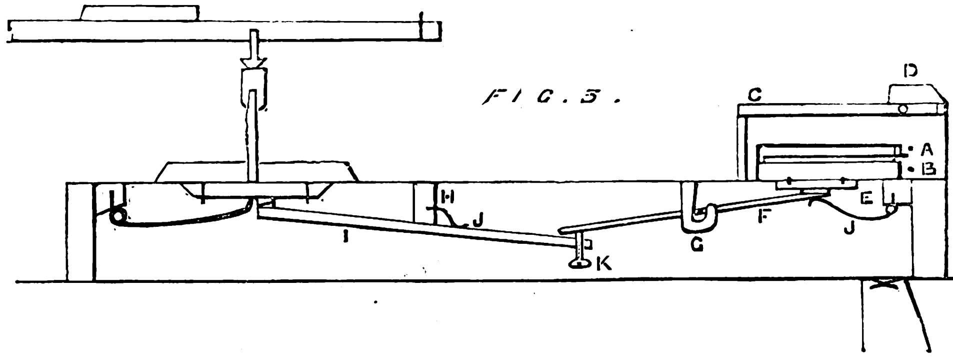


FIG. 3.

FIG. 1.

FIG. 2.

TWO-MANUAL AMERICAN ORGAN.

[20108.]—I was very pleased to see "Joiner's" description of his organ a few weeks back, and hope that by this time he has got it into satisfactory working order. When he has a little leisure, I am sure he would earn the thanks of amateur reed organ-builders if he would kindly give us some account of the various contortions of that "scratch set" of reeds. I feel sure he knows a thing or two about reed-voicing, which would be very acceptable to some of us.

Also, as to size and length of tubes. I have always understood that for a given reed, a tube of a certain size was essential. If this is not so, and the tubes can be varied at pleasure, it must afford a valuable means of altering the tone of the reeds, and thus gaining variety. Perhaps "Joiner" could indicate the limits between which such variation is of any advantage. I presume that in all cases, the scale of the tubes must correspond with that of the reeds, however much their absolute size may be altered.

Having been successful in making one fair-sized instrument, I intend, when circumstances permit, to start on a double manual, most likely with pedals; in fact, I have an idea of making it as much like a pipe-organ as possible. With this in view, I propose to confine the swell action to the upper manual, providing, however, shutters to the lower, which will be normally open, but capable of being closed by a stop. I should also arrange the stop knobs upon upright jambs on each side of keyboard. Would "Joiner" or "Organon" (who has kindly given me his assistance before) pass his opinion on this scheme, which would include an independent pedal stop of 16ft. pitch, and side-blown bellows, weighted so as to give uniform pressure; also coupler, manuals to pedals.

It appears to me that a reed organ is a very suitable thing for an amateur to make: it brings out his skill in wood and metal working, exercises his designing capabilities, and when finished, can be appreciated by almost everybody, which latter advantage does not always attend his attempts in other directions.

J. E. Floyd.

CHANGING-BOX FOR USE WITH DRY PLATES.

[20109.]—Since writing let. 20054, I have found that the plates did not enter and withdraw from the boxes freely by means of the tape, so the following alteration has been effected:—In place of the plain wooden partitions between the boxes, A, B, &c. (vide Fig. 1, p. 240 of present Vol.) have been substituted partitions of grooved wood, placed back to back, so as to hold the plates lengthwise, thus making the box capable of holding three dozen plates, viz., one dozen in each box. The centre box is covered by a panel, which lifts out, the fillet above the groove in longitudinal partition being cut away to admit of this. I find the whole to work well, even in the full glare of the sun, it being perfectly light-tight.

S. G. Horton.

TO MR. WASSELL.

[20110.]—It is extremely gratifying to me to find that my letters have been useful. I was rather afraid that trade methods would not hit the mark required by amateurs. I am glad this is not so. With regard to zone testings, the short reply of Mr. Calver to "Orderic Vital," is pretty much what all opticians would reply. The artificial star, or real one, for the telescope either refractor or reflector; the minute globule of mercury for the microscope; and the monochromatic sodium flame for the spectroscope, are the infallible tests for the optician. Each is a test for every error that can possibly exist. Every error is depicted in the first-named two, to the eye at once by a little motion of the eyepiece. Definition, adjustment, and achromatism are seen with unerring certainty, as well as the position of error, if any. This is only got off by practice, I know. So the mode described by Mr. Wassell will stand the amateur in good stead, if the ratios are once perfectly known. I am sorry I cannot help in that way. It will at once be seen that the flat, some sort of trial body, and eyepieces, are the first necessity in the trade mode. I should advise the amateur to get these first. In his case the body he means to use finally would be best. Make or procure flat and eyepiece. It is quite possible to test a mirror on artificial star without silvering it. The flat should be silvered. I will give a method for making flats in my next to the Editor. I shall be glad to answer any questions regarding the working of the mirror that may crop up.

Sir John Herschel ("The Telescope," art. 56, page 81), says:—"The geometrical distinctions between the parabola sphere, and hyperbola, become mere theoretical abstractions in the figuring of specula, there being no practical mode of ascertaining, by *any* system of measurements on a *scale* what form the surface has," &c. I hope Mr. W. will eventually disprove this statement.

Prismatique.

THE LARGEST LOCOMOTIVE IN THE WORLD.

[20111.]—I send you details of what is claimed to be the largest locomotive in the world, recently turned out of the Central Pacific Railroad Works at Sacramento, U.S.A., which may be of interest to many of your readers. The *Sacramento Record Union* says:—"The work has been done in the most complete manner, and the engine is well-proportioned, not showing to a casual glance that she is so immense. A. J. Stevens, general master mechanic, designed and superintended the construction. G. A. Stoddard, chief draughtsman, made the drawings to carry out Mr. Stevens' ideas. The trial trip was a success, and Sacramento can now boast of a successful inauguration of locomotive building. The boiler was made by Chas. H. Hooper, foreman of the boiler shop, under the direction of Mr. Stevens, of the following dimensions:—Thickness of the shell, 7-16in. Otis steel; whole length of boiler over all, 29ft. 2¼in; shell, 60in. in diameter, 17ft long, containing 166 tubes, 2¼in. diameter; firebox, 108in. long by 56in. deep, made of 5-16in. steel, being thinner than the outside shell, so as to make steam easier; combustion chamber, 53in. long, 36in. deep. The crown sheet is supported by 37 bars, made of best bar iron, 5in. by ¾in., placed 4in apart, each bar supported by two slings strung to the waggon top of the boiler by two stays. The stay bolts in the firebox and combustion chamber are ⅞in. in diameter, and perforated with a 3-16in. hole.

"The dome is 26in. in dia. and 40in. high; the smoke arch is 56in. in dia. and 37in. long; the whole weight of the boiler complete is 14 tons. The cylinder of the engine is 19in. dia., stroke of piston 30in.

"There is an independent cut-off valve working on the back or top of the main valve, which is a double valve with a double exhaust at each end of the cylinder worked by six eccentrics. Two on each side work the link motion, and one each side works the cut-off on the cylinder. There is a steam cylinder in the cab attached to the reversing lever, to enable the driver to work the reversing-gear easily, also a cylinder on one side to work the steam brakes, which are attached to three pairs of the driving-wheels. There are four pairs of driving-wheels, 4ft. 6in. in diameter, two pairs of which are flanged to hold the engine on the track, and the others blank.

"There is an instrument attached to the back of the tender connecting with the draw-bar, called a dynometer, to test the strength and pulling capacity of the engine.

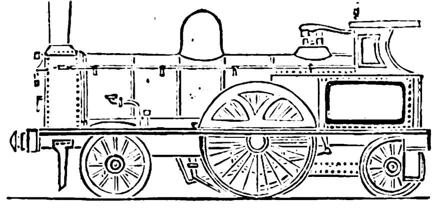
"The weight on the driving-wheels is 53 tons, on the forward truck 8½ tons, whole weight of the engine, with water, exclusive of tender, 61½ tons.

"The driving-wheel base on track is 15ft. 9in.; capacity of tender, 3,000 gallons of water, and 5 tons of coals. This engine is nearly all of an original design, and not copied from Eastern manufacturers. The double valves are an invention of Mr. Stevens, and are a new idea for a locomotive engine."

Scotchman.

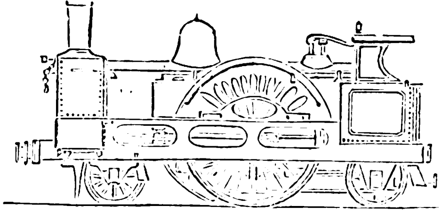
LONDON AND NORTH-WESTERN RAILWAY ENGINES.

[20112.]—To redeem my promise, I forward sketches of one of the "Bloomers," and "Cornwall," which I hope will be acceptable. The "Bloomers" were designed by Macconnell, a former "loco." superintendent of the company; there are two classes, distinguished as "large," and "small." The sketch I send is that of a "large Bloomer."



A few dimensions are as follows:—Drivers, 7ft.; Cylinders, 16in. by 22in.; Heating surface, 1,294 square feet; 195 tubes; boiler, 11·9 by 4·1; weight, 29 tons.

With regard to "Cornwall," she was designed in 1847, by Trevithick, for fast running. The driving-wheels were 10ft. in diam., the boiler being *under* the driving-axle. She, however, did not keep on the road well, and was on this account modified to the ordinary arrangement.



The chief dimensions are as follows:—Driving-wheels, 8ft. 6in.; leading and trailing, 3ft. 6in.; cylinders, 17½in. by 24in.; boiler length, 10ft. 6in.; boiler diameter, 3ft. 11in.; total heating surface, 1,070 sq. ft.; total wheel-base, 14ft. 10in.

Clyde.

GREAT NORTHERN ENGINES AND THEIR WORK, PAST AND PRESENT.

[20113.]—Many inquiries have been made in these columns regarding the engines which used to perform the express work on the G.N.R. before those now in use were introduced. Special interest attaches to the matter in the minds of those who have compared the work of twenty-five or thirty years ago with that now done. In a former letter I pointed out that, in respect of speed, the G.N. expresses of twenty-five years back compared very creditably even with the "Flying Scotchman" and Leeds express of the present day. So long ago as 1853, and, I think, ever since the opening of King's Cross terminus, the down Scotch expresses starting at 9.30 a.m. and 8.50 p m were timed to run from King's Cross to Hitchin (32 miles) in 40 minutes, and thence to Peterborough (44¼ miles) in 58 minutes; while the 5 p.m. ran from Hatfield to Hitchin (14¼ miles) in 18 minutes. In 1857 the special expresses to Manchester were put on, to compete with the L. and N.W., and then the time to Hitchin (32 miles) was reduced to 38 minutes, thence to Peterborough (44¼ miles) in 55 minutes and Peterborough to Grantham (29 miles, up the Globe bank) in 40 minutes. On the up-journey, the 44¼ miles from Peterborough to Hitchin were timed to be done in 52 minutes. Here, then, we have timed speeds of 50·5 and 51·1 miles an hour—start to stop. The trains usually consisted of from 8 to 12 coaches. Time was excellently kept, and after any delay at stations was often made up to the extent of several minutes in the longer runs. I have known the 32 miles to Hitchin done in 37 minutes. I need not remind my readers of the numerous gradients on the G.N R., which have been shown in the sections kindly given by Mr. C. E. Stretton in back numbers; but I may just remark that there is a two mile rise of 1 in 105 and 1 in 110 at starting, and then another of 1 in 200 continuously for eight miles to Potter's Bar, which is 250ft. above the starting point at King's Cross. Thus, out of the 32 miles, 17 rise about 1 in 200, and a summit of 250ft. has to be climbed. Therefore, I think I am warranted in saying that this run of 32 miles in 38 minutes, over such a road, by the old Manchester expresses, will stand favourably against the fastest narrow-gauge work done in the present day. Almost equally good was the run of the "up" express from Peterborough to Hitchin (44¼ miles) in 52 minutes, more than a third of the distance being up-hill, with fully a dozen miles of 1 in 200 rise. On the "down" journey, the 12¾ miles bank to Potter's Bar was ascended in 17¾ to 18 minutes. Down this and other inclines, speeds of 60 to 70 miles an hour were commonly run, with great steadiness; and I once timed a train at 72 for a short distance. As to weight and speed combined, I may instance a run from Hatfield to Holloway, with 16 coaches and one engine (a 6ft. 6in. rebuilt Crampton "single," with 16in. by 22in. cylinders), in 22 minutes, starting and stopping, the last 5 miles being up a bank of 1 in 200, and the last 2 miles having to be "slowed" over. So much for the work. Next, as to the engines.

The G.N.R., in the years 1851—60, had 27 regular express-engines. Of these, one was the well-known old experimental bogie-engine, No 215, whose 7ft. 6in. wheels are now running under No. 92. She has already been described in these columns, and I have no personal information as to her work. She was the only one of her class, and, so far as I could ascertain, was not a favourite or a success. Nos. 201, 202, and 222 (about which questions have often been asked), were also a class by themselves. They were of the celebrated "Jenny Lind" type, built by E. B. Wilson, of Leeds. Nine of the same class were employed on the L.B. and S.C.R., and five on the G.E.R. They had 6ft. "single" driving-wheels, 4ft. leading and trailing; cylinders, 16in. by 20in.; inside bearings to driving wheels; outside to leading and trailing; outside pumps working on driving-axle; peculiar fluted iron cover to dome and safety-valve; the former placed on middle of boiler; latter over firebox. They were much liked, and did excellent work. The main stock of express-engines, however, 23 in number, were divided into two classes: the Hawthorns (numbered from 203 to 214 inclusive), and the rebuilt Cramptons (numbered from 91 to 100, and No. 200), both having single drivers, 6ft. 6in. in diameter, and inside cylinders 16in. by 22in. They differed, however, in details. The Hawthornes (No. 203 of which class was in the Great Exhibition of 1851), had raised fireboxes, and the leading-wheels were set a little behind the smokebox. The Cramptons were originally built, like the "Folkestone" class on the S.E.R., with two pairs of leading-wheels, drivers behind firebox and intermediate crank-shaft. They were rebuilt by Mr. Sturrock with "single" driving-wheels on the crank-shaft, and a pair of carrying-wheels behind the fire-box, the leading-wheels being right under the smoke-box, as in the modern 7ft. "singles." They had flush-boilers and no domes; the safety-valves were over the firebox. This was also the case with Nos. 203, 213, and 214 of the Hawthornes, Nos. 204—212 having central domes with curiously-shaped flat-topped covers. Both classes had large boiler-power (about 1,300ft. h.s.), and weighed some 30 tons loaded, of which 13 or 14 tons rested on the drivers.

These engines did the fastest express work, especially between London and Peterborough, and also took their turns with the ordinary main-line trains, excepting the morning Parliamentary, and an afternoon moderately fast train to Peterborough, among the down trains, and the corresponding up trains, which were run with coupled engines. The other "single" engines on the G.N.R. were of two classes. Nos. 1 to 50 were the well-known "Sharps" (illustrated page 435, Vol. XXX.), of which I have previously given dimensions, the principal ones being—cylinders, 15 by 20; driving-wheels, 5ft. 6in., h.s. 748ft., weight 20 tons. Nos. 51 to 70 were "small Hawthornes," resembling the 203 express class, but having 6ft. wheels; cylinders, 15 by 21; h.s. 906ft.; weight 25 tons. Nos. 51-60 had flat-topped domes: 61-70 none. Both these classes occasionally took light fast or express trains, but were mainly employed on the ordinary stopping or short-service trains. I believe some are still in existence.

The old G. N. four-wheel coupled engines had cylinders 16in. by 22in.; driving and trailing-wheels, 6ft.; h. s., 904ft.; weight, 26 tons; no dome; were numbered 71—90, and were built, some by Wilson of Leeds, others by Hawthorne of Newcastle. Nos. 223—228, with 6ft. 6in. wheels and 16½in. by 22in. cylinders, were built at a later date. Nos. 101—199 were goods engines, mostly six-wheel coupled; wheels, 5ft.; cylinders, 16in. by 24in.; weight, 30 tons; all had domes; builders chiefly Hawthorne and Wilson. Nos. 216—221 were small four-coupled engines, with 11in. by 17in. cylinders and 5ft. wheels, originally built for the Ambergate line. Nos. 229—240 were the 7ft. "singles" built by Kitson, which are still running, and have often been described. They came in at a later date than I refer to. This completes the list of the old G. N. R., and I believe it to be correct in all respects. Such information as was not within my personal knowledge was communicated to me by a gentleman who was in the locomotive department at that time. This letter practically answers a number of long-unanswered queries, and I regret that my engagements have prevented my sending it earlier. **C. R. M.**

Wellington, N.Z., March 25.

INDIAN WORKMEN: ALSO THE WRITINGS OF "EOS" AND "KHODA BUX."

[20114.]—BEING myself a long resident in the East, I particularly enjoy and appreciate the writings of our former correspondents, "Eos" and "Khoda Bux."

When I was last in India I met a sonar, a Brahmin, who had come to Central India from Lucknow during the troubles of 1857. He was one of the most intelligent natives I ever came across. This old man, who was over seventy years of age, was named Bulwant Rao, learned his business from his father, who had had the advantage of being thoroughly trained as a watch and clockmaker by an Englishman who had settled in India about the year 1745, having left home in consequence of his having been a follower of Prince Charlie. He settled down as a watch and clock maker at Lucknow, and at his death in 1783 he bequeathed his business and stock-in-trade to the father of Bulwant Rao, a sonar, or goldsmith, of the Brahmin caste, who had come to him as a boy, and learned all he could teach him. When he, in his turn passed away, his belongings came to Bulwant Rao, who had the credit of being the best native watchmaker in Central India. I made this old gentleman's acquaintance in the following manner:—

Duty sent me to reside at the capital of a native State, and as my duties were not very arduous, and I had plenty of time on my hands, I decided on setting up a workshop; and when I had settled down in my bungalow, I unpacked my Holtzapffel's lathe and tools, and set to work.

In a day or two, I had a visit from a native lohari, or blacksmith, to ask for custom, should I require anything in his way. He was a very clever smith, and I found him very useful. He made me a number of small forgings; and caught at my ideas so readily, that I took a liking to him, and used to go to his place in the bazaar and watch him at work. He had a very nice back-gearded lathe 6in. centre, with a good slide-rest, which had been made at the Government Engineering Works, Rawul Pindee, or Roorkee—I forget which—where he had served an apprenticeship and had worked for years as a *maistru*, or, as we would call it, a journeyman. He was an excellent smith and a very fair turner. He was a Brahmin by caste, and his name was very similar to the Sonars, being Gunput Rao. He was, however, no relation, and of quite a different division of the caste.

From my spending a good deal of time at the vice and doing some turning in metal, and from my often going to Gunput Rao's workshop and remaining there looking at him and his brother at work, the attention of the natives round was drawn to me, and my servants informed me that it was current in the bazaar that I was of the *Lohari Ki Jat*. At any rate, my mechanical amusements began to be talked about, and Bulwant Rao heard that I had a lathe from which somewhat complicated work could be produced. So he paid me a visit, and I showed him my Holtzapffel lathe, its oval and eccentric chucks, and ornamental slide-rest, and how to ornament plain surfaces by use of the division-plate and a single point in slide-rest; also how to use the cutting-frame. He spent two whole days with me, and was very much interested in what I had to show him.

He told me that he had a lathe with a great deal of apparatus, with which his father used to do ornamental work like mine, but that he had never been shown how to use it. He had kept it all very carefully in the cases belonging to it, which had belonged to the Englishman. When with his father he had used this tool as an ordinary lathe, and also since it came into his possession, but he did not know how to do ornamental work with it.

So I went to his house and inspected it. From what I had read in the *Journal of the Amateur Mechanical Society*, the MECHANIC, and "The Lathe and Its Uses," I recognised it as a Rose engine. The standards, if ever there had been any, had been made away with, and the bed was not in use; the head was mounted on a low table about 18in. high, fixed to the ground, and the lathe was driven by a large wheel at the other end of the room, turned by a Coolie. When he did any turning he did not stand like an Englishman would, but sat on a mat cross-legged at the side.

The head was properly mounted between its vibrating points, but fixed immovably by wedges.

I made rough sketches of the arrangement, as I thought it would enable me at some future period to add to the capabilities of my own lathe.

Having, with some little trouble, put the tool together with the pattern plates *in situ* and having put up the supports for the guide-points, and fitted the levers and springs to their places and connected them together, I was able to show him the principle of the machine, and how, by acting on the lathe head from one side, he could cause a vibration which would make the tool in the slide-rest cut a wavy line on the surface of any work to which it was applied, and how the division-plate was used to adjust the successive lines to one another.

We proceeded to test the capabilities of the lathe as to side-work by utilising the pumping action of the back spring on the traversing mandrel. While doing this we discovered a parcel of screw-guides, of which there was a considerable variety.

He worked away by himself for a week, and was not long in finding out that a number of his pattern-plates and rosettes had an oval in them instead of a centre round hole. He discovered that he could by this alter his patterns very materially. He also mastered the principle of the oval chuck, and, before a month was over, he was able to utilise his tool to the utmost. As may be supposed, he and I became great friends, and when I was ordered to another part of India, he made me a present of two conundrum discs to mount on my lathe.

I shall be happy (if you would like to have them) to send you copies of the sketches I made of his own engine. **Gereb Admi.**

[Please send.—ED.]

SPECIFICATION OF A STEAM-LAUNCH.

[20115.]—WOULD any of your readers of the ENGLISH MECHANIC be kind enough to give their views of the following specification of a small yacht I am purposing to have built? The specification is by an eminent designer, and I want to have some criticism upon it by practical people.

Length, stem to after-post, 39ft.; extreme length, 42ft.; breadth, moulded, 8ft.; depth amidships, 5ft. 3in.

General Description: To be clincher-built of timber, with square yacht-stern and straight stem. To be decked forward and aft, and about 16in. round sides; but to be completely covered in with raised coach-roof, the coamings of which are to extend about 9in. above deck. Cabin forward of machinery-space, fitted with usual yacht-lockers and sofa seats; cupboard-fitted pantry in fire-end of saloon; aft of machinery-space to have accommodation for a man.

Keel of American rock-elm, 6in. by 4in., tapered at ends and under side to 3in.

Iron Keel Strap Galvanised, 2¾in. by ⅜in., to run right fore and aft from rudder-post to top of stem, secured to wood-keel by ⅝in. through bolts 2ft. apart.

Stem of British oak, sided 3in. moulded to drawing.

Stern-post main of British oak, sided 4in., moulded to about 10in. to keel, with boss for screw worked out of the solid, to be bearded off at after-edge to about 1½in. or 2in.

After-post of oak, 5in. by 3in.

Frames of American rock-elm, 1⅞in. by 1⅝in., spaced 9in. apart, and with two copper clenches between.

Floors.—Natural crooks of oak, sided 2½in., 4in. deep at centre line, and extending well up bilges, one at every second frame for 20ft. amidships, and one at every third frame at ends.

Keelson.—On top of floors extending right fore and aft of pitch-pine 4½in. by 4in.

Deadwoods.—Good oak crooks sided 3½in.

Engine and Boiler Seats of oak, and to be half chequed into floors and bolted.

Coal-Bunkers on each side of ship of white pine, feather and groove 1in. thick.

Bilge Stringer, ¾-length, 4 by 1½ of pitch-pine.

Beam Ledge of pitch-pine in one length right fore and aft, about 9in. by 1½in. amidships.

Planking, ¾in. thick, streaks to be in not more than 2 lengths, 5 bottom planks each side of American rock elm, rest of planking yellow pine, and top streak teak; no plank to exceed 5in. in width.

Deck, ⅞ yellow pine, feather and groove.

Beams of larch, sided 2¼in., and moulded 3in., coach-roof beams of galvanised cope iron ⅜in. by ⅜in.

Coamings of coach-roof of pitch-pine 1¼in. thick, and standing about 9in. above the deck; small rectangular windows, 9in. by 3in., let into coamings.

Coach Roof of ⅝ yellow pine, feather and groove, and covered with canvas, painted.

Bulwark of mahogany, 2in. high, fastened to covering-board with stout galvanised iron screws; rail on top of American elm 2in. by ⅜in., fastened with brass screw and dowelled.

Life Rail.—Stanchions of galvanised iron, not more than 4ft. apart, &c.

Fairlead.—Forward, of galvanised cast-iron, &c.

Companion of mahogany to main cabin, with mahogany steps down into cabin, flap to lift to get down to engine-room; also to men's room aft; the after scuttle to have light iron ladder.

Fastenings of copper or yellow metal throughout, the nails into bent frames to be clenched on rooves, the through fastening in beam-ledge and bilge-stringer to be clenched also. The centre line fastening may, however, be galvanised iron, and the iron keel is to be secured. ⅝ counter-sunk headed bolts, hove up with nuts on top of keelson; covering board to be secured to sheer streak and beam stringer with brass screws, all fastenings about deck to be brass. Fittings below, *painting and varnishing, &c., described.*

Engine, &c., 5in.. Willan's three-cylinder engine, three-bladed propeller.

Boiler.—Vertical, 4ft. in. high by 3ft. 9in. dia., shell B. boiler plate, 7-16 thick; crown of B.B. boiler plate, 7-16 thick; firebox and up-take tube best mild steel ⅜ thick, and across the firebox three Galloway tubes to be fitted of approved dia., &c., &c., &c.

Edinburgh.

MEDICAL REPLIES.

[20116.]—DIPHTHERIA (46928).—I never before heard of "the celebrated Dr. Field," and know nothing of any cases treated by him by means of sulphur. The queries as to the fungoid character of diphtheria, and its possible cure by sulphur, would lead me into a long, and, at present, unpractical discussion, for which neither time nor space can be spared. Anyone suffering from diphtheria should consult a medical man instantly—anyone who has only a theoretic interest in the subject, must consult the medical textbooks. The only practical point is, at present, that diphtheria is a highly infectious and contagious disease and that wherever bad drainage and filth accumulate, there diphtheria and its allies appear. Whether the systemic disease is the result of blood-poisoning from local fungoid growth, or the fungoid growth is a mere result of the diseased processes, is not easy to say in any of these allied diseases: but where the carrion is, there will the vultures be. Whenever diphtheria breaks out, the safety of other members of the family requires the most profuse ventilation of the sick-room, so as to carry off morbid exhalations before they are breathed by others.

CUTS AND BRUISES (46931).—I will write a paper on this practical and important subject; but at this moment am overworked and have not time.

SPRAIN (46943).—This peculiar feeling in athletes, when straining their muscles to the utmost, is hardly a "sprain," but rather a too great tension of the muscle, producing a strain for the moment. More careful action and pushing it rather less, are all I can suggest. It is probably a pain similar to that experienced in "ricking the neck." It is very foolish to risk the integrity of one's bodily structure merely for the sake of performing useless feats. Up to a certain point athletic exercises are healthful and invigorating—beyond that point they are dangerous and exhausting, and produce premature decay.

J. DENVERS (46968).—Query not answerable. Consult some good medical man, or take patient to a hospital physician, who can *see* her and examine her.

GRAVEL (46975).—Continue to abstain from all alcohol. Eat more sparingly, and starve down to normal weight, at the rate of a pound or pound and a half per week. Eat no sugar, not much flesh, and plenty of vegetables. When the gravel loads the urine, take—directly on waking in the morning—half a pint of hot water, a pinch of ginger, and a seidlitz-powder.

DISINFECTION.—The problem of dealing safely with "large quantities of clothing, bedding, furniture, rooms," &c., after they have become infected by small-pox and other diseases, say, in an hotel, is one that has often puzzled me greatly, and is one that must be adjudicated upon at the time by the responsible medical officer of health. The practical point is that, so soon as such sickness occurs, the patient should be removed into a clean, airy, but bare room, containing only the simplest and most washable things. Theoretically, all such materials as cannot be efficiently exposed to steam-heat at a temperature of 230° to 250° Fahr., should be destroyed. Practically, I rarely order such destruction unless in very special cases. A few months since, in consequence of neglect in arranging for the removal of a case of small-pox in a lady's maid at a west-end hotel, I had to adjudicate upon what was required for wealthy people coming to the hotel afterwards. The hotel was shut up, and practically cleared out and redecorated, and the cost was some £2,000. All this might have been prevented had the importance of the case been foreseen by the medical man who was called to see the case, and who "let it slide" until the patient was too ill to be removed without jeopardising her life. It may be laid down that all such materials, if put into a steam-boiler-case into which steam is turned from a high pressure boiler until it issues at a temperature of 220° Fahr. from a pipe at the other end of the steam-case will come out clear of infection after an hour's digestion. But this means destruction to much of such property as "T. R. S." inquires about. Carpets should be sent to a steam laundry, and other things must be boiled. The use of chlorine, or chloride of lime, for such property, means entire destruction. The goods come out discoloured and rotten. Small quantities of linen, &c., should be put direct into a 1 per cent. solution of carbolic acid, and afterwards boiled. I think I have already gone through this subject in the "E. M."

SEA-SICKNESS (47023).—An abstainer is less likely to suffer from sea-sickness than a user of alcohol. Take no physic in sea-sickness. It is the result of a mechanical disturbance, which continues until the muscles can co-ordinate with the unstable platform on which they are suddenly called upon to act, and digestion is therefore arrested. My own practice is to avoid the cabins where people are drinking spirits and defiling the atmosphere with vomit. Keep on deck if possible, well wrapped up, as much amidships as possible, where the motion is least and the air is clear and fresh. Take no food but draughts of thin well-boiled oatmeal gruel until the digestive power returns. All remedies are useless until the body has learned to adapt itself to the motions of its novel location.

James Edmunds, M.D., &c.

Grafton-street, Bond-street.

CALCULATING SIZE AND POWER OF BOILERS.

[20117.]—I DO not recollect to have seen the question about calculating the power and size of boilers answered. The examples given in Molesworth of the dimensions of boilers are in terms of nominal H.P., now out of date. Boilers are now calculated as actual H.P., which may be done in the following way:—

Example—Boiler-power is required for a single-cylinder condensing-engine. 20in. in dia., pressure of steam in boiler, 40lb.; speed of piston, 250ft. per min.; steam to be cut off at half-stroke. The actual H.P. of engine is therefore 40 + 15 × ·693 = 38·1 − 3·1 imperfect vacuum = 35lb. average pressure; then 314 × 35 × 250 / 33 000 = 83·2 H.P., say 83 H.P. To find the evaporation of water for 83 H.P., stroke 4ft.: 314 × 24 × 2 = 15,078 cub. in. of steam used per revolution; 15,078 × 31¼ = 471,187·5 × 60 = 2,827,125 cub. in. per hour = 16,360 6 cub. ft. of steam per hour; vol. of steam to 1 of water at 55lb. pressure = 474. 16,360 6 / 474 = 34·5 cub. ft. of water evaporated per hour. 1 cub. ft. requires ¾ sq. ft. of grate-surface, which gives 34·5 / ·75 = 25·875, say 26 sq. ft. of grate-surface; 26 × 16 = 416 sq. ft. of heating-surface, allowing 16ft. to 1ft. of grate-surface, requiring two boilers therefore, each having 208ft. of heating-surface and 13ft. of grate-surface. A boiler 6ft. dia., with a 3ft. tube, would give the following sectional area of heating-surface, viz.:—

Heating-surface in tube..........	3 75ft.
Surface under boiler	3 00ft.
Vertical sides at 3ft. each, estimated as 1 effective	3 00ft.
	9·75 sq. ft.

of heating-surface. 208 / 9·75 = 20ft. nearly = length of each boiler. Grate-surface, 13 / 3 = 4⅓ft. = length of firegrate for each boiler.

J. H.

CONUNDRUM BELLOWS FRONT CAMERA FOR 18 DRY QUARTER-PLATES.

[20118.]—FOLLOWING the advice of a correspondent of the *British Journal of Photography*, reproduced in "ours" Aug. 19th, 1881, I have made a camera of ⅜in. mahogany like his, but having only one box with bellows-front and having a sliding door at the back. I have put racks and pinion to the front for focussing, as also two narrow brass plates in front for raising the lens. The blocks for tripod I have screwed to the bottom of camera. The ruby glasses at the sides, I am sorry to say, are of not much use; weight 5¼lb. with lens; size, 10¾ by 7¾ by 5¾; the bellows are made of leather.

Cost: brass, &c., 1s.; mahogany 2s., rack and pinion 3s. 6d., lens 25s. (Lancaster's, Birmingham).

There is nothing loose except the lens of focussing-glass. Further particulars if needful.

FIG. 1.

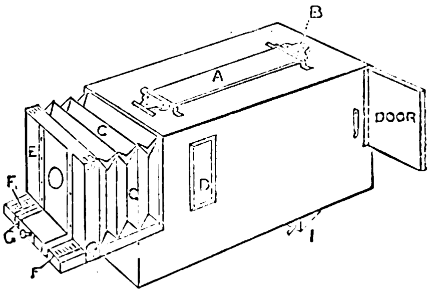


FIG. 2.

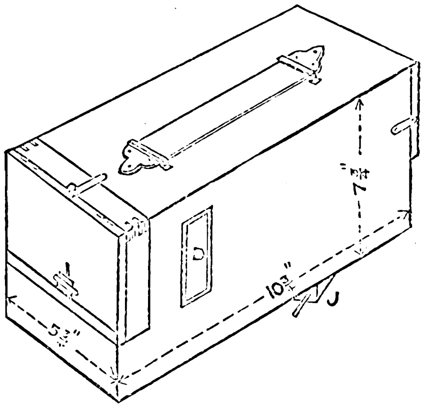

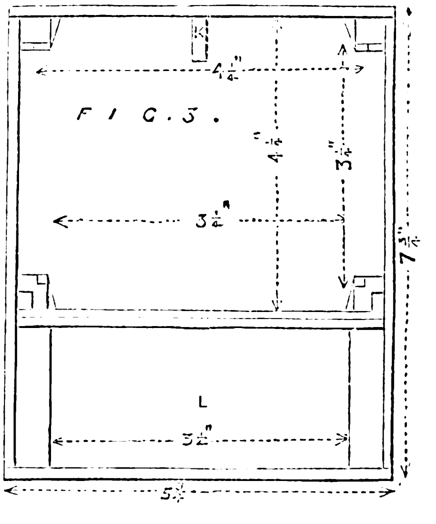

FIG. 3.

References to sketches: Fig. 1, open; Fig. 2, shut; Fig. 3, section; *a*, leather handle; *b*, brass; *c c*, bellows; *d d*, ruby glass (on each side); *e*, brass for sliding front; *f f*, rack; *g*, slot for front; *h*, for tripod; *i*, slide for fixing tailboard; *j*, three blocks screwed to camera for tripod; *k*, opening; *l*, well.

J. R. Brown.

Irthlingborough, Higham Ferrers.

GRINDSTONE TRUING DEVICE.

[20119.]—THIS tool, which is to be seen illustrated in several of the lists of American tools, seems a simple and effective arrangement for the purpose, but the price is very exorbitant, so also is Brunton's patent grindstone dresser. The prices of these tools run from £4 10s. to £10. Consequently it is quite out of place for amateurs to think of them. I have made a tool for myself that answers admirably. I have taken the lower slide of a small slide-rest, and mounted on it a small lathe head which is driven from an overhead on its spindle. I mount a cutter 6in. in diameter; this cutter is traversed across the face of the grindstone, which is revolved slowly in the opposite direction. The cutter is made out of one of Lloyd's cog-wheels, which had lost a number of teeth. I turned down the teeth till the stumps all stood up about a ¼in. above the bottom of the space, and made it the foundation of my cutter. I took this to a blacksmith, who made an old file into a ring about ⅜in. thick, and ⅝in. across the face, and this he drove in the wheel while it was red-hot, the wheel itself being cold; he put it in the vice, and with a cold chisel cut it across the edge into a very coarse file, requiring to heat it once or twice in the process to enable him to get a deep enough cut When this had been done equally all round, it was put into an iron box filled with burnt hoof-parings and placed in the fire and made red-hot, and kept so for two hours; it was then thrown into a tank of cold water, and when taken out the edge was so hard that no file could touch it. It answers perfectly, and a very few minutes suffice to give a true face to a grindstone.

The material out of which it was made, excepting the casting of small lathe-head and its mandrel, was waste, and of no intrinsic value. Exclusive of my own labour, which was my recreation, the cost of this really efficient tool was under four shillings, as follows:—

Lathe-head casting	1	0
Steel forging for mandrel	1	2
Babbit's metal for collars	0	6
Blacksmith, for fitting old file to wheel, as described	1	6
	4	2

Gereb Admi.

Erratum.—Wenham and Watson's Stands.—In letter from "Another F.R.M.S." (page 261), the last line but four should read "The additions in Mr. Wenham's *stand*" (not stage)

REPLIES TO QUERIES.

*** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[46276.]—**Newtonian Telescope.**—The large mirror should be, as you suppose, parabolic. Grind it to a spherical curve first, and flatten the curve to a parabola afterwards in polishing. Plenty of instructions in recent volumes.—Paugul.

[46346.]—**M.S.L.R. Engines (U.Q.)**—I saw the M.S.L. single-engine a few days ago, but was unable to procure dimensions. The cylinders are placed outside. The driving-wheels seemed to be 7ft. dia., or slightly over. The leading and trailing wheels have outside framing, and the driving-wheels inside; but the outside framing is carried along from the leading to the trailing wheels, and thus it appears that the driving-wheels have outside frames; but, as far as I could see, the framing was in no way connected with the driving-wheels. The engine is numbered 399, and dated M.S.L. Works, 1882, and was running express trains between Manchester and Liverpool on the Cheshire lines.—Meteor.

[46378.]—**Bevel Wheel.**—As my opinion is opposed to that of "Glatton" (see reply to query 46378 in No. 894, p. 223), I should esteem it a favour if he would give his reasons why he prefers a larger pair of wheels.—R. Kanthack.

[46394.]—**Timing French or Other Pendulum.**—I am not a watchmaker, but the expression you quote seems to me plain enough. If you examine any clock by taking the pendulum in your fingers and moving it slowly from side to side, watching the 'scape-wheel meanwhile, you will see that each time the pendulum moves to one side half a tooth passes the pallets, so that two beats are necessary in order that a tooth should pass Thus, for every tooth in the wheel two vibrations are necessary in each revolution of 'scape-wheel, and, if there are *n* teeth, there will be 2*n* vibrations of pendulum per rev. As these clocks are said by Britten to make two revolutions of 'scape-wheel per minute, we have twice as many beats per minute as there are per revolution, *i.e.*, 4*n*, or four times the number of teeth in wheel.—Glatton.

[46503.]—**Jamming of Tapered Journals.**—Imagine the part C B D not to exist, then if A B C is equal to the angle of repose, the wedge A B C would be just on the point of jamming. After going through a similar course of reasoning with regard to the lower half, B C D, we may imagine the two portions working together. This makes it clear that a wedge slanted on one side only may be half as thick at the back (in proportion to its length) as a wedge slanted on both sides. A mandrel may, of course, be considered as a circular wedge. I don't know that the jamming angle governs—I am not very sure that it should govern—the cone of a lathe-mandrel.—Paugul.

[46503.]—**Jamming of Tapered Journals.**—I am really much obliged to "J. J. A.," Liverpool, for his endeavours to help me; but though he thinks "such a rule as I require will not be readily obtainable," I feel convinced that there is such a limit as I have mentioned, and that the only question is, which of the two angles shown in my original query is correct? Let me define what I mean by "jamming." Suppose journal to be pressed with any force into bearing, and revolved slowly; the motion to be stopped and pressure removed (not reversed). If jamming has taken place, the journal will be found to be stuck (more or less tightly, according to end-pressure at first applied; but still, "J. J. A.," "if it means to jam it will be" stuck), and on applying force to move it, it gets loose with a jerk. If "the" angle is greater than the angle of repose, on relieving journal from end-pressure it will be found to be as free as ever. In the case of your water-cock, the pressure of water against one side of plug keeps the plug pressed against the opposite side of cock, and the friction prevents the weight of plug taking effect. —Glatton.

[46598.]—**Half-Chronometers.**—Your Stockton correspondent has not given a correct definition of the common use of the term. Morton's patent is an escapement never used, drawings of which are in Saunier, plate 10, Fig. 11; but half-chronometers, as they are called, are sold every day, and are lever watches with compensation balances; the term is shopkeepers' clap-trap to hoodwink customers, and nothing more. "Chronometer" is a word that can be applied to any timekeeper; it simply means a time-meter, and a verge watch or a Yankee clock is as much a chronometer as any kind of timekeeper, but as a trade term it is only applied to a watch with a detent escapement and a compensation balance. This was not always so; the word seems to have been first used by Harrison: he applied it to the timekeeper that got him the Government reward of £20,000 but his watch was not a chronometer as we understand the trade definition: it had a kind of verge escapement, a train remontoire, and a compensation curb, the remontoire to correct the variations of power in the escapement, and the curb to compensate the contraction of metals. This was, I believe, the first chronometer for which Harrison got his money, but the Government got a thing that was never used; a dozen of them never were made. The only thing used in a modern watch used by Harrison is the maintaining power, and that Reid says he got from a "roasting-jack." Chronometers are rated to the tenth of a second by the eye and ear only, and by practice, and is a very simple matter. A standard clock beating seconds is used. If you are testing, say, a marine chronometer that beats half-seconds, listen to the clock, and if you see the chronometer-hand falls as you hear the clock, it is on the second; if before, it will be one, two, three, or four-tenths fast. This you will determine by the time the hand is at rest on stroke before you hear the clock; if it beats with the clock in middle stroke, it is 5-10ths fast, and if it gets there before the clock it is 7, 8, or 9-10ths as the case may be; or if it is taken slow in the same manner, a little practice, and it is easy to tell to a tenth of a second with certainty. —T. M.

[46603.]—**Induction-Coil Failure.**—I scarcely know what to recommend, but should think the fault is in insulation of secondary, which should be two or three layers of paraffined tissue-paper. Glad you have altered the primary. Two layers of 16 only short-circuits the cell. If I were going to make a coil of your dimensions, I should have wound primary of two layers of twenty, or three layers of eighteen. If you do not succeed you may send it to me, and I will examine it.—George Tolman.

[46623.]—**Nos. of Midland Coaches (U.Q.)**—On noticing the carriages lately, I find that the vans are numbered separately from the carriages, and also that there is an innumerable amount of duplicates. Most of the small 4-wheeled coaches are duplicates, as they are now replaced by large bogie carriages. I notice also that most of the carriages in the continuous local trains in the London and Bradford districts are duplicates. Two duplicates and a van may account for the 3 carriages bearing the same number which "Dunbritton" saw.—Meteor.

[46650.]—**Electrical.**—(1) The current of a battery in absolute electro-magnetic units may be measured by means of a tangent galvanometer. Let r represent the radius of the galvanometer coil (in centimetres), and let there be only one turn; then the total length of the coil $= 2\pi r$. Then, if $i =$ strength of current, $i \times 2\pi r / r^2 =$ force (in dynes) at centre; or $i \times 2\pi / r = H . \tan \delta$, where $H =$ horizontal magnetic force at the place, and $\delta =$ the angle of deflection. Hence, $i = r / 2\pi . H . \tan \delta$. H and $\tan \delta$ can readily be found from the tables. If the galvanometer has more than one turn of wire, we shall put $r / 2\pi n$ instead of $r / 2\pi . -$. Another (relative) mode of measuring current strength is by observing how many cubic centimetres of hydrogen are given off per minute in the electrolysis of water. (2) Besides the deflections, you should know the horizontal magnetic forces at the places.—A Medical Student.

[46668.]—**Dyeing Fawn Colour.**—The following is a method of dyeing fawn on cotton goods:—First boil catechu in the proportion of 1lb. to 7 or 8 gallons of water; add, when dissolved, 2oz. of nitrate or sulphate of copper, and the solution, well stirred, is ready for use. Work the goods in this solution. Have ready some warm water, in which 2oz. acetate of lead has been dissolved. Wring out of catechu, and work in the lead solution for fifteen minutes; wash in cold water, and dry. The querist can vary the proportions almost at pleasure. If he wants household dyes he should try what he can do with Bismarck brown. There is also an iron-buff—yellower than the catechu-fawn—made by dissolving 4lb. sulphate of iron and 2lb. acetate of lead in a gallon of water. The clear liquor can be diluted at pleasure: but the colour must be brought up by passing through cold solution of soda-ash. It is really a rust colour.—N. C.

[46681.]—**Windmill Pump.**—"O." will find what he requires on p. 312, No. 325; in several of the back volumes there are devices for pumping water by means of windmills.—T. P.

[46713.]—**Bleaching Cotton, &c.**—First, for clothes or cotton goods that have not been bleached: boil the clothes in a soap ley for half an hour (yellow soap will do), rinse well in cold water, and put them into the sours for half an hour. Sours is a mixture of vitriol and water; no particular quantity is used, but the oil of vitriol is added to the water until it tastes as sour as a lemon. Now mix chloride of lime, one pennyworth to two gallons of water; rinse out of sours, and immerse the goods in the liquor (as the lime mixture is called), stir them about to let the liquor act on every part, lift them out occasionally with a stick, and the air will turn them quite white. When the process has been carried far enough, rinse well after the liquor, and hang out in the fresh air to dry. This process will not rot them, and will give every satisfaction. Caution.—Never allow these chemicals to remain in the reach of children, as they are poisonous; never use the liquor hot, or it will rot the clothes; and, remember, a thorough rinsing is necessary between each process. For ordinary linen, immerse in sours and liquor as above; or to remove stains, ironmould, &c., put one pennyworth of oxalic acid (poison) in two gallons of hot water, immerse clothes for half an hour, wring out and rinse in hot, then in cold, water, when the stains will have disappeared, leaving them white. I think this fully answers both queries on bleaching; but any further information with pleasure.—Lockstitch.

[46761.]—**Compensated Watch.**—I have been waiting to see if any one in the trade would answer this query. I also have bought a compensation balance watch, and the same kind of experience has led me to make inquiry. The result is that I learn that the "compensation balance" is simply a trade deceit. The title leads ignorant outsiders to imagine that a watch with a compensation balance is compensated and adjusted. The trade say, "How can you expect this? Look at the expense!" But outsiders cannot be expected to understand all this until it is explained. A fairly-made lever watch will keep a fairly regular rate, either losing or gaining with such regularity that the owner knows what he is about; but when the watch has a compensation balance stuck in, without being compensated, it being a delicate and sensitive piece of mechanism, the watch is seldom alike two days together. Sometimes its timekeeping is marvellous for a day or two; then, without warning, it has some eccentric variation and lets in its owner for loss of train or some other annoyance. If I had been acquainted with the difference beforehand, I should have preferred stretching a point to have a watch properly adjusted; as it is, I am saddled with an article which is a nuisance, and which yet I cannot afford to throw away. Will someone in the trade tell us if such a watch can be properly adjusted and compensated at any less cost than buying a new one?—M. F.

[46782.]—**Explosion in Loco. Fire-Box.**—The case mentioned by this querist is by no means the first of its kind, though happily it is not of frequent occurrence. Ed. Gobert says (page 244) it is the rush of air to fill a vacuum that causes this accident to happen; but he evidently has not had experience in this matter, or he would know better than to make such a statement; my own opinion is that a gas of some kind is generated by the contents of the tube, which, not being condensable, retains it pressure after all is cold, and when the plugs fit perfectly steam-tight, and the rupture in tube covered by the plugs, thus perfectly imprisoning the contents of tube, this accident may be repeated any time; but, luckily, this perfect imprisonment seldom occurs: hence the rare occurrence of these accidents.—LOCKSTITCH.

[46847.]—**Equation.**—I do not see that "A Medical Student" has solved the equation as a quadratic. Towards the end of his calculations we are introduced to an equation containing powers of β up to the fourth, and in the next line this is reduced to a cubic equation by taking out the factor $(\beta - 3)$. But how are we to know that this is a factor of the expression without solving the equation? Unless we knew that $\beta = 3$ we should have to make a good many trials. Mr. J. Lane Davies's solution, although it gives values of x, y, and z which satisfy all the equations, yet only does so by a curious coincidence. What he does, in fact, as pointed out by "A Medical Student," is to put the equation E into the form $x y / 2 - 3 = - (x y / 3 - 6)$. He then, in a roundabout way, squares both sides, by which he gets rid of the negative sign of the right-hand side of the equation. He then takes the square root of both sides, but omits to replace the negative sign; so that he gets $z y / 3 - 6 = - (z y / 3 - 6)$, or a positive quantity equal to a negative quantity. This can only be the case when these quantities are each $= 0$; and by a curious coincidence this happens to be in the present case, and $z y / 3 - 6 = 0$, from which $z y = 18$ −. This, however, gives us a clue towards the discovery of the solution, as, if we could prove the truth of this last equation, the difficulty would disappear, and no squaring would be required. But, after all, why should we expect to be able to solve the equation in the form of a quadratic?—M. I. C. E.

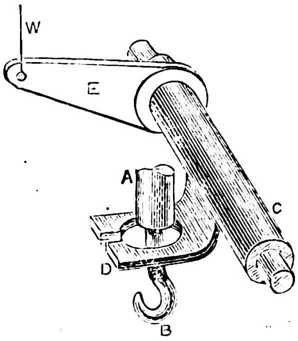
[46847.]—**Equation.**—The little real criticism which your correspondent's letter contains is frivolous though amusing, and this he prefaces with the information that "satisfying" is a relative and vague expression—for the benefit, I presume, of those of your readers who may not be in possession of a dictionary. The way he states his first objection is curious. He does so by quoting a truth well known to every tyro in algebra, viz., "Every quadratic must have, in one form or other, two roots." How the statement of a truth like this can form an objection to my solution he does not say. And then he proceeds to give a series of objections based upon the assumption that I never noticed what appeared to him *apparent*, forgetting or ignoring the fact that "apparent" is also a relative and vague expression; and he further objects to my solution on the score of its being "a very artificial one," and asks the question, "if completing the square on both sides in order to destroy them in the next line is not an 'impoliteness' to quadratics?" May I ask him if he can give any authority besides his own condemning the use of artifice in the solution of equations, and if it is not the usual and legitimate process to extract the square root after completing the square? So much for "A Medical Student's" criticism. I will only make one or two observations on the solution he has furnished. 1. It does not satisfy the conditions of an adfected quadratic by completing the square. 2. He has introduced, unnecessarily, two additional unknown quantities into the equation (an artifice, by the way, which he thinks others should not adopt), and which only succeeds in producing a cumbrous biquadratic expression, which is found by trial to contain the factor $(\beta - 3)$, and, moreover, his method of finding a factor is the most circuitous and bulky that has yet appeared in this journal, which, upon his own authority, is a great mistake in the science of mathematics.—J. LANE DAVIES.

[46850.]—**Electro-Magnet.**—If "Perplexed" will wind on each core five layers of No. 20 cotton-covered wire, it will make a first-class magnet. The resistance will suit a bichromate or Bunsen cell.—GEORGE TOLMAN.

[46862.]—**Telegraph.**—Wind twice the length of wire on the coils, than the line, if of the same gauge.—GEORGE TOLMAN.

[46865.]—**Cod-Liver Oil.**—When I was in Newfoundland five-and-twenty years ago I had symptoms of lung-disease, and was ordered to take cod-liver oil, to which I took a great disgust. I was, however, determined to overcome my reluctance to it, and went to see its preparation. I observed that the livers were allowed to get semi-putrid before the oil was extracted, so I procured some fresh cod-livers, and had them fried with mashed potatoes. I found them delicious, and really enjoyed my potato-cake fried in cod-liver oil taken from livers the day the fish was caught. In the winter I always had myself sponged with cod-liver oil all over after having my bath. As the oil was fresh and scented with essence of bergamot, it proved no inconvenience, and I found it was equally useful in this form as if taken internally.—GEREB ADMI.

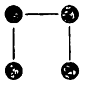
[46854.]—**Mechanical Action.**—I am sorry my first design was of no use. Will this do? Over each cell is a sort of bolt (A) sliding in guides (not shown) attached, like brackets, to sides of chest. The lower end is turned to a smaller diameter, and bent into a hook, to which the rod from zinc is attached. C is a rocking shaft, worked, as in former sketch, by means of a lever E, and wire W, from lid of chest. The lid, therefore, cannot move without rotating C, and in order to fix the lid, all we need do is to fix C. A piece of brass, D, has a hole of shape shown cut in it, and is fixed, like an arm, on C. The rod A passes freely through this hole, but the rod C (and, therefore, the lid), is locked, unless the narrow part of A is in the position shown, when the slot in D allows of the motion of C.—GLATTON.



[46867.]—**Bichromate Battery and Intensity Coil.**—You can have a coil to work with any number of cells. I cannot suggest a better cell than Bunsen's for lighting.—GEORGE TOLMAN.

[46871.]—**Platinising Silver.**—May I suggest to the querist whom "Nun. Dor." has replied to, another mode of rendering Smee's plates available without platinising, which I, some twenty years ago, "evolved from my inner consciousness," on finding that my plates were bare, and no platinum was to be got? It simply consisted in thoroughly cleaning the silvers, placing them on a surface of soft wood, and then piercing them well with holes with a fine needle. The rough burrs round the holes evolved the hydrogen at a tremendous rate, and the plates never wanted anything more doing to. Mere roughening is not of much use. I saw some pierced plates in an "air battery" at the present C. P. Exhibition, but I have seen none anywhere else, except mine.—B. H.

[46879.]—**Telephone Transmitter.**—At your request I send you description of transmitter. It is the arrangement of one of my assistants. Although simple, it more justly deserves being patented than any other I have ever tried. It consists of 3 pencils and 4 blocks. I have arranged it so that the compositor can set it up in lines and dots, thus—



The two free blocks are for connecting-wires. The pencils are ⅜in. square and 1¾in. long, cut from coarse-grained carbon, not lighting pencils, and are fixed on the centre of a horizontal sound-board of pine or spruce, ⅛in. thick, 8in. by 6in. It is the loudest and clearest of any, and never fails. The coil should be 1¼in. between flanges, 5-16 core. For primary wind 5 layers silk-covered wire, No. 24 gauge. Secondary, 10 layers, 35. Bell's receiver is all that can be desired. About 20 miles.—GEORGE TOLMAN.

[46892.]—**Japanning.**—This is quite unnecessary on copper vessels. Nothing can look better than the polished metal. In India copper vessels are often tinned to save trouble in cleaning. You can tin them yourself if you first clean them thoroughly. All you have to do is to heat them to the temperature at which tin melts, and rub them with powdered sal ammoniac, rosin, and melted tin. I have seen this done frequently by the Kalai Walla (tinman), in India.—GEREB ADMI.

[46899.]—**Heating Room for Turkish Bath.**—This can be done most economically with gas. Some sixteen or eighteen years ago I experimented a good deal on this matter, and was, I think, fairly successful. I took my idea of a hot-air bath from "Griffin's Hot-air Bath," No. 1281, illustrated on page 131, and found it efficient; this supplied me with hot air, but I had to devise another arrangement for ventilation, and for getting rid of the air charged with perspiration, and I made the whole apparatus myself out of the cheapest material. I shall be happy to write a paper on the subject.—GEREB ADMI.

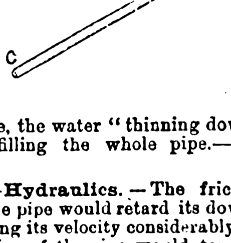
[46912.]—**Medical Coil.**—Wind on four layer No. 20 cotton-covered wire; six or eight layers No. 28 silk-covered for secondary. Fill the core with iron wires, and work the contact-breaker from the end. A brass tube placed on the outside of coil will regulate it to any nicety. If you cannot get a brass tube, copper will do, or get the tinman to make one in tin or zinc. A bichromate cell would work it, or two Leclanchés would work it for 20 minutes or half an hour.—GEORGE TOLMAN.

[46916.]—**Carpenter's Bench.**—You will find full instructions in a monthly periodical named *Amateur Work*, and if you have access to the back vols. of the ENGLISH MECHANIC you will, no doubt, after some searching, find what you want. At p. 271 of *The Forge and Lathe* there are full instructions, illustrated, for making a cabinet-maker's bench.—GEREB ADMI.

[46925.]—**Water in Gravel-Pit.**—I am truly obliged to "Glatton" and H. Barnaby, but I fear the difficulty will not easily be got rid of. No doubt I ought to have given more detailed information about this particular gravel-pit, which I will now try and do. At 9ft. deep I come to spring water, but on account of the slope of land and the use of a 6in. drain I can go 12ft. deep, and if I could only get rid of the water at a lower depth I could go 20ft. or 30ft. deep; hence my difficulty. I dug a well some two years since 18ft. deep, and I found the soil as follows:—2ft. of top soil inclined to be a little loamy or clayey; next 4ft. dirty round gravel, the next 12ft, a mixture of clean fine sand and gravel; the sand increased towards the 18ft., and I am inclined to think the lower I could go the more fine white sand I should find, as within half a mile of this spot the main sewer was put in about 100ft. deep, and it was all white fine sand—some call it silt, or running sand. I do not think there is a substratum of heavy clay, as H. Barnaby supposes, but am inclined to think the sand would lie so close that water cannot pass easily through it. I fear this subject will not be very interesting to the majority of readers, and may be taking up valuable space. If "Glatton," H. Barnaby, or any other kind friend would write to me, shall esteem it an act of great kindness.—H. BOOKER, Sidcup, Kent.

[46927.]—**Gas Bath.**—If paraffin would dissolve the lime I should think your plan of cleansing it would answer; but I would suggest you fill it from the bottom pipe the same as it now fills with water, afterwards I should well swill it out with water from the top pipe, and if the first operation does good service, I should repeat it several times. It is the only thing you can do to it besides having it taken to pieces and thoroughly done, which would be more expense and trouble than making a new boiler. These boilers are not a coil, but made up of sheet water-space layers so constructed that the heat from the burner acts on every inch of boiler surface. Geyser's instantaneous water-heaters would not heat the thirty gallons of water in the half-hour for the same consumption of gas. The establishment in question (which has died out) used to make some good and useful articles on principles which modern makers, though different in shape and design, strictly adhere to. Their forges were lit and worked by gas twenty years ago. People reinvent things and make them the subject of "patents."—JACOB MACLOSKIE.

[46930.]—**Hydraulics.**—In practice I think the pipe would be quite full, unless the diameter of the pipe is altogether out of proportion compared with the tank. But theoretically there would be an air-space or a partial vacuum near B, as shown in the figure, the water "thinning down" at first, but soon filling the whole pipe.—A MEDICAL STUDENT.



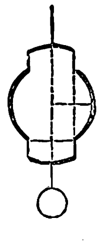
[46930.]—**Hydraulics.**—The friction of the water on the pipe would retard its downward progress, keeping its velocity considerably below what the inclination of the pipe would tend to make it, and tending, therefore, to keep it full. And if the head of water were large, the pressure at B being great the friction would be much increased, tending still more to keep the pipe full. But every increase in the size of the pipe increases the volume of the water much more than the friction, and tends to keep the pipe less than full. So that the question of whether the pipe would be full at the mouth depends on the pressure at B, the inclination and length and diameter of the pipe, and the value of the friction, and not only upon relative, but actual, sizes.—PAUGUL.

[46931.]—**Cuts and Bruises.**—Why do not some of the workmen join a centre of St. John's Ambulance? They would then learn the best methods, and be able, in case of need, to stop arterial as well as venous bleeding. "Ambulance Lectures," by Dr. Weatherly, price 1s., is a capital book, as is also one by the late Surgeon-Major Shepherd.—M. W. G.

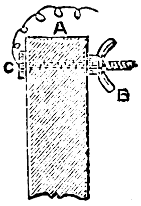
[46931.]—**Cuts and Bruises.**—I have no experience in the treatment of these with the glue, French polish, or black ink recommended by your correspondents; but I can speak very highly of tincture of arnica for bruises, and of calendula officinalis in cases where the skin is abraded or cut. They not only heal quickly, but take the "sting" out of the wound directly they are applied. A lotion is made of either of these by putting 30 drops of the tincture in a teacupful of cold water. A rag wetted with the lotion should be kept continuously applied to the part. These tinctures, with a little court-plaster, should be kept in every workshop.—DOCTOR.

[46931.]—**Cuts and Bruises.**—Some of your correspondents recommend glue and Friar's balsam; and so do I. Glue is handy, and of a healing nature. Friar's balsam is a most excellent thing, and one I am never without. In case of a cut from a chisel, wipe off the blood, apply the balsam, and bind up with brown plaster. I always find the latter better than the common yellow plaster. Being a joiner, I have seen some serious cuts now and again—some which have required the skill of the surgeon; but in ordinary cases, I have plastered up some hundreds of bleeding fingers. Some men shrink from these jobs. In extreme cases I have staunched blood with castor-oil. This is an excellent thing, and with two or three thicknesses of soft rag, will heal the place as well. I believe many a chemist is not aware of this.—FISHER SHAW.

[46942.]—**Resistance of Ring to Collapse.**—The maximum bending strains or moments when the ring and weight are suspended, will be at the top and bottom and at the two sides, and these will be all equal. This can be shown by the elementary rules of statics. The strains at the sides will be of an opposite description to those at top and bottom—the former tending to straighten the ring and the latter to make it curve more; hence there will be some point in each quadrant of the ring where there will be no bending strain. These points are called "points of contrary flexure." The position of the points is found by bisecting the radius on both sides of centre and drawing perpendiculars; it will be shown presently why this is so. At these points the only forces acting are the shearing strains caused by the direct action of the weight; we may, therefore, to make the calculations more easily understood, cut the ring at the four neutral points, and connect the pieces by very strong suspending links, as in the figure; the lowest piece may be taken as a beam supported at the ends and weighted in the middle—the bending moment of which is the well-known formula $Wl/4$. In this case l, or length of beam is = half the diameter of the ring—say, $d/2$, so that the bending moment is $Wd/8$. Again, the bending moment at the side of the ring is found thus: the crescent-shaped portion of the ring sustains a weight of $\frac{1}{2}$ W applied to its lower end; this multiplied by the ver. sine of the crescent, or $\frac{1}{4}\,d$, gives the bending moment at the side of the ring, or $Wd/8$. As this is the same as the bending moment at the top of the ring, it shows that we have found the points of contrary flexure correctly. All we have to do now is to find the "moment of resistance" for the particular section that the ring happens to be. Suppose the section to be square, as this is the simplest form, and let its side $= x$, which we have to find. The moment of resistance for a square is $Cx^3/6$. This is to be equated to the bending moment, or $Wd/8$. The Constant C may be taken at 5 tons for a safe load. W is 13 tons, and d, 8in., so we have $5x^3/6 = 13 \times 8/8$, from which x will be found to be about 2½in. The diameter of the ring is supposed so be measured from centre to centre of the square iron.—M.I.C.E.



[46944.]—**Battery.**—This query was addressed to Mr. Lancaster, but I hope I shall not be intruding to answer it. The best way would be to electrotype a copper head on the carbons. The batteries sold have a lead cap cast on, as you supposed. I beg to suggest a little plan I have tried with success. It consists of a brass rod with a head C. The rod is screwed. It passes through a hole bored in the carbon, and is clamped tight by means of the butterfly nut, B. The connecting wire may be soldered, as shown, or twisted round the rod before screwing up the nut. A is a section of carbon. To prevent corrosion of the connections, paint them over with melted paraffin-wax.—BEETLE CRUSHERS.



[46945.]—**Leclanche Battery.**—Take the cells to pieces, and well wash the broken carbon. Ordinary sal-ammoniac, clean water, and not the slightest trace of grease.—GEORGE TOLMAN.

[46945.]—**Leclanche Battery.**—You had better have new porous pots, as no doubt they have become choked with crystals, as also the carbons. You might be able to clear them by boiling them in water for several hours, but this you could only partially do, as insoluble matter has (after all that time) penetrated them as well as soluble. Pure sal-ammoniac should be used.—BEETLE CRUSHERS.

[46949.]—**Sodium Salts.**—I should say, in all probability, there is hydric sodium tartrate. Both the precipitates produced by KHO and NaHO would be soluble in an excess.—J. C. BELCHER.

[46949.]—**Sodium Salts.**—You mean bitartrate of soda, a salt very useful in analysis for the detection of potash. Caustic soda may be used in most cases as a substitute for caustic potash, the reactions being identical. I allow the students in my laboratory to use either, it being a matter of which comes first to hand.—EXPERIMENTER.

[46949.]—**Sodium Salts.**—There is such a salt as the one you mention. The formula you write is quite correct. Caustic soda, or sodic hydrate, will precipitate, when added to a zinc salt, the white zinc hydrate. Caustic potash or potassic hydrate produces the same precipitate. This precipitate is soluble in excess of the reagents also in ammonic hydrate or ammonic chloride. Re-precipitated almost entirely on diluting with water, or on boiling.—THOS. RICHARDSON.

[46952.]—**Reaction.**—Both salts named being "commercial," contain impurities in the shape of alumina, silica, iron, magnesia, and possibly lime. Those present in the salt (NaCl) would be precipitated by the carb. of potash, while those present in the latter would fall immediately on making a solution.—EXPERIMENTER.

[46952.]—**Reaction.**—If your NaCl and $COKO_2$ were pure, and if these were really the salts you used, I think no precipitate should have been given. Possibly your NaCl contained magnesic chloride, in which case you would obtain a precipitate of carbonate of magnesium, leaving KCl, &c., in solution.—THOS. RICHARDSON.

[46952.]—**Reaction.**—The precipitate was no doubt caused by some impurity in the salts: in order to find out of what the precipitate consists, it would be best to analyse it if the querist possesses the necessary things. The following reaction would take place:—$K_2CO_3 + 2NaCl = Na_2CO_3 + 2KCl$.—J. C. BELCHER.

[46953.]—**Pearlashes.**—The ordinary method of assay with bichloride of platinum, if done with care, will give very accurate results, and may be relied upon to give results varying no more than ¼ per cent or less.—EXPERIMENTER.

[46953.]—**Pearlashes—Estimation of the Potassium Carbonate.**—The main thing is to possess a correct standard solution of H_2SO_4 (1cc. = 040) standardised by precipitation with $BaCl_2$. The analysis is performed as follows:—10grm. of the sample are dissolved to 500cc. with distilled water, agitated, and filtered if necessary. Measure off 50cc. (corresponding to 1grm. of the sample) transfer to a beaker, add a little neutral tincture of litmus, and add from a graduated burette the standard H_2SO_4 until the liquid has a reddish tinge; if now the solution be boiled, the blue colour will be restored owing to the CO_2 being driven off; add a little more standard acid till the liquid is violet, and again boil; repeat this until the solution is neutral, and boiling no longer renders it alkaline, taking care not to make the solution acid towards the end of the operation, if you do not happen to have a standard solution of sodium hydrate at hand to work it back with. Each cc. of the standard H_2SO_4 = ·069 grm. of K_2CO_3. With care this ought not to differ more than ·5 per cent. on the same sample.—J. C. BELCHER.

[46954.]—**Dividing Apparatus.**—To F. W. MACKENZIE.—Referring to p. 277, Vol. XII., ENGLISH MECHANIC, I see that a Mr. Joyce is mentioned whom I have forgotten long ago. I overlooked this query at first, and have been very busy since. If you merely want to drill a division-plate for ordinary lathe use, the plan I mentioned would be found near enough, and a great deal more accurate in its results than a good many by the "best makers" are. But, again, if you want to make a "dividing apparatus," it is worth doing well if at all, and for this purpose the edge of the dividing-wheel itself must be made of two flat rings, bolted together so as to be able to alter their relative positions, and by comparing together different groups of their teeth, in order to ascertain the truth of every part of the circumference. I have a strong idea that I described this method of making a dividing-wheel many years ago, but at the present moment I cannot refer to my private index of these matters in the ENGLISH MECHANIC, that for me have more particular interest, as I have lent the book containing it to a correspondent of the paper who has hitherto proved as deaf as I am physically to my prayers for a return of the same. As to size of a tangent screw, within moderate limits, one might say, the greater the diameter the better; not less than three times the acting thickness of the wheel into which it works. Then a wheel (that is to say, a "cut" wheel, finished by means of a screw-hob), of which the thickness is ⅝in., should have a screw nearly or quite 2in. diameter; otherwise it is almost, or, say quite, impossible to get the wheel-teeth what they ought to be in a good job. Remember, the less you leave for the finishing-hob to do, the better for your peace of mind.—J. K. P.

[46955.] — **Elementary Optics.** — Spherical abberration results from the surfaces of a lens being spherical, thus bringing the outer rays to a focus nearer the lens than the more central rays. This is clearly a result of the outer zones of the lens being too much curved, so we have to flatten them, the amount of the flattening depending upon whether the rays are parallel, divergent, or convergent, and so on. This is a simple case, obtaining freedom from spherical aberration (aplanatism) in a single lens, but I believe it answers the query, how is it done? The conditions of aplanatism in objectives, microscopic and telescopic (which are aplanatic as well as achromatic) is necessarily more complex, and could hardly be usefully stated in the "Reply" column.—PAUGUL.

[46957.]—**Battery.**—Make the following solution: 100 parts of water (by weight), 10 parts of cyanide of potassium, 1 part of cyanide of silver. Place the solution in a jar, across the rim of which then lay two metal rods. From one rod suspend in the solution by a metal wire the articles to be plated, and from the other by a silver wire, a piece of silver. Connect the rod with the poles of the battery, and leave until the plating is sufficiently thick. For gold plating or gilding, 1 part of dry chloride of gold, 2 parts of cyanide of potassium, 100 of water. The articles to be plated should be thoroughly cleansed from grease, &c. The expense of gold-plating is such that I do not think it would repay "Amateur." Electro-plating is explained in a book called "Magnetism and Electricity," by Fred. Guthrie. Collins' advanced series.—W. F. K.

[46961.]—**Battery.**—To MR. TOLMAN.—Have you soaked only one end of the carbon plates? The wax will scrape off clean with a file. You must have two carbon plates in each cell.—GEORGE TOLMAN.

[46961.]—**Battery.**—It is the paraffin-wax that has prevented the action of the battery. Stand the plates on the kitchen-stove till the wax has all melted off. Another time do not dip the plates in the wax, but paint it on the parts required with a brush.—BEETLE CRUSHERS.

[46967.]—**Coin Brooches.**—To "ALFOJOE."—I beg to dissent from your assertion, my friend "Revel," that binding wires are out of the question in soldering coin-jewellery. If the wire you use is of a consistent size (it may be got as fine as silk if you need it), you may solder any sized coin and ring. I never have any difficulty, but I own it was not so in "the long ago." Experience has taught me little expedients in the work. I give you a couple of figures to illustrate my mode of binding and holding the rings, &c., in position, while soldering them together. There are other ways, but I give these as the most simple way I know. Fig. 1 shows the ring bound in position upon the coin, and held in a pair of pliers B, Fig. 1. The solder in very small pieces is placed on each side of the ring at A; borax having previously been applied and the moisture expelled by a low heat. The wire should be so arranged as not to touch the coin just where the ring is to be attached, and should only touch the ring sufficiently to hold it in position. Another way, as in Fig. 2, is to lay the coin upon a flat piece of charcoal or pumicestone, and bind it across with a piece of wire to prevent slipping, as at B. In this figure you will observe that the ring is held by a wire, which in its turn is held by the thumb or finger, the coin being securely bound, as before mentioned. Whichever plan is adopted, the after-part of the work is the same. Bring the heat gently up with the blowpipe, taking care to keep the solder over or near where you wish it to run. Do not play the flame upon the ring, but just away from it; blow steadily and without force. It will be a little help to you if both the coin-edge and the edge of the ring are squared off with the file. The ring is then more likely to keep an upright position during the process of soldering. The smallest coin ever made can, I am sure, be manipulated in this way.—Alfojoe.

FIG. 1

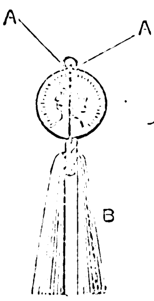


FIG. 2

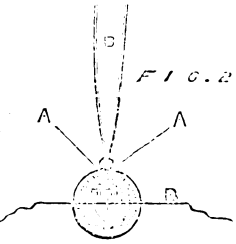

[46973.]—**Musical Shorthand.**—The book you inquire about, entitled "Musical Shorthand for the Representation of Harmony as well as Melody," was written by J. Walis, and published in Ryde during the year 1875. I am unable to give publisher's name.—Fred. T. Gissing, Shorthand Writer, Lincoln.

[46976.]—**Canary.**—Your canary does not suffer from asthma. Birds so diseased hardly ever sing, and when they do it is with difficulty. The heat of the gas stifles the bird, especially if it is hung close to the ceiling, the heat being greater overhead. Remove the bird into another room where there is no gas, or place a piece of thin muslin over the cage at night.—A Breeder.

[46977.]—**Folding-Canoe.**—A folding-canoe is a very troublesome thing to make, and not entirely satisfactory when made. The best form is that which consists of curved longitudinal ribs or ribbons, hinged at the stem and stern so as to fold down flat upon the central frame of kelson, stemson, and sternpost, something like the hood of a phaeton. But if "G. J. H." tries to construct his canoe on fairly fine lines, he will find the attachments of the curved ribs very difficult, and the connection of the solid floor or battens nearly as much so. By carefully studying one of the Rev. Mr. Berthon's folding-boats, which, however, are always made with bluff bows and round sterns, he may succeed in making a more or less shapely canoe. A simpler plan is to get two thin, straight-grained white deal boards, 9ft. long, 9in. wide, and ¼in. thick, strengthening the inner edges of these by nailing a strip of ash or beech ⅝in. square, and hinging them together at the ends, so that they will lie parallel and flat, and yet can be sprung open to a width of 2 or 2½ft. in the middle. The hinges at the ends may be fastened to an upright piece 9in. long, 3in. wide, and 1·5in. thick at the inside edge, tapering to nothing outside, but slightly rounded. Or one of each of these uprights may be nailed to one end of each of the sides, a ¼in. deep, 8in. wide, rabbet being made to receive it, two ½in. 3-holed brass hinges being used to fasten the other ends of the sides to these upright pieces, which will act as stem and stern-post. The bottom may be made of thin white deal, ⅛in. thick, strengthened by cross pieces ½in. wide and 1in. deep. These cross-beams should be 6in. apart amidships, or even less, gradually becoming wider apart, until at the ends they may be 1ft. or more from each other. The bottom must be cut to such a curved shape as will fit between the sides when opened out, and should be 25in. or 26in. in the widest part, which should be at about three-fifths of the length from the head of the proposed canoe. The cross-beams should project ⅝in. beyond the edge of the bottom, and should be notched out so as to rest upon the upper edge of the lower strengthening fillet. Four feet of the bottom should be covered with strips of ¼in. thick deal, 2in. wide, with inch spaces between them, to form a floor for the canoeist to sit on. About 1ft. of this floor should be behind (abaft) the centre of gravity of the canoe, and the rest before it. To keep open the upper part of the canoe, two cross pieces must be fitted, which may be about ⅝in. thick, 2½in. wide, and at their ends pieces of sheet iron or brass must be screwed, and bent down at right angles so as to clip the outside of the top edge, and means must be provided to prevent these cross pieces from slipping out of their places. The aftermost of these cross-pieces will support the canoeist's back-board, the other the stretcher for his feet, the lower edge of which may be hinged to the forward end of the floor. Finally, a covering of elastic tarpaulin, or, better still, of that strong india-rubber cloth used for waggon tilts, must be put over all. This may be nailed to the woodwork with flat-headed wire tacks, or made loose, and just drawn over the frame, and made so that it can be laced across the top of about 2ft. of the fore and after part of the canoe. Such a craft would require a light double paddle, about 7ft. long, with blade 6in. or 7in. wide. Indian shape is the handiest. It is convenient to have the paddle in two pieces, jointed like a fishing-rod, by a bit of stout brass tube. A 6ft. bamboo mast could easily be added, passing through a hole in the forward cross piece to a step on the floor, and a sail made of one breadth of 48in. or 50in. linen or cotton, bleached or unbleached, the fore leach 3ft., the after leach 5ft., bent to a light bamboo yard; but the canoe would only sail before the wind. The weight of this craft would be about 30lb. She would carry about 60lb. for each inch of immersion—that is, about 3in. with a sitter of 10st.—Robinson Crusoe.

[46978.]—**Canaries.**—You either give them improper food, or your cages are placed in an unhealthy spot. Examine the nests and see whether the young birds were troubled with vermin. I have lost many from that cause.—A Breeder.

[46983.]—**Concrete Bed for Engine.**—For making the concrete use one of Portland cement, four of gravel, and two of sand; the gravel and sand must be perfectly free from loam if you want good concrete. You cannot have anything better for engine bed; and where you have a good surface a loamy sand will answer very well. Mind and get the bottom on solid ground.—F. R.

[46984.]—**Hardening Copper.**—I suppose you mean sheet-copper. It can only be hardened by hammering it—a feat not to be performed by a novice. It requires a skilful hand to do it.—Jacob Magloskie.

[46985.]—**Gilding the Edges of Mounts.**—Have tried the gilt paper, but never made a decent job, and now use for the purpose the ordinary "liquid gold" (fine gold-dust in ether), sold by the water-colour makers, and can make them look well. Can be laid on either with a fine brush or a pen, just according to width required. You can have it either dull or bright, just as you fancy.—Experimenter.

[46987.]—**Tinning or Bronzing Small Malleable Castings.**—To tin, lay the articles in a weak solution of oil of vitriol and water to cleanse off all dirt; then rub them over with spirits of salts and dip them in molten solder; wipe clean while hot. For the others use copper bronze paints.—Jacob Magloskie.

[46987.]—**Tinning or Bronzing Small Malleable Castings.**—10 parts diamond fuchsin and 5 parts Hofman's methyl violet, are dissolved in water or sand-bath in 100 parts alcohol of 95 p.c., then add 5 parts benzoic acid, and boil from five to ten minutes, until the whole has acquired a brilliant bronze colour. This varnish adheres firmly to all articles, possesses a beautiful gloss, and is very durable.—B. P. Bismarc.

[46988.]—**Straightening Shaft.**—Certainly this can be done, by means similar to those used upon railway and tramway rails, &c. Have you not observed men at this? A strong frame, shaped like the letter Y, has a powerful screw in the middle; the ends are claw-shaped, and grasp the rail or shaft, and the screw is brought to bear upon a chalk-mark indicating the hump. Experience teaches the amount of bend in the opposite direction necessary to straighten the shaft.—J. J. A., Liverpool.

[46990.]—**Ships' Compasses.**—Ships' compass needles are generally magnetised by rubbing with a permanent magnet; but the easiest way is to use, if at hand, a coil and a battery, looking out to put the needle in through the coil the right way, by first magnetising a needle, and trying its polarity. Of course, anybody who has studied the subject would know the polarity of the coil at once by the direction of the current.—Torpedo.

[46990.]—**Ships' Compasses.**—The best way is to place the piece of metal in a coil through which an electric current is made to pass; but you would probably find it quite sufficient to rub it with an existing magnet, rubbing the end you wish to be the north or blue end with the south end of your magnet, and always taking the magnet up from the centre of your intended magnet. If your compass needles are, as they should be, of about the size of knitting-needles, the above method will do well.—Paugul.

[46991]—**Wages.**—It seems to me most unlikely that you have set out the whole of the facts, and in your case there may be some special circumstance which would affect the advice to be given you; but I may state, as an abstract point of law, that wages, whether payable weekly or otherwise, like any ordinary debt, may be recovered at any time before the claim is barred by the statute of limitations.—Schyremote.

[46994.]—**Brass Door-plates.**—The composition was merely sealing-wax run on the plates when they were hot, and then scraped off with a scraper.—Beetle Crushers.

[46995.]—**Sutton's Storage Battery.**—The answers depend upon the conditions, which are not stated. If the electromotive force of the dynamo exceeds that of the secondary sufficiently to be able to send a fair current into it, the cells should be charged all at once in series. If this is not the case, a simple commutator should be used, which will reduce the series enough to allow the current to pass, and to place them also in multiple arc so as to divide the current among them. There is no danger in handling, but there might be a slight shock, which indiarubber gloves would prevent.—Sigma.

[46997.]—**Piano Warranty.**—Without knowing the exact words used in the warranty given, it is impossible for me to say what would be its legal effect. But as the piano seems to have been in use for three years, the broad question would probably be whether the strings have broken by reason of any defect in the manufacture or through wear and tear. If from any defect, the makers would most likely be liable upon their warranty to repair them; but not so in any other event.—Fred. Wetherfield, Solicitor, 2, Gresham-buildings, Guildhall.

[46997.]—**Piano Warranty.**—To Mr. F. Wetherfield or Mr. W. H. Davies.—The "warranty" of a piano is simply a responsible declaration that it is well and substantially put together, and is of good and properly-seasoned material. Such a fault, for example, as a continued liability to broken strings would, if it could be traced to a faulty scale, prove that it was not well made, and would render the guarantor liable either to make good the defect, or to exchange it for a new piano. But if it could be shown that the number of broken strings was not greater than might reasonably have been expected, from the amount of work it had received, or that it was caused by rusty wires, the maker could not be held responsible, since he could not be expected to exercise control over the piano after it had left his hands. Though, in the latter case, I think few makers would claim total exemption (unless they were threatened with legal proceedings), but would, for their own credit sake, willingly bear a portion of the expenses of repair. In the instance referred to by Mr Jones, the rusting of the strings was evidently caused by the cloth that underlies the strings having become damp. I have often known this to be the case, and believe it to be the effect of acetates used in dyeing the material, and, on this account, use none but self-coloured woollens for the purpose. This is, however, rather a delicate point of law, on which I would rather not give an opinion. The phrase "loose touch" is rather vague, and may mean either that the touch requires less pressure, or that the keys have begun to rattle. If the former is meant, it is not usually considered a disadvantage; but it may easily be rectified by adding to the balance-lead at the end of the keys. If the keys rattle on their pins, it can only have been caused by constant wear, and would be quite outside the conditions attached to the warranty.—W. H. Davies.

[46999.]—**Piano Repairs.**—To put a new string on an upright piano, it will, first, be necessary to remove the action, which is kept in its position by steady-pins and buttons. After turning the buttons, the action should be pulled forward at the top, and then lifted out of the dowel-holes at the bottom. If the damper-rail is attached to the action, it must, of course, be removed with it; but if otherwise, it will make the action lighter to handle if it be first removed. The bottom door may be taken out like the top door. The wrest-pins belonging to the broken strings may then be taken out by unscrewing them with the tuning hammer. One end of the new wire should then be pushed just through the pin-hole, and about a couple of turns given to it from left to right, when the wrest-pin can be hammered into its place, and the wire passed round the hitch-pin, or pins, at the bottom, and cut off about 2in. above the pin it is intended for, and treated as before. The wire may now be guided between the bridge-pins; but before tightening it will be necessary to see that the wrest-pins are knocked into their proper level, and that the wire is at the bottom of the hitch-pins. I should strongly advise a renewal of the cloth that seems to have caused the injury; the strings may then be cleaned from rust with a little fine emery-cloth, and slightly oiled to prevent a recurrence. In replacing the action, it must first be allowed to drop into the dowel-holes, and then slightly pressed forward at the top until it is felt to slip into its place. The operation is perfectly simple, and in no case should force be exercised, for if this is necessary there must be something wrong. The best motto to be observed in all such cases is to take your time, and not to get in a flurry if things do not seem to go right just at first.—W. H. Davies.

[47003.]—**Storage Battery.**—What kind of gain is proposed in using a storage battery (which is sure to waste a large part of the energy put into it, and would require constant attention) to do work which a simple battery will do? Of course it might be used if there were means of occasionally charging it from a cheap source, such as a dynamo; but to charge by a battery in order to do no work but what a battery would do better, is mere waste. A storage battery so charged is useful only when we want to accumulate the prolonged work of a small battery so as to apply it, and get the results for a short time of a powerful battery.—Sigma.

[47006.]—**Collodion Balloons.**—The usual method is to take a glass-flask the size of the required balloon, and pour sufficient collodion in to form a coating all over, and then to pour the surplus out. Then, while wet, take a quill and move it round inside the neck, so that the collodion then sticks to it on all sides. Then suck the air out through the quill, which will make the balloon collapse, so that it can be drawn out through the neck. —W. H. L. H.

[47006.]—**Collodion Balloons.**.—Clean a flask of 4 to 6in. dia. well, and pour into it collodion, that from the least highly nitrogenised gun-cotton being the best. Now turn the flask round so as to coat the whole inside of the flask; invert it, and pour the superfluous collodion out. Let the film dry. Now twist the edge of the film on a quill let down into the neck of the flask, and draw the balloon out; but be careful to arrange matters so that the air can freely escape as the balloon leaves the flask.—R. Kanthack.

[47008.]—**Ferrous Oxalate Developer.**—I find those negatives, developed with the above, intensify with mercury better than those developed with Pyro, as I could never get the latter quite white. —W. E. K.

[47008.]—**Ferrous Oxalate Developer.**—There are only two methods that I know of for intensifying a plate developed by the ferrous oxalate developer—one before varnishing, and the other after. (1) Having developed the plate, wash it and expose to sunlight until the unaltered silver salts take a brownish colour, then proceed as usual. (2) If, after varnishing, iodine be added to some more varnish till it becomes of a light port-wine colour, and the plate is revarnished with this, the plate will be found to be intensified. I learnt these methods from Capt. Abney's book on "Instruction in Photography."—F. H. H.

[47010.]—**Magneto-Electro Machine.**—(1) Take a coil of wire through which the current passes, and move it along the horseshoe, always in one direction from end to end. The resistance of 60 cells would be very great, as they are so small. I should join up half in multiple arc, or even more. (2) You could use the machine-magnet to magnetise the steel one. (3) Coils to be wound so that if horseshoe were straightened out, the wire would always be wound in the same direction.—W. H. L. H.

[47014.]—**Steam-Power.**—You will probably not be interfered with by any official for using a steam-engine. But I can speak from experience as to the way in which the water company will mulct you. I find that the best way to be comfortable all round is to have a gas-engine.—O. P. Q.

[47015.]—**Portable Greenhouse.**—I would not advise "Glatton" to botch up his greenhouse in the manner he mentions, as it would be a very unsightly object. Widen the grooves for the glass, so that the panes overlap in the usual manner to allow the rain to run off; and, if necessary, get another pane or two of glass, and fill up the grooves with putty.—Os.

[47015.]—**Portable Greenhouse—Glass Not Meeting.**—If "Glatton" has never seen a greenhouse glazed entirely, without the glass in the roof touching at all, he cannot do better than try the same plan in his own where needed. The annexed letter H laid down will explain it, ⌶. This, we will say, represents a section of the old-fashioned window lead; if, therefore, "Glatton" places a piece between the two squares he alludes to, so that the edges will be towards the centre bar, and press or rub the edges of the lead on to the glass, he will find it will answer his purpose well, and keep all drip out. "Glatton" can either slide the lead upwards on to the two panes at once, or place it on to the first pane, and then slip the other into it. I do not know upon what principle his greenhouse is constructed, but I should not be surprised if "Glatton" did not do more than the two panes he refers to, the plan or system being so very good, and well worth a trial. Do not be persuaded to use cement on any account, the rather get a large pane of glass, and overlap it ½ to ⅝ of an inch, if you dispense with the lead.—Horticulture.

[47018.]—**Marine Screw-Propeller.**—I am of opinion that the advantage of your plan would be negative; that the speed of boat would be decreased. The stream of water from the first propeller would impinge on the second one, which would do little more than act as a drag, as it could not lay hold of such agitated water. The only way, I think, in which you could gain by such an arrangement would be by having the after-propeller fixed to a shaft running through that belonging to the forward one; the propellers to revolve in different directions, the after one the fastest, and, of course, to be of right and left-handed pitch respectively. If you use two propellers, as you suggest in query, let the after-one have a quicker pitch than the forward screw. Can you not enlarge your present propeller? An apron over the stern would lift the water so as to cover propeller within moderate limits.—Glatton.

[47020.]—**Mus. Bac. Degree.**—Residence at Oxford or Cambridge is required for any degree of either university. There is a B. Mus. of London, but this examination, as all London examinations are, is far "stiffer" than that of any other university. Besides, you are required to pass the London Matriculation at least a year before you go in for the intermediate B. Mus., so that it will take you about 2½ years before you get your degree. Write to the Registrar of the University of London, Burlington-gardens, London, W.C., for the prospectus of the Intermediate B. Mus.; or get a Calendar of the University of London.—A Medical Student.

[47021.]—**Telescopes.**—The querist, as far as I can judge, must have obtained his information about the above at the Crystal Palace, from someone who has not tried them, as, when I had that pleasure they were not even achromatic except for a very small space in the centre. I could see as well again with 12s. tel. of Negretti and Zambra. The o.g. is about 1½in. in diam.—W. E. K.

[47022.]—**Shafting.**—Are you sure that the noise is in the bearing? I have known a belt to rub against an iron bar and produce a great noise like a big fiddle-bow: this was attributed by the "engineer" (!) to any cause but the right one, until I noticed this bar, which he had fixed up to keep the belt from slipping off the pulley. Possibly you may find something foreign to the shaft rubbing against it. Have you taken bearing apart and examined brasses for bright spots? If not, do so, and scrape them down. I have heard of plumbago being applied with advantage as a lubricant in a somewhat similar case to yours. If you find out the cause of the noise, I hope you will let us know.—Glatton.

[47024.]—**Secondary Batteries.**—To "Sigma." —I am afraid the querist would find that the game would not be worth the candle-power of the lamp. A good many Sutton cells would be needed to work the lamp, though they need not be large ones. I do not like to give random answers to questions which may induce my readers to expend time and money with unsatisfactory results, and to give a trustworthy answer would require a good deal more thought than I can devote to a matter which on the face of it would be an unprofitable affair. It must be remembered that the secondary battery gives us nothing; on the other hand it charges a commission of some 40 per cent. for receiving and returning the power we put into its custody. Therefore, if we want to charge a storage battery from a voltaic battery, the question at once arises, Why not use the battery itself? The only convenience would be that we might use only just so many cells as would overcome the force of one secondary cell, and then, by a commutator such as Planté uses, charge a number of secondary cells in multiple arc by a slow current, and use them in series as required. For such a purpose I should employ four large Smee cells of the odds and ends description, mounted in series permanently, and so that they could be used in actual work along with the secondary. But it would be a costly mode of getting light.—Sigma.

[47026.]—**Melting Brass Dust**.—I doubt your "large" fireplace will have too large a flue for your purpose. It will take too much fuel to maintain a proper draught. A friend of mine tells me he once made a very successful brass-melting furnace by building a grate with firebrick, and continuing the flue up to a considerable height with 6in. drain-tiles.—Glatton.

[47027.]—**Electric Current.**—Nearly all the tubes of force which run from one pole to the other of the permanent magnet are concentrated in the substance of the iron ring, one half traversing the upper and the other the lower half ring. Each convolution of the coil, in ascending from its lowest position to its highest, cuts each of these tubes once, and all in the same direction, namely, from below to above. In descending, the same tubes are cut, each once, in the opposite direction, namely, from above to below. So we see that the soft iron ring is chiefly used for the concentration of the tubes of force. In current off commutator only the two coils at the neutral points yield. There is, at present, no better ring armature than the Gramme, nor any other form, that I am aware of, that would not give alternating currents.—A Medical Student.

[47030.]—**Watch Repairing.**—To "Alfojoe." —In reply to "Country," I fancy, from your description of the state of your watch, that you have "topped" the wheel too much—*i.e.*, you have shortened the teeth so much that they pass the verge-pallets. To remedy this defect, your whole efforts must be directed to setting the wheel forward. This will have to be done by filing away a portion of the potence-slip, also the counter-potence, which is the name given to the square-shaped stud with a horizontally-pierced hole in, near to the under edge of the top plate, and which carries the "follower." Take off a little from each, filing perfectly square, and then try the escapement. If found short still, take a trifle more off each as before. You will, of course, have to take the watch to pieces to do this; and the collet and hairspring should be removed, which is easily done with a penknife. Before doing this, mark the position of the end of the hairspring, so that it may be replaced in its former position. To try the escapement, set the wheel in its place, together with the verge, and, with a pointed peg, press forward the wheel as the balance is being moved backward and forward as it ordinarily goes. There should be the same amount of "drop" and "draw" to each pallet. At this point I must pay "Fellow-Workman" the compliment to refer you to some drawings of the verge escapement, in one of his articles upon watch repairing, published about three weeks ago. You will there see exactly how the escapement should be set to work correctly, as he gives an accurate description of the "drop and draw" of the 'scape wheel teeth upon the verge pallets. The little slit which carries the wheel-end pivot is movable. If there is too much drop upon the bottom pallet, force the slip a very little way through. To do this accurately, score a fine line across the face of the potence and slip; by that means the minutest alteration is observable. If too much drop is found at the top pallet, then the slip must be moved the reverse way. Observe, after these alterations, that the 'scape-wheel is not bound in the holes. It must be perfectly free. Small steel broaches are used to free out the holes. The watch is set "on beat" after being put together. To effect this, place your thumb, while holding the movement in the left hand, upon the contrate wheel, and, noticing the position of a certain bar of the balance, or the banking-pin, and making a small dot with a needle or drill point where it rests, press the contrate wheel forward in the way the watch goes; this will send the balance to one side. Now notice exactly the distance the pin or bar moves, and make another dot; then press the contrate-wheel on again, to send the balance on the other way. Mark the distance it runs till the fall comes; make another dot, and notice if the first-made dot is exactly central. It must be so for the watch to be "on beat." Presuming the drop is right, and the wheel free and beat correct, the escapement may then be considered perfect. If it is really your intention to try to put new verges to the other watches, you will find almost insurmountable difficulties, unless you have had some experience at turning. It is only after several years of practice in various simple ways that the necessary light-handed skill is acquired. If you are not gifted with the bumps of patience and perseverance, I should advise you not to attempt it. You can get a verge turned, and properly freed and 'scaped, for about 3s., providing you do the other part of the work. You will find advertisements of workmen to whom you could send the job if you refer to the "Sixpenny Sale Column." All you would have to send would be the "top-plate," with regulator cover screwed on; balance-wheel, with hairspring collet on; balance-cock, 'scape-wheel, potence, and follower. If, after this, you still wish to try your hand, I will do what I can to put you in the way. I may add, however, that the subject has been ably treated by other correspondents not so very long ago.—Alfojoe.

[47032.]—**Stonehenge and Sun Worship.**—The following is extracted from Mr. Geo. C. Yates's paper, as reported in the Proceedings of the Manchester Scientific Students' Association:—"Directly in the entrance line to the circles at Stonehenge stands erect an unwrought monolith, 16ft. in height, popularly called the 'Friar's Heel.' A person standing on the so-called altar-stone at the summer solstice will see the sun rise immediately over the 'Friar's Heel,' the top of which stone exactly coincides with the line of the horizon."—Diamond.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list and send what information they can for the benefit of their fellow contributors.

QUERIES.

[47035.]—**Safety-valve for Kitchen Boiler.**—Which is the best safety-valve for the boiler of a kitchen range, both for an open and for a close boiler?—PLUMBER.

[47036.]—**Photographing Public Buildings.**—To MR. WETHERFIELD.—Allow me to call the attention of amateur photographers to a fact not, I think, generally known—viz., that no public building can be photographed without the permission of the Board of Works, as I learnt to my cost when, after having taken a long walk in the early morning for the purpose of photographing the sculpture at the base of the Albert Memorial, I was prevented from doing so by one of the keepers on the ground that I had no order. I should be glad if Mr. Wetherfield could inform us how far the Board of Works have power to make such arbitrary rules without giving notice of the same among their other by-laws on their notice-boards? Also, whether it is necessary to obtain an order to draw or sketch public buildings?—J. P.

[47037.]—**Watchmakers and Jewellers**—Is there any Directory published of these trades, similar to those published by Kelly of the builders, engineers, stationers, and other trades?—W. B.

[47038.]—**Mustel Organs.**—Can any of your numerous readers describe the double expression in the harmoniums of Victor Mustel. In Vol. XXIV. of the "E. M."? I find a description of it as patented by W. E. Evans; but this is a different arrangement of it. I believe in Mustel's instruments there are two small reservoirs in addition to the large reservoir—one for the treble, and one for the bass.—J. H. K.

[47039.]—**Clock Query.**—I have an American clock which strikes so fast that it is almost impossible to count it. Can any of our readers kindly inform me what is the cause of this, and the best method to remedy it? and oblige—CHICK.

[47040.]—**Filmography.**—To MR. PUMPHREY.—I have been anxiously hoping that Mr. Pumphrey would give us some account of his latest departure in filmography. I have a camera lens, &c., for work with ordinary double dry plate slides, and although were I buying a new one, I should have little hesitation in adopting the filmograph, I have not yet seen any method which seemed to me feasible of adding the use of the films to what I already possess. Now, however, Mr. Pumphrey advertises in your "Sale Column" a filmographic dark slide to be applied to ordinary cameras, and if he would give us some description of it, it would, I am sure, be of interest to many of our readers as well as—AMATEUR.

[47041.]—**Rain-spots on Green Velvet.**—How can I remove rain-spots from green velvet?—DELTA.

[47042.]—**Fixing Alarum to American Clock.**—I have a small American clock, by Seth Thomas, maker, and I want to fix an alarum to it. The face of the clock has a hole (perhaps 2in. diam.) in the centre.—MINING AGENT.

[47043.]—**Camera.**—I have an objective, 3 c.m., of Jamin, at Paris (portrait et paysage). Will any kind reader give full particulars of size, &c., to make a camera for it?—A DUTCH SUBSCRIBER.

[47044.]—**Gramme Engine.**—One of my friends intends to make a model Gramme engine. He will follow Ganot's "Physics," who gives core 180 mètre, 32 bobbins, 4·4in. each, diam. wire core 9-10mm., diam. wire bobbins 11-10mm. He wants still following particulars: Diam. bobbin, wire of bobbins, silk or cotton-covered? Can the horseshoe magnet be replaced by an electro-magnet? If so, what dimensions, diam. of wire, and quantity? A distinct description will be thankfully received by—A DUTCH SUBSCRIBER.

[47045.]—**Wire Harness for Weaving.**—Could anyone give me any information about the machine for making wire heddles, mentioned in Vol. XIII., No. 313, letter 1624?—H. MACMILLAN.

[47046.]—**Telephone Experiment.**—Will any owner of a pair of "Bell" or other magnetic telephones assist a hard-up inventor by trying an experiment for him?—thus: Soak some cotton wool in salt and water, and pack the wet wool into each ear, so as to get as large a contact surface as possible; stick one of the ends of wire from each binding-screw of the telephone into the cotton, and put the telephone diaphragm downwards on a piano or musical-box, and if any hearing can be obtained two to each wire from the telephone; connect respectively, a 2in. slip or wire, and a copper or platinum one, and let these dip into a glass of acidulated water, and note the difference of hearing; if any, report progress in the "E. M."—CONCHLEA.

[47047.]—**Medical.**—To DR. EDMUNDS.—I am troubled with a red patch or rash on the breast. It comes and goes without any apparent reason, and sometimes altogether disappears. Within the last few days it has appeared under my right arm. In both places it seems to grow amongst the hair which covers these places. As I do not wish to see it spread any further, I should be glad if you would point out the cause and suggest remedy or means of avoiding the ailment.—SUNFLOWER.

[47048.]—**Greenhouse.**—I have a large greenhouse connecting two parts of the house together, wall along one side, and glass the other side, end, and roof. I had thought of having a vine or two along the wall, but have heard that flowers will not do well along with a vine. Is this so? Can anyone make some suggestion as to laying out the place to look well?—EXPERIMENTER.

[47049.]—**Gilding Book-edges.**—Can anyone tell me the best way to gild the edges of book-leaves? I tried both the receipts given in Spon's "Workshop Receipts," but the gold leaf would not stick on to the edges properly with either of them. My book of gold-leaf has pieces of waxed tissue-paper adhering to each leaf to take it out of the book with.—J. K. B.

[47050.]—**Hot-air or Vapour Baths.**—Surely some of your readers can give us the benefit of their experience in the construction of hot-air or vapour baths for domestic use? It is quite twenty years ago since Mr. Urquhart lectured and wrote on the Turkish bath and its many advantages; and it has now become quite fashionable for both ladies and gentlemen to spend a month or two at hydropathic establishments. But as the cost of residence in such runs from six to fifteen shillings a day, it restricts the use of such establishments to the rich. An arrangement for such baths in one's own house, in which the bather could attend on himself or herself, or if an invalid could be looked after by a relation without expense, would be a real boon to the poorer gentry and the middle class generally. So many fathers, brothers, and sons are now fair amateur mechanics, I am sure that a paper of expicit instructions for the construction of such would be welcomed by many. If the principles were only fully detailed, many amateur mechanics could apply them to their own houses, and give their families the benefit of what is too often looked on here as a luxury, but which, in the East, is recognised as a necessity.—ISABELLE STUART.

[47051.]—**Crutches, &c.**—Can anyone tell me the kind of wood used for making crutches and wooden legs? I wish to make a pair of stilts, and require a light, strong and straight-grained wood.—R.

[47052.]—**Paint on Mowing Machines.**—I have several times noticed a kind of paint of a silvery nature on grass-mowing machines and the like. On examination, I believe the iron first is painted white. Would some kind correspondent inform me how it is made?—DAYLIGHT.

[47053.]—**A Question for Spectrum Analysts.**—I have recently gone into a house where there is a small conservatory inclosed by ground-glass windows. Both the previous occupier and myself have found it almost impossible to keep plants alive in it, and that, evidently, from no fault in the amount of heat supplied. The few plants that do drag out a miserable existence are pitiable to look at, and induce in one a fit of melancholiac every time we visit them. I may mention that the windows face the south, and there is, therefore, plenty of sun. Now it has struck me that the fault probably lies in the windows being ground-glass? and that possibly the actinic rays of the sun are obstructed by this glass, and prevented from reaching the plants. Has anyone taken the spectrum of sunlight through common ground-glass? And if so, what light does that spectrum throw upon this question? If I am right, can anyone tell me whether any other glass than plain clear glass will do, as the conservatory looks into a yard, and I would therefore prefer something that would obstruct vision. That is, is there anything that will obstruct the vision, and not obstruct light and the life-giving portion of the sun's rays?—ADIANTUM.

[47054.]—**Incandescent Lamps.**—There are now being sold small incandescent lamps (5-candle power), said to be lighted up with two Bunsen cells. Could any of "ours" kindly inform me if it is possible to light one of the lamps with Leclanché cells, and how many would it take to do so? Are not six or eight Leclanchés equal to two Bunsens? and can this number of cells be joined up without setting up a resistance? Also, kindly tell me the greatest number of quart Leclanché cells that can be joined up without losing any power. The above lamps are 2s. 6d. each.—BELL.

[47055.]—**Cardboard**—Is often used for flaps and shutters of small dark slides, and answers extremely well. I wish to know how to make this cardboard suitable—it must be elastic, stiff, smooth, and durable. I have tried to saturate "Bristol-board" with hot glue. This, however, softens in damp weather. I also tried thick coating with shellac varnish; but this, too, has its defects. Will some experienced friend give his experience?—E. B. F.

[47056.]—**Bacteria.**—Will somebody give a practical hint on the best means of keeping barm (intended for distilling alcoholic fermentation) free from objectionable germs, or is there a means of separating them from the proper torulæ. The barm in question is made on the Continental system from rye and malt meal, and lactic fermentation, encouraged by its standing 24 hours before the active fermenting mother is added. I find acetic germs are developed in a few days, and that all the maladies of Pasteur would appear unless the mother barm were changed frequently. I find the barm skimmings of a back attenuated with such yeast contain no bacteria. I consequently use such skimmings as "mother"; but, unfortunately, barm containing bacteria, or with an old "mother," does not throw the yeast to the surface. So I cannot avail myself of skimming. During this warm weather, would it be advisable to keep all barm-tubs covered? If so, with what—linen or wood? Would be very grateful for any information.—CYGNET.

[47057.]—**Glaze or Enamel on Iron.**—In the MECHANIC of Feb. 2, two recipes were given for a coating of glass on iron, one of which, it was stated, would not stand wet; the other, on trial, was found too infusible for the purpose required. Perhaps some of your numerous correspondents will oblige by giving a recipe for glaze or enamel easily fusible on a surface of iron, say at a low red heat, and which would stand exposure to the weather. Colour is of no consequence.—L. A. S.

[47058.]—**Chlorate of Lime.**—To W. J. LANCASTER AND A. ALLEN.—Will you be kind enough to give me a practical process for the manufacture of chlorate of lime? A method by chlorine gas preferred. Also, can chlorate of lime be made from bleaching liquor or bleaching powder at 35%?—JAMES LEATHERBARROW.

[47059.]—**Iron Boiler Chimney Rusting.**—I have a vertical boiler with wrought iron chimney projecting through roof of building about 9ft., and do all I can I cannot keep it from rusting. Paint, tar, &c., all come off in a few days. It has only been up about 12 months, and what with scraping and painting, the original 16th iron is reduced to 1-32nd Can any reader kindly suggest a remedy? and greatly oblige—F. R.

[47060.]—**Atmospheric Nitrogen.**—Has it been determined what quantities of combined atmospheric nitrogen are brought down to the soil by rain in the form of nitric acid? If it has, can anyone give me the quantities per acre per annum?—LEHRER.

[47061.]—**Mixing Brass for Melting.**—Will any reader inform me how to mix brass for melting, so as to have it to a nice yellow colour and soft?—AMATEUR MOULDER.

[47062.]—**Plaster Casts.**—Will some kind reader inform me how plaster of Paris casts are finished after being taken from the mould?—as I cannot get a glossy appearance upon mine.—ANXIOUS.

[47063.]—**Hydraulic Mortar.**—Is it possible to make an hydraulic mortar containing caustic alkalies, as my materials contain caustic alkalies, and I want to make a firm mortar? Will any of "ours" kindly oblige with a formula?—DEEPDOWN.

[47064.]—**Flight of Rifle Bullet.**—Suppose a rifle-bullet to be fired at a mark 600 yards away, with a wind blowing at right angles to the line of fire, what curve (in a horizontal direction) does the bullet describe in consequence of the wind, and, if the deviation of the bullet is 6in. at 100 yards from the muzzle of the rifle, what will be the amount of deviation at each successive 100 yards? Will some mathematical friend oblige?—A RIFLEMAN.

[47065.]—**Gaiffe's Medical Battery.**—Would Mr. Lancaster, or someone else who knows, kindly inform me how the coil in Gaiffe's medical battery is constructed? I have access to one which had, originally, a small chloride of silver cell. This has been removed, and the coil is used with a small bichromate cell, and it gives a much more powerful current than a coil three or four times the size, which I constructed myself. I don't like to take it to pieces, as it is not mine.—OS.

[47066.]—**Scissors and Razor Grinding Machine.**—Will anyone oblige by giving me instructions (with a sketch) for making the above, a small one to run as light as possible, with only one treadle, as I have only one leg for driving of it?—ONE LEG.

[47067.]—**Dynamite.**—I was much interested in "M. C.'s" account of dynamite, and should like to know his opinion as to whether it should be applied on the surface of a root or rock, or put in a hole bored for the purpose? Some of the workmen complain that the dynamite vapours, after the explosion, give them a headache. Is this "M. C.'s" experience also? Does he consider it equal or superior to tonite, gunpowder, or litho-fracteur for blasting tree-stumps?—S.

[47068.]—**Swelling and Pain about the Knees.**—Five weeks ago, my son had a somewhat severe attack of rheumatism throughout the right leg, the result, I think, of getting thoroughly wet a day or two before the attack. After a fortnight's duration, the rheumatism, during the following week, gradually left the leg until, at the end of the week, there was scarcely a trace of it left; but after three more days had passed it returned with increased vigour to the knee, where it seems to be settled, and which, at this time, is rather stiff and swollen, and extremely painful if walking is attempted. It is worse when heated. Will Dr. Edmunds give a little advice on the above? Will he also give a little advice concerning my daughter, who is the subject of slight swelling and pain in both knees, resulting from falling on the knees whilst skating on a rink a few months ago?—PONTUS.

[47069.]—**Fruit-growing.**—Wanted the name of a good work on growing strawberries, raspberries, black currants, and other fruit?—HIGHLANDER.

[47070.]—**To Mr. Allen.**—Could you give me a list of harmless aniline colours for confectionery—blue, black, red, yellow, and green? Also, if the ordinary commercial colours will do, or must they be specially prepared for the purpose? And can they be mixed one with the other to alter the tints, or must each be used by itself?—HIGHLANDER.

[47071.]—**Railway Trucks.**—To MR. CLEMENT E. STRETTON.—Would you kindly give me the exact lengths of the trucks used for goods traffic for various purposes, and the widths? I know the widths vary very little, but I think the lengths are different with almost each Company. Strangely, Barry's "Railway Appliances" does not give any lengths at all in the article on Trucks.—MEM. SOC ENG.

[47072.]—**Zinc from Spelter Fumes.**—Can any of your readers inform me a way to precipitate zinc from the spelter fumes of a dirt furnace? They are a great nuisance to the neighbourhood, and it would be a saving if the zinc could be caught It has been suggested that a bridge of red hot carbon in the flue would answer the purpose. Have any of your readers any experience in the matter, or could they suggest any other way?—GARNET.

[47073.]—**Astronomical Eyepiece.**—Will "Aldebaran" kindly advise me as to an astronomical eyepiece I wish to purchase for a 2in. terrestrial, 30in. focus, by Harris, Holborn? The telescope has good definition, but the field is not so bright as in modern instruments, in consequence, I think, of the o g. being made of the old-fashioned green glass. What kind of eyepiece ought I to get, what power, and what would be about the cost?—TIRO.

[47074.]—**Steam-Whistle.**—I am wishing to make a new whistle to my 2½-h.p. engine, as the one now on it is far too small and shrill, and I shall be much obliged to any of our kind readers if they will give their opinion or opinions as to whether I shall be able to make one out of an old force-pump barrel. It is made of a very good piece of brass pipe and perfectly true. It is 1½in. in dia., and 6in. long, being 1-16in. in thickness. I want a very strong and deep tone, as it has to be heard a long distance, and distinguished from two other steam whistles. Also, their opinions whether allowing the steam to strike on the bell through a number of small holes drilled in a circle of the same diam. as the bell will make any difference as to the sounding of the whistle, or whether I must make a perfect circle? The former will be much the easiest for me if it will answer. Also, what is the proper distance for the edge of the bell to be above the plate from which the steam issues? May I have the bell any length, or is there a limit? I always have from 50lb. to 60lb. of steam in at the time I should use the whistle.—REHCSAF.

[47075.]—**Oval or Elliptic Chuck.**—In the "E M." No. 852, July 22nd, 1881, Dr. Schobbins has an article with the above heading. Not having sufficient mathematical knowledge, I cannot make out either what he proves or how he proves it. Could not some of your readers give a plainer statement than that published by the doctor? As a further and relative question, it may be asked—"Does the 'Elliptic cutter' produce the same kind of curve as the chuck does?"—R.

[47076.]—**Bunsen Battery.**—To MR. BLACKWELL OR "CATON."—I should like to know the process in its entirety. I have got a good spark. Silver and gold-plating and gilding are most particularly wanted; but I understand to get the various shades the articles have to be previously coppered. Kindly say how to make the several solutions, and if the acids have to be removed from the cells when not in use? Do the solutions require heat? Thanks for former replies.—AMATEUR.

[47077.]—**Case Hardening.**—Can any reader tell me how to effectually case-harden two wrought-iron collars for the ball-bearings of my tricycle? Can it be done with prussiate of potash? I was going to make these collars of steel; but as they have grooves turned in them, I was told they would fly to pieces in hardening. Is this so? An answer will greatly oblige—CYCLE.

[47078.]—**G.W.R. Engines**—Can any correspondent inform me what single and four-wheel coupled engines (N.G.) have the vacuum and automatic brakes? and also give their numbers and stations, if possible?—CLARENCE FIELD.

[47079.]—**Regulator.**—Will any horological reader inform us what the index plate at the bottom of regulator pendulums is for?—FRED NASH.

[47080.]—**Fits.**—I should feel grateful to Dr. Edmunds if he would kindly inform me of the probable cause and cure of periodical fits to which I am subject, and which have occurred for the past seven years at intervals of about three months, and always during the night when asleep. During the attack I make a great noise, become bathed in perspiration and very violent. When roused before the fit is entirely over, I feel very much frightened, and always awake with a headache, and feel very weak. I, myself, think they are epileptic.—MEDICINE.

[47081.]—**Polishing Granite.**—How is this done? Particulars will oblige. I have some small blocks of concrete to dress and polish. Any information will be most acceptable.—GRANITE.

[47082.]—**Hardening Leather.**—Will some reader inform me of a way to harden leather, so that it will stand for valves in a soda-water machine? The valves in new machines work for a long time, and are very hard. Could the leather not be compressed in a die to render it more durable?—D. W. B.

[47083.]—**Diabetes.**—Would Dr. Edmunds kindly give his advice?—I am a young man between 21 and 22 years of age. I have been suffering, more or less, for three years from a complaint called diabetes memphis. Have been to many doctors without obtaining permanent relief. Doctor I am under at present says it is due to the liver making too much sugar, which is excreted by the kidneys. The remedies I have been trying lately have been bodeia in the form of a pill, and lactic acid—but both have failed to effect a cure. Feel a hot burning pain over the kidneys, flitting from side to side, and a soreness over the region of the stomach. Am an engineer by trade. Would Dr. Edmunds say if there is any chance of being permanently cured? Would a sea-voyage do any good? If so, where is it best to go to?—DIABETES MEMPHIS.

[47084.]—**Ebonite Coefficient of Expansion.**—Will some reader kindly tell me if ebonite has a negative coefficient of expansion? And if so, what is the value of it?—LEHRER.

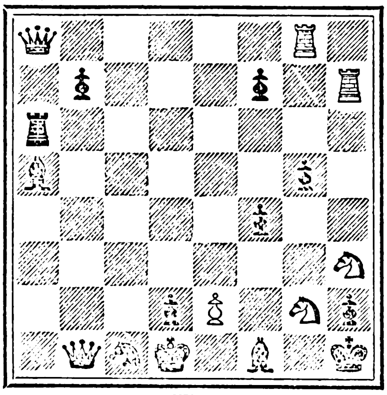
[47085.]—**Dynamo-electric Machine.**—To GEORGE TOLMAN.—Many thanks for answer to former query a few weeks back. I have tested my armature, and found that there was a leakage between iron ring and coils of wire. I therefore unwound it and insulated the ring with two layers of tape, and rewound the coils. The coils are all wound in one direction, and I have connected the end of one coil, and the beginning of next one to one copper slip, and so on to the end of last coil, which is connected to the beginning of first coil and copper slip. My pole pieces are screwed to base, and are 6in. high, 5in. wide, with a 5¼ circle cut from them in which the armature revolves. The electro-magnet which I have used is of ¾in. round iron, each leg is 6½in. long, and is wound with about 20ft. of 16cc. wire each, and it is stood upon the two pole pieces. When excited with a battery and the armature revolved, I get a small deflection of galvanometer, but no spark, and when connected to collecting brushes I get no effect at all. What would be the best form and size of electro-magnet, and size and quantity of wire to give best results? Any suggestions as to failure will be acceptable, as I am still—IN WANT OF HELP.

CHESS.

ALL Communications for this department must be addressed to the Chess Editor, at the office of the ENGLISH MECHANIC, 31, Tavistock-street, Covent-garden. W.C.

PROBLEM DCCLI.—By C. R. BAXTER.

Black.

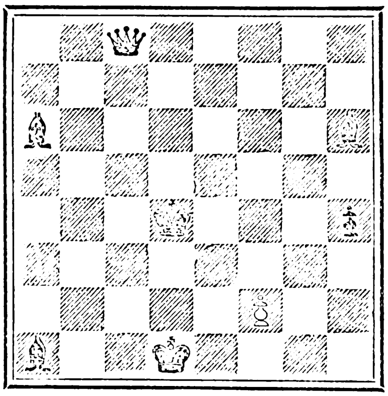


White.

White to play and mate in three moves.

PROBLEM DCCLII.—ANONYMOUS.

Black.



White.

White to play and mate in three moves.

SOLUTION TO 747.

White.	*Black.*
1. B to Q 5 2. P to Kt 3 (ch) 3. Kt to B 4 4. B or Kt mates	1. Kt to Q 7 (a) 2. Kt takes P (b) 3. P takes Kt, &c.
3. Kt to Kt 7, &c.	(b) 2. B × P
2. P to Kt 3 (ch) 3. Kt to Kt 7 4. Mates	(a) 1. B takes B 2. B takes P 3. Anything
2. Kt to Kt 7, &c.	if 1. P takes P

NOTES.

If in main play, 2. $\frac{\text{Kt to Kt 7}}{\text{Kt to Kt 6}}$; if 1. $\frac{\text{K B takes P}}{\text{Kt to Q 7}}$ 2. $\frac{\text{B to B 2 (ch)}}{\text{B covers}}$ 3. $\frac{\text{Kt to Kt 7}}{\text{Kt to K 5}}$; if 1. $\frac{\text{B to Q 5}}{\text{Kt to Q 7}}$ 2. $\frac{\text{B takes B}}{\text{P takes P}}$ 2. $\frac{\text{Kt to Kt 7}}{\text{Kt to Kt 6}}$.

SOLUTION TO 748.

White	*Black.*
1. Kt to Q B 7 2. K takes P 3. Kt mates	1. R takes P (ch) 2. R moves
2. K to K B 6 3. Kt mates	1. R to Q 7 2. Anything

NOTICES TO CORRESPONDENTS.

SCHMUCKE.—Your solution to 748 is correct. You are right as to 745; but 746 is more elegant than difficult.

A. BRIGGS.—Thanks for the problem, which shall be examined and reported on. You have solved 748 correctly.

Holloway's Pills.—These famous Pills purify the blood, and act most soothingly on the liver, stomach, bowels, and kidneys the great main-spring of life. They are wonderfully efficacious in all ailments incidental to females. To the emigrant, traveller, soldier, and sailor they will be found invaluable in the time of need.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6 Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, May 31, and unacknowledged elsewhere:—
